Under the title "Experimental Subterranean and Subaqueous Explosions at Chatham by the Voltaic Battery" a correspondent of the *Mechanics' Magazine* on April 20, 1839, described the progress being made under Colonel Pasley's direction. "For several months past," he wrote, "the Royal Engineers at Chatham under Colonel Pasley have been trying experiments in firing gunpowder by the voltaic battery, and after many vicissitudes of partial success and of failure, they have at last succeeded in bringing this process to as much perfection as it seems capable of—that is, as much certainty as the former method of firing mines in dry soil. They have repeatedly fired gunpowder at the distance of 500 feet, with their conducting wires either buried underground or led entirely under water, excepting a few feet connected with the battery, which in their subaqueous explosions was in a boat on the Medway, the powder being lodged at the bottom of that river. . . . The voltaic battery used was that of Professor Danielli's improved construction, which from retaining its energy much longer than any other form of voltaic battery he has named the constant voltaic battery." Colonel (afterwards General Sir) Charles William Pasley, F.R.S. (1780–1861), in 1839–41 used the methods he developed at Chatham for blowing up the wreck of the *Royal George* which had foundered at Spithead on August 29, 1782.

Photographic Plates for Scientific Purposes

Photographic plates prepared in the Kodak Research Laboratories have for some time found application in many laboratories where work on spectroscopy, astronomy, infra-red and ultra-violet photography and allied subjects calls for a specialised photographic product. These are available in a wide range of emulsions of varying speed, contrast and size of grain and can be sensitised for any region of the spectrum from the ultra-violet to the far infra-red ($\lambda = 13,000\text{\AA}$). A booklet entitled "Photographic Plates for Scientific Purposes" giving further details will be gladly sent on request to: The Research Laboratory, Kodak Ltd., Wealdstone, Harrow, Middlesex.

Research in Africa

IN June next the generous grants of the Rockefeller Foundation to the International Institute of African Languages and Cultures for the promotion of linguistic and anthropological research in Africa will cease ; and the Council of the Institute, it is stated in its annual report for 1938 (*Africa*, 12, 1 ; 1939), being fully aware of the urgent need not merely of continuing, but also of extending and strengthening this work in every way, now has under consideration its arrangements for the future. These must necessarily depend upon the funds available ; but the wide interests implicated in the vast field to be covered, and the gravity of the issues to which the researches of the Institute contribute understanding, should ensure that financial considerations will not be allowed to cramp its work.

Since 1931, when the scheme of research which is now nearing its final stages was first formulated by the Institute, sixteen full-time research fellowships have been awarded. Of the holders of these, three are still in the field, completing their investigations in Uganda, Nyasaland and Bechuanaland respectively. The remainder, having finished their field work, either have reported or are completing the preparation of their material for publication. These investigators have covered a wide field and have recorded observations of the culture of markedly diverse peoples. Research among African peoples has so vast a range that it may be said that even this organized scheme of investigation has done little more than pass beyond the fringe. Nevertheless, substantial progress has been made. Cultural records have been made among peoples in such widely distributed areas as the Anglo-Egyptian Sudan, Algeria, the Gold

Coast, Sierra Leone and Nigeria, Uganda, Kenya, Tanganyika, Nyasaland, Rhodesia, the Transvaal and South Africa.

Further to, and arising out of, these activities in research, discussion among the research fellows and other experts has led to the preparation by the Institute of a symposium on African political organization. This will be edited by Dr. M. Forrester, research fellow, and Dr. E. E. Evans-Pritchard.

Obviously, discussion of political organization raises many questions with wide ramifications in their bearing on the future of the African. For some time there have been indications here and there of a certain mistrust among the native populations—confined in the main, no doubt, to the more advanced and sophisticated—of both scientific investigation of native institutions and of the relation of indirect rule to such research. It has been alleged, with no small show of confidence, that the aim herein of the white man is “to keep the native in his place”—to stereotype his institutions and to fix his status once for all. If as the result of any discussion or research it should be possible to indicate the lines of a progressive policy of institutional development, adaptable to changing conditions of the day, while avoiding disintegration, it would placate discontent by eliminating ambiguities in the present position.

The linguistic side of research, which has always been a major interest of the Institute, has not been neglected. At the moment, two important works dealing with African languages are in the press ; one on the languages of the Sudan by Dr. A. N. Tucker, based partly on material collected on an expedition financed jointly by the Institute and the School of Oriental Studies of the

University of London, and one on the phonetic structure of the Kikuyu language by the late Miss L. E. Armstrong; while three other linguistic studies are either ready in manuscript form or are in course of preparation.

A further significant development of the Institute's research work, of wider scope than its application to the African field, is concerned with the nutrition of backward peoples—one of the most important subjects to which the attention of research fellows has been directed, if the trend of recent investigation is to be accepted in all its implications. Not only has this matter been under observation by Dr. Audrey Richards among the Bemba of Northern Rhodesia and is now being examined by Dr. Margaret Read among the peoples of Nyasaland; but also the plans for a nutritional field survey, which were drawn up by the Institute with a view to the needs of Africa, have been adopted, with revision and expansion, by an organization set up under the aegis of the Medical Research Council, of which the purpose is the co-ordination of nutritional research work throughout the British Colonial Empire. The nutritional investigation which Dr. Read is carrying out in Nyasaland now forms part of this scheme, which is being conducted under the direction of Dr. B. S. Platt, senior member of the staff for the co-ordination of the research. An ecological survey of Nyasaland is being carried out, in conjunction with the work on nutrition, by an agricultural officer, assisted by forestry and veterinary experts where necessary, the anthropological and sociological side of the investigation being entrusted to Dr. Read. As this is the first survey of the kind under the new organization, it is of particular importance for the development of technique, with a view to future research; while it is of no less notable significance that the socio-anthropological side of this very important question receives due recognition. The Government of Nyasaland has shown that it is fully alive to the value of the inquiry, and has granted every facility to the members of the expedition for their work.

Research such as is too briefly outlined above cannot be financed on a parsimonious scale; and the more closely the problems of Africa are scrutinized, the more evident does it become that future research must be extended to the limits of capacity in resources and personnel. When the results achieved by those who have worked in Africa during the last five or six years on behalf

of the Institute of African Languages and Cultures are more fully available, confidence in its competence to continue to direct this work will be more than doubly assured. Further, the methods of investigation which have been followed by many, if not all, of its research fellows have been such that their results not only have conduced notably to the advancement of scientific knowledge, but they are also readily adaptable to the needs of administration, or other provinces of practical affairs. Nor have they failed on occasion to probe weak points in administrative methods, even under indirect rule, where a failure in the understanding, which the anthropologist alone could discern, has led to misinterpretation of custom, mistrust and even friction.

It is further to be noted that both the administration of the Institute's scheme of research and the selection of research fellows have had a marked effect in promoting that international co-operation which, in the eyes of those most competent to judge, is one of the essentials in the future guidance of development in Africa along right lines.

Meanwhile, a word of warning may not be out of place. The interest of African problems at the moment is so insistent, and at the same time so widespread, that there is a very real danger of a dissipation and waste of energy and resources, which could, and should, be concentrated in a single direction of effort to African research. The number of appeals for funds for purposes of research of widely varied character is growing apace, as is the number of organizations, some already in existence, others projected, on behalf of which these appeals are being made. As each one comes forward, it might indeed be considered to strengthen the argument for centralization and the concentration of effort in a single African institute, of which the purpose would be to co-ordinate and direct inquiry, as well as to pool information, and thereby the better to direct suggestion for the application of the results of research to practical ends, while at the same time advancing scientific studies. Not the least of the advantages of such an institute would be the greater weight it would carry, when urging upon authority that the benefits accruing to administration from the results of its researches, and more especially of such anthropological investigations as have been carried out by the Institute of African Languages and Cultures, were of a nature to merit a liberal subvention from public funds, as a return for services rendered or to come.

Fifty Years Growth of London

History of the London County Council, 1889-1939

By Sir Gwilym Gibbon and Reginald W. Bell. Pp. xxi+696+33 plates. (London: Macmillan and Co., Ltd., 1939.) 21s. net.

AT first sight, this comprehensive history of the growth and development of the work of the London County Council to commemorate its jubilee would seem to be an authentic record of significant progress of social and political value. It is not directly concerned with Nature, or the knowledge of Nature commonly called science. Yet much of its nearly 700 pages affords a striking example of the application of science—social science, educational, physical, even biological. We usually associate the familiar name of our local government authority in the Metropolis with the early chairmanship of Lord Rosebery and the enthusiastic band of public-spirited men who gathered round him in 1889, and their not less enthusiastic successors over the fifty years of its history—with their personalities and social ideals, with their programmes and policies and battle-alogans, with an improved London and a rising rate. But here is the actual history of their doings and the vast organization which has grown up under their hands.

The size and variety of the activities of the London County Council are in themselves almost bewildering. Two million electors appoint 124 Councillors every three years; eighteen standing committees consist of a dozen to fifty members to deal with the education of 750,000 children and grown-ups in 1,400 schools, with general purposes, with hospitals and medical services, with housing and highways, and parks and open spaces, with public assistance, public control and supplies, with fire brigades, ambulances and main drainage, even with entertainments and recreation. The powers and duties cover all that concerns the life and labour of five million people, living in a metropolitan area which has grown to nearly 116 square miles. Little wonder that its official staff numbers 78,000 persons and its expenditure amounts to £37,000,000 a year. Yet from this vast undertaking there is excluded the control of transport, the provision of water-supply, electricity and gas, and the governance of the port of London, all of which have separate authorities.

When we turn to the application of science, we shall discover many signs of growth and extension. The old London School Board did great things in

its day, but after the Education Acts of 1902 and 1903, the whole subject of education fell to the duty of the local authority, and something of a revolution took place. In the first place, all forms and grades of education, elementary, secondary, technical, came under one body, and they were made subservient to each other; then the quality of the teaching has been reformed by particular training of the teacher, and the provision of modern plant and equipment; the physical and mental state of the children has also been greatly improved, by medical and physical care; the special schools have been extended and reformed for defective children; continued education beyond fourteen years of age has been developed, in trade schools, junior technical classes, and evening classes for 260,000 students; the infant schools have been radically amended, and nursery schools for the pre-school child have been established. Particularly has there been great progress in the school medical service, under 20 whole-time medical officers, and 56 part-time officers, with 77 school dentists, added to which there are 250 medical men and 112 dentists at the school clinics and 420 school nurses. There are 18 hospitals in the Council's scheme, and 81 school clinics, treating 315,000 children, and some 900 voluntary care committees with 5,000 members. It is the largest organization of a school medical service in the world, and comprises inspection, treatment, after-care, open-air education, physical training, special schools, child guidance, residential schools and institutions, and indeed everything medical that a sick, or healthy, child can require.

A new departure was made a few years ago in the field of research. The provision made by the Council was so wide that it recognized that the improvement of medical education and research could be facilitated by the better use for scientific purposes of its institutions and laboratories. With the co-operation of the Ministry of Health and the University of London, the Council established a post-graduate medical school at Hammer-smith which was opened by King George V in 1935—the first instance of a medical institution created by co-operation between the Government, the county council and the university, which has proved an invaluable service to medical education at the heart of the Empire. Further, Sir Frederick Menzies, the eminent medical officer, has organized a scheme of research work among the hospitals, units, maternity hospitals and special institutions under his charge, and the four special reports on

the work accomplished in 1934-37 indicate an immense sphere of valuable clinical and laboratory research. This also is a unique undertaking for a municipal authority, and reveals an unexpected source of new knowledge. Yet another scientific adaptation has been put into practice in medical education in respect of the training of students in the fever hospitals, for smallpox, and for mental diseases; in the last named, substantial advance has been made in diagnosis and treatment. The mental services of the Council, with 35,000 beds, offer unrivalled opportunities, and these are now being more widely used than has hitherto been the case, in public institutions under local authorities, and especially under the London County Council. Hence new therapeutic, and even preventive methods, are being undertaken in place of mere custodial care.

The application of scientific knowledge by the skilled advisers of the Council has extended even more widely than the sphere of medicine and surgery. This book contains a variety of examples in unexpected quarters, as in the development of the methods of the fire-brigade, the building of the bridges over the Thames, street improvements, the provision of open spaces, slum clearance, the housing estates, main drainage and sewage treatment, flood prevention, even in the unlikely direction of poor relief and public assistance: dietaries, classification and the training and employment of the able-bodied. When science, particularly the scientific method, is applied with knowledge, discrimination and imagination, it is really wonderful what can be achieved to make the public services a scientific, constructive and enduring agency of social reform. G. N.

Modern Aspects of Spectroscopy

(1) Kontinuierliche Spektren

Von Dr. Wolfgang Finkelburg. (Struktur und Eigenschaften der Materie: eine Monographiensammlung, begründet von M. Born und J. Franck, Herausgegeben von F. Hund und H. Mark, Band 20.) Pp. xi+368. (Berlin: Julius Springer, 1938.) 34.80 gold marks.

(2) Der Smekal-Raman Effekt

Ergänzungsband 1931-1937. Von Prof. Dr. K. W. F. Kohlrausch. (Struktur und Eigenschaften der Materie: eine Monographiensammlung, begründet von M. Born und J. Franck, herausgegeben von F. Hund und H. Mark, Band 19.) Pp. x+288. (Berlin: Julius Springer, 1938.) 25.60 gold marks.

THE series of distinctive yellow-backed volumes published under the general title of "Struktur und Eigenschaften der Materie" have long been known to physicists and physical chemists. The volumes are written by a series of distinguished specialists, and are valuable for their clarity and detailed reference to original papers. The subject of spectroscopy has been well represented in earlier volumes by the work of Stuart, Sponer, Back, Matossi, and Hund. Of the two volumes under review, that of Finkelburg is an entirely new contribution, that of Kohlrausch being a volume supplementary to vol. 12 of the series. These books reflect, in fact, two important aspects of present-day spectroscopy.

(1) The best-known examples of continuous spectra are those of hot bodies, and Planck's inception of the quantum theory as a result of his work on

their radiation properties has perhaps by its very completeness led indirectly to a neglect of other interesting problems in this field. With Dr. Finkelburg's volume we welcome a book on continuous spectra that is a landmark of its kind, for it is the first volume to treat of continuous spectra as met with in a wide variety of physical and chemical problems. The importance of continuous spectra in such subjects as astrophysics, photochemistry, luminescence, and the technology of lighting is sufficient to give us high hopes of a volume ranging over such widely different fields. One of the pleasing features of the author's treatment is the way in which various items are brought together. We are in the habit of dealing, for example, with such problems as the line spectrum of iron vapour and the continuous spectrum of a hot iron rod as entirely separate; we thus do not easily realize that a study of highly compressed iron vapour would be of particular interest as something intermediate between these two extremes.

"Kontinuierliche Spektren" contains fifteen chapters, the first of which is an introduction to the study of the continuum as it appears in physical and chemical problems, together with some theoretical groundwork. There follows a useful account of the general theory of the electron-continuum, and a chapter on absorption edge continua, and photo-ionization. Five chapters are given up to continua associated with molecules, and good use is made of potential energy diagrams to make clear the various types of absorption and emission continua such as predissociation and

recombination spectra. Chapter x, on the continuous spectra of particular diatomic molecules, including hydrogen, halogens, silver halides, van der Waals molecules (Hg_2 , Cd_2 , Zn_2), is specially valuable. A good account is also given of line-broadening, and temperature radiation receives due attention. Chapter xiii, on liquids, solutions, and crystals, is the least satisfactory; it is disappointing to find virtually no mention of fluorescence continua in solids. The book concludes with more than seventeen hundred references and a comprehensive index.

(2) Prof. Kohlrausch's book is supplementary to vol. 12 of the series published in 1931. It is divided into eleven chapters, the first five of which form an introduction to the study of the Raman effect. It is, however, for the accumulation of data to be

found in the succeeding pages that the book is chiefly valuable. There are sections on molecules containing from two to five atoms, and highly symmetrical molecules with more than five atoms (such as O_3 , N_2O , and SnCl_4) are also dealt with. Hydrocarbon chain and ring compounds are treated separately.

The indexing of a volume of this nature is of great importance. The literature references (more than eight hundred) follow on numerically from those of the earlier volume, and it is possible to search for any compound either under an alphabetically arranged substance index, or under a chemically classified index. In conclusion, one may perhaps express the doubt as to whether it is wise to try and fuse together a text-book and a mass of data in this way. J. T. RANDALL.

Vitamins

(1) Vitamins and Vitamin Deficiencies

By Dr. Leslie J. Harris. Vol. 1: Introductory and Historical. Vitamin B₁ and Beri-Beri. Pp. xiv + 204. (London: J. and A. Churchill, 1938.) 8s. 6d.

(2) Ergebnisse der Vitamin- und Hormonforschung

Herausgegeben von L. Ruzicka und W. Stepp. Band 1. Pp. xvi + 470. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1938.) 34 gold marks.

(3) Vitamins in Theory and Practice

By Dr. Leslie J. Harris. Third edition. Pp. xix + 242. (Cambridge: At the University Press, 1938.) 8s. 6d. net.

THESE three books typify well the existing state of our knowledge in the field of vitamin science and in its applications. The comprehensive and co-ordinated survey of existing knowledge, useful alike to specialist and general practitioner, to chemist, physiologist and medical man, is represented by this, the first volume of Dr. Harris's series of seven projected monographs. At the opposite extreme we have the new edition of the same author's now well-known popular exposition, one of the best examples of a difficult but important technique—that of making scientific facts and hypotheses understood by the layman without sacrifice of truth or clarity.

Perhaps the least successful type of book is that represented by vol. 1 of the new "Ergebnisse". Some of the contributions to it are of a high order, but there seems to have been little planning either in the selection of subjects or in the methods of

their presentation. In spite of this criticism—maybe rather a hypercriticism—the book is of considerable value, apart from reference purposes.

(1) If the remaining volumes of this series—a further six are promised in the near future, covering vitamin C and scurvy; vitamin D and rickets; vitamins A and E; pellagra and vitamin B₁₂ complex; other vitamins; applications and dietetics—reach the level of the first, they will inevitably become the standard works of reference on their subjects, especially as Dr. Harris is one of those compilers who seem anaphylactic to out-of-date editions, and will therefore feel the urge to keep all seven volumes in a state of constant revision. It is to be hoped that his publishers will be able to show the same sensibility.

The present volume is an excellent example of what Dr. Harris has set out to do by way of "comprehensive synopsis"—to use his own phrase. In reading it—and it is so readable that the reviewer found not the least difficulty in proceeding 'from cover to cover' in a time of about three hours spread over two days—one has the impression that the author himself has read, and read critically, every paper that has been published on his subject, has evaluated them all and selected for his readers information from those papers only that have contributed significantly to our knowledge. It may be arguable whether this first volume could or could not have more successfully achieved its object; what is beyond dispute is that no one could have made a better job of it than Dr. Harris. Its readers will eagerly await all six of its companions.

(2) The names of the contributors to this volume give it an air of great erudition—and great erudition is to be found in its pages, as well as much speculation of the kind rather more usual in certain parts of Europe than in Great Britain and the United States, at any rate in books of this type. The contrast can be well observed by comparing the authoritative articles of Dr. C. A. Elvehjem (the B-vitamins, apart from aneurine and flavin), of Prof. R. R. Williams (aneurine or thiamin) and of Prof. G. F. Marrian (the oestrogenic hormones) with those of their Continental colleagues. Here, though, one must make the reservation that Dr. T. Reichstein's contribution (the chemistry of 'Cortin') puts him among the English-speaking contributors, in method if not in tongue. The other authors whose names add distinction to the "Ergebnisse" are Profs. von Euler and Glanzmann and Drs. Giroud, Stehle, Berblinger, Guggisberg and Goldberg.

Besides the subjects mentioned above, this volume includes forewords by Sir Frederick Gowland Hopkins and by the editors, Profs. L. Ruzicka and W. Setpp, and articles on vitamin problems in relation to the growing child, vitamin C and its distribution in the living (animal) organism, the hormones of the posterior pituitary gland, 'ergones' and similar constituents of the living cell, the connexion between the pituitary and the reproductive glands, vitamins and reproduction, and the chemistry of the male sex hormones. Authors have been left free to write in English (four contributions), German (six contributions) or French (one contribution).

It is pleasant to welcome so cosmopolitan a volume, especially as it is rumoured that this feature is to be maintained in future volumes of the series. The chief difficulty of the new venture as a whole—new volumes are promised at roughly annual intervals—lies in the rather artificial association of vitamins and hormones, for chemically the connexion is only striking and well established for vitamin D and the steroid hormones of the gonads and the adrenal gland. The natural association, at least for the water-soluble vitamins, seems to be much more with the cellular enzymes, but they have their own "Ergebnisse" already.

The volume is not expensive, considering its size and country of origin, and is well produced, with abundant bibliographical references and an author index. Whatever its defects of conception or execution, it must be on the shelves and in the hands of all workers in the fields covered.

(3) In the gestatory throes of producing "Vitamins and Vitamin Deficiencies", reviewed above, Dr. Harris has yet had time to revise this admirable popular exposition. As well as expressing our astonishment at his energy and its resultant output, we may compliment him on this particular book as symbolizing his realization that science cannot flourish continuously without public support, and that public support depends on public understanding. This little treatise, revised in a few passages to bring the last edition (1937) up to date, can play a valuable part in keeping the public informed and sympathetic.

A. L. BACHARACH.

Group Phenomena

Collective Behavior

By Prof. Richard T. LaPiere. (McGraw-Hill Publications in Sociology.) Pp. xiii + 577. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 24s.

THIS work is a fairly comprehensive study of most social interactions in small and large groups. It is equally a contribution to social psychology as to sociology. A large amount of material is discussed that has never hitherto been introduced in books of this type, and the treatment throughout is objective and scientific.

The book is divided into five parts, the first being a general introduction to collective behaviour, the second dealing with cultural types of interaction, the third with recreational types of interaction, the fourth with control types of

interaction and the fifth with escape types of interaction. There are copious examples of these various types of social interactions; of institutional, conventional, regimental, formal, nomothetic rebellious behaviour, etc.

Each chapter is, broadly speaking, patterned on the same lines. First there is a qualitative discussion of the specific kind of behaviour concerned, then an analysis in terms of ideologies, membership, overt and covert aspects, and leadership. Moreover, each chapter has a very valuable appendix, giving a critique of sources and bibliography. Indeed, these appendixes are in many ways the most important contribution of the book.

One is particularly struck by the judicious use the author makes of such sources of information and illustration as those provided by newspapers and popular periodicals. This imparts a living,

organic touch to the work as a whole; the subject and treatment never become academic or remote from familiar events.

The method, although the author seems to hope otherwise, is clearly phenomenological, that is, simply descriptive of the phenomena of social life. It has been used most fruitfully by Prof. Katz in animal psychology and human needs and by Prof. Aveling in the study of volitional processes. There is thus no real attempt at a presentation of underlying principles. This is unfortunate and perhaps the chief criticism one has to make. One feels compelled to admit that the subject is still at the descriptive level. But science is far more than a collection of interesting facts sensibly grouped and classified. It requires an economy of explanation, so that much variation is reduced to the workings of few causal forces. In this connexion, one has to deplore the fact that the author nowhere makes any explicit use of psycho-analytic findings, in spite of the fact that psycho-analysis has made notable contributions to this field of study in the works of Freud, Ernest

Jones and others. The one reference to the psycho-analytic technique is deprecatory—the meaning of 'symbolism' as used in psycho-analysis "is not clear to any but the disciples of this cult". One reason for this absence of psycho-analytic theory suggests itself, namely, that if the author once commenced with such an approach he would find himself bound to sustain it throughout the work, which would entail acceptance of unconscious processes as fundamental determinants of social behaviour.

Sociologists with an eye for the part of economic conditions controlling the patterns of human behaviour, will find this factor somewhat neglected.

A specific instance where the author takes an extreme position unwarranted by experimental data is in connexion with collective thinking. There is quite inadequate evidence for the statement: "collective solving of any problem is *per se* a socio-psychological absurdity" (p. 378).

In spite of these defects, the work will be of much use to the student as an introduction to the phenomena of social life. J. I. COHEN.

The Present Position of Botany

Principles of Paleobotany

By William C. Darrah. (Plant Science Books, Vol. 3.) Pp. vi + 239. (Leyden: Chronica Botanica Co., 1939.) 7 guilders; 15s.

THEY say the trouble with palaeobotany is the number and plasticity of its theories; but these are only symptoms. The real trouble is its facts. To be sure, there are lots which are clearly enough established, but nearly all are incomplete; of the 60,000 fossil plant species which Darrah says have been described, perhaps not more than a dozen or two are known as fully as the fossil botanist can expect to know his material. The result is that nearly everything that can be said in a palaeobotanical discussion is of doubtful relevance or equivocal. It is a situation offering splendid opportunities and rewards for research; but for the writing of a fairly short book it is beset with difficulties. However, Dr. Darrah believes in his task, for he writes near the beginning: "From 1885 to 1915 paleobotany underwent its modernization chiefly because of the appearance of the textbooks and reference books".

This book is called in the prospectus "an integrated summary of the present status of Paleobotany" and that does indeed describe it. In a book of this modest length much must be left out,

and although every palaeobotanist will regret the suppression of some favourite line, the book must be conceded to be well balanced. It appears best when on fairly general topics which fall nearest the title "Principles of Palaeobotany" and is certainly least good when it describes, as in the chapters on the Devonian, genus after genus after the manner of an extremely condensed text-book. There are some pleasant little line drawings which help but only illustrate a few of the plants described.

Somewhat more space is given to morphology (and resultant ideas of phylogeny) than to floristics (and ideas of plant migration); but both are dealt with, as also more limited topics like the formation and structure of coal; palaeobotanical technique and history.

It should be made clear that this book was written for the unspecialized botanical reader. It is in no way, however, a popularized account; on the contrary the reader is assumed to be painstaking, and the list of relevant literature at the end of each chapter offers him the possibility of weeks of further study. It is a lot to hope for, but the author's enthusiasm is so evident that it may go a long way to inspire equal keenness.

T. M. HARRIS.

The Sun:

its Phenomena and Physical Features. By Giorgio Abetti. Translated by Alexandre Zimmermann and Frans Borghouts. Pp. 360. (London: Crosby Lockwood and Son, Ltd., 1938.) 20s. net.

IT is a commonplace to refer to the sun as the nearest star, unique in presenting a disk for detailed study and thus deserving the closest of observation. In this book, Dr. Abetti, the director of the Arcetri Solar Observatory at Florence, surveys our knowledge of solar phenomena gained from the rather restricted direct telescopic observations to those embraced by the extensive field of spectroscopy. How rich the results have been may be quickly appreciated by looking through the numerous illustrations. Behind some of these lie years of devoted research and great inventive ability, as in the case of a spectroheliogram of beautiful definition, the detection and measurement of the magnetic field of a sunspot, or the recording of the sun's inner corona without a total eclipse.

Of astronomical readers of the book, the solar observer will perhaps derive the greatest profit and pleasure, because the book is written from his point of view. To the theoretical worker, however, this comprehensive survey will be of use as a reminder (to quote from the prefatory note) "of the existence of a large body of observational material which cries out for investigation by the inductive theorist". During the last few years, there has been a growing body of wireless research workers and others who require information of the sun's behaviour during its 11-year cycle of activity. To these also, Abetti's book can be recommended to answer their questions. It will be surprising if nothing more than a transitory interest is felt after this introduction to a star in action.

Du pétrole

Par Victor Forbin. (Ce qu'il faut connaître, 28). Pp. 158. (Paris: Boivin et Cie., 1938.) 8 francs.

THERE is no doubt that M. Victor Forbin in his book "Ce qu'il faut connaître du pétrole" has satisfied a long-felt desire of the French layman. Every intelligent person at some time or other is driven by an urge to find out more about petroleum, that commodity which in an unbelievably short time revolutionized modern standards of living and which is used in some form or other every day by the poorest and richest alike. The development of the petroleum industry has been, and still is, romantic, and there is no reason why its romance should be buried and lost amid chemical formulae and statistics of text-books comprehensible only to technologists and others directly concerned with the industry.

M. Forbin has written an easily assimilated story of petroleum, but at the same time there are included in it much authentic information and a number of judiciously inserted statistics. There is so much information in this small paper-covered book that it should provide a satisfactory answer to practically all non-technical queries about petroleum and a great many technical ones, whether concerning origin, production, refining or commercial distribution.

Mosquitoes of the Ethiopian Region

2: Anophelini; Adults and Early Stages. By the late Dr. Alwen M. Evans. Pp. x+404. (London: British Museum (Natural History), 1938.) 20s.

A SHORT time before her death in August 1937 Dr. Alwen Evans brought to London the MS. and drawings for a monograph on the Anophelini of the Ethiopian region. This work was, happily, nearly complete, and has been seen through the press by Dr. F. W. Edwards of the British Museum (Natural History). In rather less than twelve years the number of Anopheline mosquitoes known from the region in question has become about doubled. This increase in knowledge has made the present monograph one of great value and necessity. *Anopheles*, it may be added, is the only genus of these mosquitoes that occurs in Africa, and is represented by the two subgenera *Anopheles sens. str.* and *Myzomyia*. Wherever possible there is included, under each species, a description of the adult insect, the pupa, larva and egg. There follow accounts of the larval habits and breeding places; habits of the adults; relation to malaria; and, finally, distribution.

We have nothing but praise for this comprehensive and scholarly work, which is admirably arranged and clearly illustrated. In every respect it forms a worthy memorial to its author, whose decease, in the midst of an active and scientific life, was a great loss to workers in medical entomology. A. D. I.

Chemie und Technik der Gegenwart

Herausgegeben von Dr. H. Carlssohn. Band 18: Feuerfeste Baustoffe: silikatischer und silikathaltiger Massen. Von Dr. Claus Koeppel. Pp. xvi+206. (Leipzig: S. Hirzel, 1938.) 17 gold marks.

THE first part of this book deals with the various modifications of silica (quartz, tridymite and cristobalite) in a very clear and satisfactory manner, the quantitative data being summarized in tables and curves. In the second part, the system silica-alumina is described, followed by the system silica-alumina-lime. The changes of state of silica in refractories owing to changes of temperature and the effects of various other substances are systematically described. The remaining part of the book deals with the effects of silica in other refractories, namely, magnesite, dolomite, natural magnesium silicates, chromite and zirconia.

Domestic Pests:

What they Are and How to Remove Them. By L. Hunter. Pp. xii+235. (London: John Bale, Sons and Curnow, Ltd., 1938.) 7s. 6d. net.

THIS little book is intended to give information regarding the various kinds of animals—from mites and insects to rats and mice—which invade human dwellings. Besides giving accounts of preventive and remedial measures, something is also said about the life-histories of the various creatures likely to be met with. In addition to animal invaders, a short account of the common domestic moulds is also included. The book has been well planned, and its subject-matter is scientifically accurate and well adapted for the purposes intended.

Structure of Proteins*

By Prof. J. D. Bernal, F.R.S.

THE structure of proteins is the major unsolved problem on the boundary of chemistry and biology to-day. We have not yet found the key to the problem, but in recent years a mass of new evidence and new lines of attack have enabled us to see it in a far more concrete and precise form, and to have some hope that we are near to solving it.

The problem of protein structure is twofold: the first is that of the form and properties of the protein molecule, and the second that of its internal structure. Owing to the extreme instability of the protein molecule, only the gentlest physical methods can be used; nevertheless three lines of attack—centrifugal, electrical, and X-ray—have already led to great success. The most fundamental has been the ultra-centrifuge, particularly the work of Svedberg and his school¹. Protein molecules will sediment in sufficiently high centrifugal fields, and from their sedimentation constant it is possible to arrive at a fairly accurate value for the weight of the molecule, though there is some doubt as to whether what is measured is that of the complete protein molecule, because of its inevitable association with the solution in which it is suspended.

The most striking discovery of Svedberg was that the weights thus obtained seemed to fall into definite classes which were multiples of each other. This suggests very strongly that all proteins are built from some common unit. What that unit is is more difficult to determine. Originally taken as 35,000, proteins are now found of 17,000 and even of 10,000 molecular weight. Critical examination of the data, moreover, shows that there is no exact correspondence to certain weights, but rather a scattering of weights concentrated in certain regions. There is no doubt that in closely related proteins there are simple relationships. Both haemoglobins and haemocyanins can, for example, be split reversibly into 2, 4, or 8 parts. But whether these relationships hold for all proteins is more doubtful; particularly as studies of viscosity have shown that proteins belonging to the same weight class such as insulin and gliadin may differ enormously in shape, the first being a flattened sphere and the other an elongated rod, and it is difficult to see what common physical structure they can have.

It has been claimed that this variation of weight of proteins of the same Svedberg class is to be expected on account of the known difference in amino-acid content. On the basis of existing analytical figures, it is as yet impossible to say whether this is or is not sufficient to account for the observed discrepancy. The figure of 288 amino-acid residues in a 35,000 molecular weight class protein cannot be taken at present as more than an inspired guess.

The second approach to protein structure comes from the electric properties of their molecules. The work of Cohn, Tiselius, and others gives us a picture of a protein molecule in solution as a particle covered with positive and negative charges due to the acid and basic nature of the amino-acid side-chains. The number of these groups depends on the condition of the medium. The protein molecule is, therefore, in its external relationship an essentially ionic structure, and probably carries with it an ionic atmosphere stretching out into the water in which it is dissolved.

The third line of attack is that of X-ray study. The beautiful crystalline forms exhibited by proteins, which have been known for at least a hundred years, were always a powerful attraction to X-ray crystallographers, but until the last five years the instability of protein crystals and their small size had defeated their efforts. Since 1934, however, it has been possible to examine a number of typical protein crystals². This has been done by mounting them in small tubes in their mother liquor, for most, if not all, proteins suffer considerable breakdown if examined dry. From the beginning, the results of this examination revealed important new facts. In the first place, the pictures yielded by protein crystals were of exceptional perfection. They showed large unit cells with a great wealth of reflections (see accompanying illustration), and these reflections were found even at comparatively high angles corresponding to such low spacings as 2 Å. This indicated that not only were the molecules of the proteins substantially identical in shape and size, but also that they had identical and regular internal structures right down to atomic dimensions.

From the size of the unit cells and their densities it was possible to compute the weight of matter in each repeat unit. This, however, does not immediately give the molecular weight, for two reasons. In the first place, the number of molecules

* From a Friday evening discourse delivered at the Royal Institution on January 27.

in the cell is not known, and in the second it is difficult to determine how much of the cell weight is due to the protein and how much to the water in the cell. By measuring the loss of water on drying it is, however, possible to arrive at a figure for the—possibly fictitious—dry weight, which can be compared with those obtained by the centrifuge or by chemical means. Here it is found that there is excellent agreement on the assumption that there are only a few, 2, 4, or 8, such molecules per cell². Thus the X-ray method furnishes an extremely accurate measure for the basic molecular weight of proteins though it cannot determine its multiplicity. It may well be that many proteins are built of sub-units, which though of approximately equal weight are not chemically identical, and are more properly to be called molecular compounds than molecules.

The most striking feature of the cell measurements of crystalline proteins is the considerable change which occurs on drying, where in many cases shrinkage of nearly 50 per cent occurs. But what is more remarkable is that the shrinkage is often confined to one or two directions in the cell. There are two possible explanations of this fact. First, that the molecules of the protein are linked together in extremely loose aggregates which collapse on the removal of water, leaving the skeleton of molecules in a now more closely packed array. The other explanation is that the molecules are held apart by their ionic atmospheres due to the charges on them, and contain, therefore, sheets of free water. It may be that both explanations hold, one more markedly for some crystals and the other for others. Thus for haemoglobin, where there is a marked shrinkage from 55 Å to 38 Å in one direction, it is difficult to imagine an ionic atmosphere, as the crystals are practically salt-free and at an isoelectric point of pH 6.8. On the other hand, it is difficult to explain the remarkable properties of tobacco mosaic virus on any other hypothesis. This virus has long thin particles which have a tendency to set equidistant and parallel, even down to concentrations of 13 per cent, and probably down to 1.5 per cent. It is difficult to imagine what force other than that of ionic atmospheres can preserve this regularity. Quite recently we have shown that the equilibrium distance between the particles depends on pH and salt concentrations, varying, for example, between 320 Å at pH 7; and 206 Å at pH 3.4. It should be possible to find a quantitative theory to explain these changes and, indeed, the beginning of such a theory has been made by Langmuir⁴ and Levine⁵.

The general picture of the external character of protein molecules is beginning to be definite. The molecules are spheroidal bodies of dimensions

varying from 30 Å. to 100 Å., are covered with hydrophil groups bearing charges of both signs, and probably carry with them in solution an atmosphere of ions.

The problem of the internal structure of protein molecules is one of enormously greater difficulty. Any effective picture of protein structure must provide at the same time for the common character of all proteins as exemplified by their many chemical and physical similarities, and for the highly specific nature of each protein type. It is reasonable to believe, though impossible to prove, that the first of these depends on some common arrangement of the amino-acids. The first hint of this comes from a study of the fibrous proteins. Here, owing to their technical importance and their much greater ease of handling, a very considerable advance has been made, due largely to the well-planned and persistent researches of Astbury⁶.

The fully extended β -keratin fibre has a strong repeat at every 3.5 Å., corresponding to the length of one amino-acid residue, and two other repeats at 10 Å. and 4.5 Å. respectively, corresponding to periodicities at right angles to the chain length. One of the most significant of Astbury's discoveries was that these two periodicities are also at right angles to each other. In other words, that the repeat unit of the fully extended protein has distinct characters in three dimensions. The significance of these repeats seems also beyond doubt, the 10 Å. spacing corresponding to the length of the side-chains of the amino-acid residues, and the 4.5 Å. to the so-called backbone spacing between the main chains themselves, which are held together by the CO and NH groups. In the shorter α form, the 10 Å. spacing remains, while the 4.5 Å. disappears, and this indicates that the chains are folded, but folded definitely in a plane and not as in rubber in two dimensions. What the precise mechanism of this folding is remains obscure, but it is of fundamental importance because it is probably very closely associated with the kind of folding that occurs in the corpuscular proteins.

The significance of these findings for the general protein problem is, first, that all soluble proteins hitherto examined give on denaturation a fibrous material which can be oriented and seems identical in basic structure with β -keratin, and secondly, that the actual change which a crystalline protein undergoes on denaturation must be very slight. This is shown by the close resemblance of powder photographs of crystalline proteins before and after denaturation, and also by the observations of Astbury, Dickinson, and Bailey⁷ that a single crystal of exocelsin gives on partial denaturation fibres orientated in the direction of the crystal

axes. Further, recent work by Perutz* has shown by an entirely different method, namely, the study of the absorption spectra in different directions in crystals, that the position of the prosthetic group in haemoglobin is not altered by denaturation.

The evidence that the X-ray study of the crystalline proteins themselves provides for the elucidation of their structure is abundant, but it is extremely difficult to interpret. Photographs of crystalline proteins (see illustration) show hundreds of spots and marked differences of intensities stretching right out to reflections corresponding to inter-atomic distances. Unfortunately, however, direct analysis of these photographs is rendered impossible by the fact that we can never know the phases of the reflections corresponding to the different spots. The ambiguity introduced in this way can only be removed by some physical artifice, such as the introduction of a heavy atom, or the observation of intensity changes on dehydration, which have not hitherto been carried out in practice. For all but one of the proteins examined, the task is made still more difficult by the presence of more than one Svedberg unit in the cell.

The resulting X-ray pattern in such cases depends both on the position of the molecules in the cell and on their internal structure. Fortunately the one exception, insulin, has only one molecule per cell. An X-ray study of dry insulin crystals has been made by D. Crowfoot* and the intensities of the reflecting planes determined. It is to be regretted that it was not possible to examine the crystals wet because in the dry crystals no planes of spacing less than 8 Å. are observed, and consequently no evidence exists as to the fine structure of the molecule. The evidence on the coarse structure is, however, striking enough; it can most easily be seen from a study of the Patterson projections and Patterson-Harker sections which Miss Crowfoot has computed for insulin.

It should be explained that these projections do not represent the distribution of the density of scattering matter in the cell, but merely the product of the densities at points separated by a constant vector. It is not surprising, therefore, that the interpretation of these diagrams has already given rise to acute controversy. It seems natural to assume, though it is in fact an arbitrary simplification, that the peaks in the Patterson projection correspond to distances between a small number of high concentrations of scattering matter. Attempts have been made to reduce the analysis of the pattern to that of finding a pattern of points in space that will give maxima at the places observed. All these attempts have in fact failed. It is easy to find a large number of point patterns which will give the correct basal plane projection, but none of these will at the same time

fit the sections. The claims to have done so¹² are based on the arbitrary selection of a certain number of vectors, and the agreement disappears if all the vectors are taken¹³. The failure to find a point solution suggests that we are dealing with groups of size of the same order as their distance apart, and that the appearance of the enhancement of reflections at spacings 10 Å. and 4.5 Å. corresponds to an arrangement of side-chains or backbone spacings similar to those occurring in the fibrous proteins.

On the basis of present X-ray knowledge, it is clearly impossible to arrive at any detailed picture of protein structure. Indeed, up to now the chief value of the X-ray method has been to disprove

HORSE MOUTH HAEMOGLOBIN, *b*. AXIS, OSCILLATION PHOTOGRAPH, THE RING COMING THROUGH CENTRAL SPOT SHOWING (450) ZONE.

such hypothetical structures as have been put forward. It is, however, possible to formulate in a broad way some of the possible modes of arrangement and to suggest working hypotheses as a guide to future work.

The formal problems of structure of the protein molecule are:

(a) What is the nature of the link between amino-acid residues?

(b) Does the linkage run through the whole of the molecule or only through parts of it? In other words, is the protein one unit held together by primary valence forces, or is it made of sub-units held together in some different way?

(c) If such sub-units exist, what is the nature of the link between them?

As to the first question, the difficulty of accounting for the structure of spherical molecules out of a linear peptide chain has led to the idea of an alternate mode of linkage in which each amino-acid residue can be linked to four others and not

merely to two. While this hypothesis at first sight has a theoretical attractiveness, it still lacks any chemical support, and has been subjected to serious criticism on chemical grounds¹². There are enough unknown factors in protein structure already without employing doubtful chemical assumptions.

The question of the unitary nature of the protein molecule arises whether the inter-residue linkage is peptide or not. With a multiple link it is easy to construct models either of the cage or solid type, but as has already been pointed out, it is difficult to reconcile such continuous structures with the definite 10 Å discontinuities revealed by the X-ray analysis. With a peptide chain, however, the unitary solution becomes more difficult. It is difficult to imagine any kind of fold or coil by which a single chain can occupy the observable space and at the same time not be so intricate that its formation by any natural process would be enormously improbable. There is, however, much evidence that at least the larger protein molecules are not unitary in structure. In the first place, some of them can be split in solution down to particles of molecular weight of the order of 10,000, and this is probably not the lower limit, as smaller particles are difficult to isolate or measure.

Two lines of X-ray evidence also point to sub-units, the high symmetry of protein crystals and the 10 Å repetitions. The symmetry of protein crystals is much higher than would be expected statistically from compounds of such great complexity. This would seem to indicate that each molecule is built of sub-units themselves unsymmetrical but arranged in a symmetrical way. The size of the sub-units must lie between that of the smallest protein observed, that is, one with a molecular weight 9,000, and that of a single amino-acid of molecular weight averaging 120, that is, it must contain some sub-multiple of probably 72 amino-acid residues. The uncertainty arises from the fact that it is not necessary for all the sub-units to be the same, though some must be to account for the symmetry. The presence of trigonal symmetry suggests that the asymmetrical unit must be a third or less of this number, that is, it must contain 24, 12, or 8 amino-acid residues.

The question of the structure of the sub-unit would seem to raise at first sight the same difficulties as the structure of the molecule itself. Actually, however, with the smaller number of residues the difficulties and the improbabilities of the coiling become much less, particularly if we postulate—which is not unreasonable—that the sub-units are closed peptide rings. Such rings would necessarily curl up owing to the mutual attraction of the positive and negative charged amino and keto groups

in the chain, and models of such coiled chains can be constructed which preserve the distances between such groups that have been found in other compounds. The difficulty is, however, that there is a very large number of such possible models, and as yet nothing to choose between them. The method of folding in the chains in the sub-units may well be similar to that of the contracted form of the fibrous proteins mentioned above, and indeed a more detailed study of these may give us a clue to the whole arrangement.

The postulation of sub-units, however, raises further questions in the molecular structure, for they must be bound together sufficiently tightly to hold the molecule together in aqueous and ionic solutions. For this purpose a limited number of bonds are available. Ionic bonds are plainly out of the question, as they would certainly hydrate. There remains the possibility of amino-carboxy links between the ends of side-chains, but this is somewhat liable to the same criticism. It seems more probable that the links are either or both of two kinds, S-S linkages and association of hydrophobe groups. With the small number of sub-units, the number of S-S linkages needed to hold the molecule together is for all proteins hitherto examined sufficiently provided for by the amount of sulphur present, and the extreme changes in activity that proteins undergo when S-S bonds are broken indicate that they may have this fundamental part to play. Whether this is so or not, however, the behaviour of the hydrophobe groups of the protein must be such as to hold it together. As Danielli¹³ and Langmuir¹⁴ have pointed out, on the basis of surface-film work, the protein molecule in solution must have its hydrophobe groups out of contact with water, that is, in contact with each other, whereas on the surface the molecule is broken up into a film of 10 Å thickness in which the hydrophobe groups are driven out of contact with the water. In this way a force of association is provided which is not so much that of attraction between hydrophobe groups, which is always weak, but that of repulsion of the groups out of the water medium.

Langmuir has used this picture as a justification of the cyclol cage hypothesis, but it is strictly quite independent of it, and the model outlined above has the advantage of accounting very satisfactorily for the phenomenon of denaturation, particularly on a surface. Once the sub-units come to the surface, their rings are brought into a plane and different rings can interact according to the familiar ring-chain polymerization process, which will result in the formation of the fibres which Astbury has shown to exist in such films. This polymerization process takes measurable time as Danielli's work has shown.

The picture thus presented is far from being a finished or even a satisfactory one. The crucial fact that requires elucidation is the precise mode of folding or coiling of the peptide chains, and for this we may have to wait for some considerable time, until the technique of X-ray and other methods have been advanced much further than at present. The problem of the protein structure is now a definite and not unattainable goal, but for success it requires a degree of collaboration between research workers which has not yet been reached. Most of the work on proteins at present is unco-ordinated; different workers examine different proteins by different techniques, whereas a

concentrated and planned attack would probably save much effort which is now wasted, and lead to an immediate clarifying of the problem.

Dr. William Thomson, F.R.S., a Forgotten English Mineralogist, 1761 - c.1806

By Dr. R. T. Gunther

WILLIAM THOMSON led two lives which seem never to have been correlated, certainly not in England. The first life culminated in his appointment as Dr. Lee's lecturer in anatomy at Oxford and his election into the Royal Society on March 16, 1786. The signatories to his certificate of candidature were the Hon. Charles Greville, Prof. R. Kirwan, John Hunter, S. F. Simmons, W. Pitcairn, Sir J. E. Smith, D. Pitcairn and Prof. T. Hornsby of Oxford. In 1790, he resigned all appointments, including the fellowship for which he had compounded on election. His second life was mostly spent in Naples during that pregnant period when Nelson and the British fleet featured so largely in all histories of Europe. There Thomson made a profounder study of volcanic phenomena than any Englishman, even counting Sir William Hamilton, had ever made before him.

That bibliographers have failed to connect the two lives is explained by Thomson's early death, and by his adoption of the name Guglielmo, and the signature "G. Thomson" for the few short articles that he published in Italian. Indeed he appears to have abandoned the use of his native tongue altogether. He was often addressed as "Dr. G. Thompson", and his only known address was "chez M. Heigelin" at the Danish Consulate in Naples.

My discovery of the identity of these two persons was due to the finding, in a contemporary collection of minerals, many fine specimens marked "Dr. T.", including a pet of Vesuvian lava moulded as a

commemorative medal to Diodato Dolomieu, with the name "G. THOMSON ANGLUS 1805" impressed on the back. Prof. Lacroix confirmed this by finding in Paris a letter addressed by G. Thomson to Cuvier from Naples in 1801, in which he is described as "già Professore di Anatomia a Oxford". With these clues the rest was simple.

William Thomson's father was a well-known physician of the same name in practice in Worcester. In 1776, at fifteen years of age, the son came up to Queen's College, Oxford, but migrated to Christ Church in 1780 as a 'Canoneer' student. In 1781 he appears to have assisted Gough in connexion with the latter's work on a new edition of Camden's "Britannia"; and in October, "to complete his medical studies", he went to Edinburgh, but returned to Oxford to take his M.A. in 1783, B.Med. in 1785 and D.Med. in 1786. As Lee's reader he gave two courses a year in the Anatomy School.

Dr. Gibson, who has traced his career as physician to the Radcliffe Infirmary from June 12, 1786 onwards, has found that one morning in the spring of 1790 two murderers were hanged. In the same afternoon "their bodies were conveyed in a cart to the Anatomy School at Christ Church where Dr. Thomson next day gave a public lecture on the two bodies, to which the neighbouring faculty as well as those of the place were invited, together with the gentlemen of the University, and many of the principal inhabitants. The bodies were also publicly exhibited the day following". Some forgotten event must have occurred, for in the

following autumn he resigned all his appointments! Christ Church paid him £240 for the anatomical preparations he had made for the School, and Oxford knew him no more.

Thomson's new scientific life abroad probably began with a visit to Prof. Dolomieu in Paris. He spent the autumn and winter of 1791 in Tuscany, there making his first discovery of a new mineral, a beautiful pearl-like opal, on the old volcano of Santa Fiora; to which he gave the name of 'florite'. In Siena he made the acquaintance of Prof. Soldani, who in after years doubtless secured the publication of his last paper, on the Pallas meteorite, in the *Atti* of the Siena Academy. His engraving of its crystalline structure shows an anticipation of Widmanstätten figures of 1808. While spending the winter in Florence he received closely related specimens from other localities; and it was there that he found that by grinding certain quartz crystals with an emery wheel, he could demonstrate the existence of minute drops of naphtha enclosed in the crystals. Several mineral specimens in his collection were obtained from Tuscan localities. On reaching Naples he was certainly influenced by the great interest of the vicinity and began to observe and collect seriously. Scipio Breislack, the manager of the alum and sulphur works at the Solfatara, was doubtless one of his early friends and guide to the extinct volcanoes of the Phlegraean Fields.

On an excursion to Castellamare, Thomson noted the successive changes produced in the burning of limestone in a lime-kiln, and compared them with those in limestone blocks cast up by Vesuvius. In 1794 he visited the volcanic island of Ischia, where upon the Lacco rock he discovered siliceous deposits comparable to florite: and so, too, in the Solfatara.

On June 12, 1794, on the anniversary of Thomson's appointment at the Oxford Infirmary, Vesuvius broke out in violent eruption. A few days later molten lava, bursting the ash walls of the volcano, flowed down to the sea, overwhelming with fire and rock the greater part of the town of Torre del Greco on its way. It being impossible to approach the mountain by land, Thomson and Breislack witnessed the spectacle from a boat, in which, like the elder Pliny, they spent the night together but a few yards from the shore. Their observation that there was no great local disturbance of the water supported Breislack's belief that the sea had no direct access to the volcano.

By July 1795 the lava had cooled sufficiently for Thomson to visit the vent from which the lava had issued. The sand near by was covered with his siliceous stalaotite. At a church at Torre del Greco against which the hot lava had come, he found crystals of pyroxene sublimed on the walls.

From pits where quarreymen were uncovering their buried city, he made a special collection of objects that had been buried in the flowing lava, and mineralized by its heat and gaseous emanations. He was thus able to study in detail the chemical and physical changes in bronze, copper, silver, lead and iron in Nature's own laboratory, all described in detail by Breislack from specimens in the Thomson collection. His long series of altered marbles and limestones provided by Monte Somma has been specially praised. The new name, 'sarcollite', for a variety of analcime from Monte Somma was due to him. Other words of his coinage were 'glastein' and 'glastenised' for glass or obsidian that had undergone divitrification; 'mère-pierre' for the rock whence lava has come.

Thomson, trained both as a chemist and as a mineralogist, brought together the most scientifically collected series of minerals and rocks that had perhaps ever been made in a volcanic region. Its importance was repeatedly mentioned by Breislack and by Faujas de St. Fond: indeed the chapters in Breislack's book are entirely based upon Thomson's ideas and classification. Alexander von Humboldt and von Buch, who witnessed the eruption of 1804, visited him in 1805 and were enthusiastic in their praise of his collection: Gay-Lussac was also one of the party. By the time of Poulett Scrope's visit to Naples, he appears to have been forgotten.

Beyond a few contributions to the *Giornale Letteraria di Napoli* (not to be found in England), there is little else known of Thomson. He seems to have been an accomplished artist, for he drew his own illustrations: one was engraved for Breislack's book. In 1801 he was writing to Cuvier. About 1807 Faujas deplored his recent and premature death, and in the same year the whole, or a large part of his volcanic minerals reached Lady Hippiisley, the wife of Sir John Hippiisley, fellow of the Royal Society, and one of the first managers of the Royal Institution, at her country home at Ston Easton near Bath; and as labelled by her on arrival, it is largely in its original state. It has led to this first sketch for a biography: the date and place of his death still remain unknown.

Dundee Meeting of the British Association

THE meeting of the British Association in Dundee, which will run from August 30 until September 6, will be the third to be held in that city. The preliminary programme has just been issued. It is stated that for Dundee the present year is one of civic jubilee, for the town "attained the dignity of a city" in 1889: this coincidence with the meeting of the Association will not be overlooked. In referring to the previous meetings, mention is made of that in 1912 as "the occasion of a splendid act of generosity by a citizen of Dundee, the late Sir James Caird, whose gift of £11,000 to the funds of the Association enabled it to commemorate his name in the Caird Fund" for research.

The requirements of the Association in the way of accommodation for meetings and other functions will be more easily met this year than they were in 1912. The great hall which bears Caird's name has been built since that date: it will amply house the inaugural meeting on August 30, at which the president, Sir Albert Seward, will give his address on "The Western Isles through the Mists of Ages." The same hall will be the scene of a civic reception in the evening of August 31, of a graduation at which the University of St. Andrews will confer honorary degrees, on September 4, and of other items in the programme. The Reception Room and offices will be located in the Training College; the Victoria Art Galleries, which provided the Reception Room in 1912, will on the present occasion house a special exhibition of pictures, some from the city's permanent collection, others on loan from private collections in the district. The sections of the Association will be conveniently established, mostly in the University College, which immediately adjoins the Training College, and some in other buildings not far away.

The subjects of the presidential addresses in the sections, so far as they are announced, are as follows: Section A: Mr. R. S. Whipple on "Instruments in Science and Industry"; Section B: Prof. E. K. Rideal on "Film Reactions as a New Approach to Biology"; Section C: Prof. H. H. Read on "Metamorphism and Igneous Activity"; Section D: Prof. J. Ritchie on "Perspectives in Evolution"; Section G: Mr. H. E. Wimperis on "The Future of Flight"; Section H: Prof. W. E. Le Gros Clark on "The Scope and Limitations of Physical Anthropology"; Section I: Prof. D. Burns on "The Assessment of Physical Fitness"; Section J: Mr. R. J. Bartlett

on "Measurement in Psychology"; Section K: Prof. D. Thoday on "The Interpretation of Plant Structure"; Section L: Dr. A. P. M. Fleming on "Education in Industry"; Section M: Sir Thomas Middleton on "Practice with Science. The Farmer's Position and the Scientific Worker's Programme".

Among other subjects announced for discussion in the sections are: In Section A, television, problems of high-speed flight, the surface temperature of stars and high-temperature problems. Sections A and B will join in a discussion on artificial radio elements. Section B will deal with light alloys and with intramolecular changes, and will join with Section I in discussing tissue respiration. Section C will deal, as usual at an opening meeting, with local geology, and in this connexion it may be mentioned that a sectional excursion will be held after the meeting during September 7-11, covering Edinburgh and a district from the coast to the north-east, to the hills to the south-west of that city. Section C will deal also with the raised beaches of Forth and Tay, and with the Old Red Sandstone - Carboniferous boundary. Section D will discuss the natural history of salmon and trout, and there will be an exhibition of biological films. Another subject to be dealt with by this section is problems of freshwater biology. Section E will discuss the national atlas which is at present under the consideration of a committee of the Section. Speakers from other sections concerned will take part in the discussion. Section F will deal with various Scottish economic problems. The programme of Section G includes problems of transatlantic aviation and air conditioning. Section H will return to the subject of the teaching of anthropology and will join with Section I in the discussion of nutrition and physique. In Section I this last topic will be associated with that of the assessment of physical fitness, and the Section will also deal with the problem of pain. This Section will hold a day's session at St. Andrews. Section L announces discussions on education as a preparation for industry, on educational research in Scotland, and on the Spens Report. Section M will review the subjects of grass conservation and seed potato growing.

Two special sessions under the auspices of the appropriate sections jointly, and a local committee, will deal with scientific aspects of the cultivation and treatment of jute and with problems associated with the jute industry.

The Conference of Delegates of Corresponding Societies will be presided over by Prof. H. L. Hawkins, who will give an address on "Local Scientific Societies and the Community".

The new Division for the Social and International Relations of Science, established last year at the Cambridge meeting, announces an afternoon session for papers and discussion on the co-ordination of scientific research, and on population, and it is understood that the possibility of a discussion on international co-operation in science is also under consideration. An evening meeting on Sunday, September 3, will hear an address from Sir Richard Gregory, chairman of the Division, on science and social ethics, and on Wednesday morning, September 6, a session of the Division will be devoted to a discussion on nutrition, which will form a complement to sectional discussions in this field already mentioned.

A new feature of British Association meetings will be the delivery by Dr. Isaiah Bowman, president of Johns Hopkins University, of the first of the lectures to be given under the arrangement concluded last year with the American Association for the Advancement of Science, by which, in alternate years, a speaker from America is to be invited by the British Association, and one from Great Britain by the American Association. Dr. Bowman has chosen as his subject "Science and Social Pioneering". A number of public lectures will be given not only in Dundee, but also in neighbouring towns. In this connexion it is of interest to recall that it was at the Dundee meeting in 1867 that the first lecture to the 'operative classes' was given, an annual series out of which the present public lectures developed: moreover, it was at the Dundee meeting in 1912 that for the first time, in response to public demand, more than one such lecture was given, a practice which has become common since that time.

The customary full list of excursions is announced—those on Saturday will include Blair Atholl, Dunfermline, St. Andrews, Braemar and other places, and there will be many visits to works and places and institutions of special interest to individual sections. Garden parties and a dance are announced, and the Dundee Horticultural Society will hold its flower show during the period of the meeting; the president of the Association will perform the opening ceremony.

The paragraph on accommodation for visitors begins with the frank statement that hotel accommodation in Dundee is rather limited, but a local committee is actively at work on the whole question of meeting visiting members' requirements, and there need be no fear of any difficulty if members will make known their wishes in accordance with the directions in the programme.

The programme includes a list of all hotels and boarding-houses in Dundee and neighbouring places, and a list of lodging houses is in preparation. There will be a limited amount of accommodation in the hostels attached to University College, and the Medical School, and it should be specially observed that students' residence halls of the University of St. Andrews will be open to receive visitors; it is hoped that a service of special trains will be worked for the convenience of members staying in that town.

The announcements concerning publications include a reference to an important change decided upon at the Cambridge meeting. As from October 1939, the Reports of the Association will be published quarterly under the title of "The Advancement of Science" and the annual volume hitherto issued will be discontinued. So also will the collection of presidential addresses which have been issued at the time of the meeting under the title of "The Advancement of Science", which title will now be transferred to the new quarterly. It is stated, however, that individual addresses will be on sale separately during the meeting.

The preliminary programme is accompanied by an appeal from the general treasurer for an extension of membership of the Association. It is common knowledge that any person can, and very many do, take up membership only for the year of a particular meeting at which it is intended to be present: in particular, special efforts are always made to ensure that all interested residents in the locality of the annual meeting are given the opportunity to do this. But it is rather startling to learn from the present appeal that "of those who attend the annual meetings (apart from life members) only a small proportion—about one-quarter—are regular annual subscribers". The Association deserves a wider basis of permanent support than that, by a largely increased number whether of regular annual subscribers or of life members. It is pointed out in the appeal that "during the past few years the British Association has not hesitated to extend in fresh directions its activities for the advancement of science". Examples are given. In a reference to the new Division for the Social and International Relations of Science, established last year, it is stated that "the fields of activity already opened to view indicate that with more ample resources the Association will be able to undertake, through the Division, new work of national and international importance". Reference is made to the recent scientific delegation to India, an example likely to be followed elsewhere; to the arrangement for exchange of lecturers between the British and American Associations, made last year, and to various other opportunities which the Association

now possesses, within the framework of its constitution, to advance science, provided only that increased financial support is forthcoming. "These wide potentialities", the appeal states, "have all emerged in recent years; but there must always be borne in mind the field of scientific research and inquiry in which the Association has honourably laboured almost since its foundation. The ability to make grants for research is of the

essence of its being, and to maintain and strengthen this activity is one of the first tasks of every successive General Treasurer."

The appeal deserves success, and it is to be hoped that it will achieve it. Its professed object, as has been said, is the extension of membership; but well-disposed persons will not overlook the possibility of strengthening the financial foundations of the Association by other means.

Obituary Notices

Prof. C. M. Jessop

CHARLES MINSHALL JESSOP, who died on March 9, was born on June 13, 1861. His father was vice-principal of Cheshunt Theological College, and it may be to this that he owed his strong religious views. Jessop was educated at King's College School, London, and Clare College, Cambridge. He was bracketed seventh wrangler in the mathematical tripos of 1885 along with James Harkness and Henry Stroud. Harkness was afterwards the joint author of Harkness and Morley's "Theory of Functions", and Stroud became, later, as professor of physics, Jessop's colleague in the Newcastle Division of the University of Durham. In the same year (1885) Jessop was elected a fellow of Clare.

After holding various teaching posts in schools, Jessop was in 1893 appointed lecturer in mathematics at the Durham College of Science, Newcastle-upon-Tyne, now King's College; in 1903 he was advanced to be professor of mathematics in the same College, a post which he held until his retirement in 1928.

Jessop's main mathematical interest was in geometry, and he frequently deplored the diversion of interest in Great Britain from geometry to other branches of mathematics. His contribution to the subject was his two books. The first, published in 1903, was a "Treatise on the Line Complex". Apart from J. H. Grace's account of the subject in the tenth edition of the "Encyclopædia Britannica", this was the first full treatment in English. It gave a complete discussion of the development of the subject at that time.

The second book was on "Quartic Surfaces with Singular Points", which appeared in 1912. This was welcomed as a valuable introduction to some of the latest results obtained by geometers and at once took its place among the standard English treatises.

Jessop also published several smaller books, of which the most popular was the "Elementary Treatise on Trigonometry" which appeared in 1893, a joint work with E. W. Hobson.

Jessop had a fine appreciation of good mathematical style. He valued the subject for its own sake and was somewhat contemptuous of mathematics as a handmaid to the sciences. He was an inspiring teacher, especially to advanced students, and many hundreds owe their interest in mathematics to his able presentation.

Dr. Alexander Hetherwick, C.B.E.

We regret to record the death of the Rev. Alexander Hetherwick, for many years prominent as a missionary in Central Africa, which took place in Aberdeen on April 3 in his seventy-ninth year.

Alexander Hetherwick was born on April 12, 1860, and graduated from the University of Aberdeen with high honours in classics, mathematics, and theology, winning the Arnot Prize for experimental physics, and being Simpson mathematical prizeman.

At twenty-three years of age, Hetherwick volunteered for work with the mission of the Church of Scotland in Central Africa under Dr. Clement Scott at Blantyre. Five years later, in 1888, he succeeded Scott as head of the mission, a position he retained until his retirement in 1928. On his arrival in Central Africa the country, which afterwards became Nyasaland, was inhabited by pagan tribes dominated by the warlike Angoni, an intrusive immigrant offshoot of the Zulu stock; but his influence soon made itself felt. On his retirement he was Moderator of the Synod of Central Africa, in which the Presbyteries of Blantyre and Livingstonia, with those of the Dutch Mission, comprised some 40,000 members drawn from these pagan tribes.

It was not, however, for its Christianizing influence in the narrower sense that Hetherwick's work was remarkable. Under his guidance the Scottish Mission was conspicuous for its endeavour in instructing the native in handiwork and agriculture, and for its work among them in medicine and hygiene. Dr. Hetherwick himself was the foremost authority on the languages of the country. He translated the New Testament into the language of the Yao and was chairman of the board for the translation of the Bible into Nyanja. He wrote handbooks of the principal languages, and on his return to Scotland took up the revision of Scott's great dictionary of Nyanja. His knowledge of native customs and institutions was no less profound than his knowledge of their languages; and he was in those early days one of the principal sources of knowledge of the subject, on which he was a contributor to the *Journal* of the Royal Anthropological Institute. Dr. Hetherwick was twice a member of the Legislative Council, and received the thanks of the Colonial Office and the C.B.E. for his services to native welfare.

News and Views

International Relations

IN a speech on April 14 to the board of the Pan-American Union, President Roosevelt emphasized the fact that the people of the Americas can no longer consider the Atlantic as a barrier shutting them off from affairs in Europe. The rapidity and efficiency of modern communications make the world, East and West, a vast unity, no part of which can be disorganized without dire results for the whole. Mr. Roosevelt followed up this address with a message, which will surely go down in history as one of the most remarkable and far-reaching documents of our time, addressed to the heads of the German and Italian Governments. After referring to recent events in Europe, Africa and the Far East, and to the anxiety and tension plainly evident throughout the world, Mr. Roosevelt continued, "Nothing has persuaded the peoples of the earth that any governing Power has any right or need to inflict the consequences of war on its own or any other people save in the cause of self-evident home defence. . . . It is still clear to me that international problems can be solved at the council table. It is therefore no answer to the plea for peaceful discussion for one side to plead that unless they receive assurances beforehand that the verdict will be theirs, they will not lay aside their arms".

As a necessary preliminary to such discussions, Mr. Roosevelt asks for an assurance that no attack by the armed forces of Germany or Italy shall be made on any of thirty-one independent States, large and small, in Europe, northern Africa and the Near East for a period of ten or, better, twenty-five years. Such assurances, if given, would be transmitted to the Governments concerned, which in turn would be asked to give similar assurances to Germany and Italy. In the more peaceful atmosphere thus created, discussions should be immediately begun, in which the United States would take part, to enable the peoples of the world to "obtain progressive relief from the crushing burden of armament", and to open up international trade so that "every nation of the world may be enabled to buy and sell on equal terms in the world's market as well as to possess assurances of obtaining the materials and products of peaceful economic life". World problems are complex, and "study and discussion of these must be held in an atmosphere of peace. Such an atmosphere of peace cannot exist if negotiations are overshadowed by the threat of force or by the fear of war." Mr. Roosevelt's eloquent appeal for calm and dispassionate study of the intricate affairs of this troubled world needs no commendation from us; it is an appeal for the use of scientific method in the approach to the problems of international relations which all men of science would wish to see implemented now and for all time.

Dr. Haakon Shetelig

THE award of the much prized gold medal of the Society of Antiquaries of London to Dr. Haakon Shetelig, keeper of the Bergen Museum and honorary fellow of the Society, is a fitting recognition of the work of Norway's most distinguished archaeologist, whose researches on the Viking Age have contributed much to the understanding of an important phase in the racial and cultural history of Britain before the Norman conquest. Dr. Shetelig was born in 1877, became keeper of the Bergen Museum in 1901, and in 1914 was appointed professor of archaeology. He was already well known to his English colleagues when his studies of the famous Viking ship of Oseberg were published. So long ago as 1906 he attended the York meeting of the British Association as a "distinguished foreign guest"; and he now has in the press a corpus, fully illustrated, of British Viking antiquities. Although Dr. Shetelig is best known for his work on the Viking period, it has by no means monopolized his studies. His work on Norway's prehistoric past is no less remarkable for its comprehensive breadth of view than for its lucidity of exposition. The presentation of the gold medal to Dr. Shetelig will be made at the anniversary meeting of the Society of Antiquaries to be held at Burlington House on April 27.

Cave Culture of Palaeolithic Age

A COLLECTION of objects of the smaller kind, mostly belonging to the class known to the French archaeologist as *art mobilier*, which illustrates the culture of the cave-dwellers of the Upper Palaeolithic Age, has been put on view for a short period in the prehistoric saloon of the British Museum (Bloomsbury). These objects, which are drawn from the collections in the Museum, are derived from the caves of the departments of the Dordogne and Tarn-et-Garonne of southern France. The phases of culture they specially illustrate are the Aurignacian and the Magdalenian. Among the specimens shown are the well-known design of two reindeer following one another on mammoth ivory, and a number of those heads of horses which are excellent examples of the skill of the palaeolithic artist in seizing the salient features of animal life. This characteristic is especially to be noted in the eight specimens shown of the finely engraved animal figures on pebbles. The familiar but much prized and rare female statuettes in ivory of gross and slender, are not represented in the original, but by casts. An exhibit previously unrecorded is a tally rod of bone of the Aurignacian period. Examples are shown of the various types of harpoons, many of which are of extreme delicacy, and of the bone perforated needles, these being accompanied by the flint implements with which they were made. Among the exhibits of characteristic, or outstanding

examples of flint implements from the caves, is a remarkable example of delicate workmanship in the form of a leaf-shaped Solutrean point, measuring about nine inches long.

Excavations on Pre-Roman Sites in Britain

DURING the past five years, land development at Ewell in Surrey has brought to light extensive evidence not only of Roman occupation, but also of a succession of pre-Roman settlements of considerable importance, some indeed dating so far back as the Mesolithic Age. A further find recently reported (*The Times*, April 14) lies west of the Epsom road, some two hundred yards west of the recently proved line of the Roman Stone Street. The discovery is due to Mr. A. W. G. Lowther. It includes relics of the Mesolithic Age, the Early Iron Age, dating at about 500 B.C. and of the Claudian and Hadrianic periods. The site is near that at Thaxley Hill, on which Roman and Saxon remains were found a few years ago. The attraction to settlers here, it has been pointed out, was the dry belt of Thanet sand, which runs through Ewell, and the plentiful supply of water available from the famous springs. Mr. Lowther has dug out at about two feet depth a Roman road, in part well preserved, of the standard width of twenty-one feet. It is constructed of chalk blocks overlying the sand, and a surface layer of flints, in which was Hadrianic and later pottery. A much-worn coin of Domitian was found in an underlying well. Below the road were first century Roman pottery and a domestic oven, two pre-Roman ditches, pre-Roman iron slag and part of an iron ingot and much pottery dating back to 500 B.C., as well as a big light brown pottery water-container of the late Early Iron Age. Some twenty yards to the west of the road were the remains of a Romano-British hut, with Roman debris. A detailed account of the find is to be communicated to the Society of Antiquaries of London by Mr. Lowther in due course.

A SITE from which it may be anticipated that pre-Roman material of no little interest will be obtained is that at Silchester, on which stands, or rather stood, the Roman city of Calleva Atrebatum. Systematic excavations are to be carried out there under the direction of the Office of Works and the Archaeological Institute. The Roman city was under excavation for a number of seasons around the beginning of this century by a Committee of the Society of Antiquaries of London under the direction of Mr. (afterwards Sir) W. H. St. John Hope, the assistant secretary of the Society. Much important material was then obtained from the site, which is now in the Reading Museum, and valuable detailed reports of the results of the excavation were issued. Attention was directed, however, exclusively to the remains of Roman date; but it is obvious that a position of geographical importance to attract the Romans must have invited prior settlement. In fact, it is believed that this is the site of a large early British settlement known as Caer Segont, and that this was surrounded by the mound and ditch, similar to that

at Avebury, which encloses a much larger area than the Roman walls, presumably erected at a later date. Trial excavations in the area between the mound and the walls were carried out last year by Dr. Mollie Cotton and a party of volunteers; but operations are to be resumed on a more extensive scale this year, the excavators being drawn from Reading and other universities.

The Science Museum: New Optical Instruments

THE Science Museum has recently received from Mr. Thomas H. Court a gift of a large number of early optical, mathematical and astronomical instruments, some of which are now displayed in a single group in the Optics Gallery. Mr. Court, who celebrated his seventieth birthday last year, has spent most of his life collecting early scientific instruments, and he is a foremost authority on the subject. For the last thirty years he has been presenting his best acquisitions to the nation, so that his gifts to the Science Museum now total more than nine hundred. The seventy objects which comprise Mr. Court's most recent benefaction include an Italian recipiangle of about 1600. This is an instrument used for measuring angles in surveying, and it is also marked with lines and scales which can be used for making calculations. There is an optometer invented by Thomas Young for testing eyesight and prescribing spectacles, there are early telescopes with vellum tubes, silver drawing instruments, a diagonal glass by means of which the visitor to the theatre or opera could observe his fellow spectators while appearing to be looking through his glass at the stage, and there are several fine astronomical reflecting telescopes by such noted eighteenth century opticians as James Short, John Bird and C. S. Passavant. Among the microscopes presented are several rare instruments of the seventeenth, eighteenth and early nineteenth centuries, notably a beautiful compound microscope of the Divini-Campani form with silver mounts, a number of very fine Culpeper-type microscopes and some of the earliest achromatic microscopes by English and Continental makers.

Gas Fuel for the Internal Combustion Engine

THE internal combustion engine began with gas as fuel, but the use of concentrated liquid fuel has determined its vast development in all fields of transport. Circumstances, too familiar to mention, have in recent years caused a renewed attention to the possibilities of reverting, in part at least, to the use of gaseous fuel from coal and even coal itself. In Continental countries this has been encouraged by fiscal and other forms of State aid. On March 27-28, the Institution of Mechanical Engineers held a conference at Swansea, when the position of the subject was reviewed. It was reported that in 1938 a producer-fed passenger bus had maintained for one year a regular service from Inverness covering 32,000 miles. Its fuel cost was £90—as against £253 for petrol and £136 for oil. There was a charge for cleaning and attention of £30. In all producer-fed vehicles one must reckon on a 30 per cent loss of power owing

to extra weight and cost due to the producer. On the Continent there are many gas-engined small vessels fed by producer gas. The position attained by engines fed by compressed gas was reviewed and it was considered that engines using injected fuel with high compression ratios will give performances equal to those of compression ignition engines operated with fuel oil. Progress with road vehicles has been determined by the use of thin walled containers of alloy steel capable of working at 3,500 lb. pressure. Dr. H. Wahl gave an optimistic account of the position and future of an engine running on coal dust.

National Smoke Abatement Society

For many years the National Smoke Abatement Society, from headquarters in Manchester, pursued its modest efforts to secure a purer air and for the last ten years it has issued a quarterly journal. Since its removal to London, its efforts have been accompanied by greater progress. Even Whitehall has almost gone over to smokeless fuel and the L.C.C. has become more active. The extensive rebuilding in progress all over Great Britain is providing an unusual opportunity to diminish atmospheric pollution. Even the coal industry, long indifferent to the manner in which its wares were consumed, is showing an increased desire to avoid the reproach of causing smoke. The Society has taken a further step by issuing its journal in a new form, larger, more ambitious and under the more attractive name of *Smokeless Air*. This will be issued quarterly at 1s. and for 2s. 6d. post free per annum. The first number of the new series is bright and well produced, containing news of the movement and interesting articles on the subject of atmospheric pollution. At its price it ought to receive a much wider circulation.

Telephone and Telegraph Statistics of the World

In *Electrical Communications* of October 1938, statistics of the telephone and telegraph services of the world are given. The telephone development of the world by countries is first discussed, the figures taken being for January 1937. North America possesses nearly 54 per cent of the total number of telephones in the world, the United States alone possessing nearly 50 per cent, and having 14.4 per cent per 100 of the population. South America possesses 2 per cent of the total and nearly 1 per cent per 100 of the population. The whole of Europe possesses 36.5 per cent of the total world number and has an average of 2.4 per 100 of the population. Great Britain and Northern Ireland, France, Germany, Italy and Russia have 7.5, 4.0, 9.25, 1.5 and 2.8 per cent of the total world telephones and 5.9, 3.5, 5.1, 1.3 and 0.6 per 100 of the population. Asia possesses nearly 4.6 per cent of the world's total, of which about three quarters belong to Japan. Africa possesses about 0.9 per cent of the world's total, of which more than half belong to the Union of South Africa. Oceania possesses nearly 2.3 per cent, Australia having 1.5 per cent. The number of telephones per 100 of the population is also given for

large cities. Washington and San Francisco head the list each with 37. Stockholm comes next with 35. Then New York with 22, London with 18, Paris with 15, Berlin with 13, Rome with 8, Tokyo with 3.9, Moscow with 3.5 and Shanghai with 3.4. In Canada, Montreal with more than a million inhabitants has 16 telephones per 100 of the population, and Toronto with more than three quarters of a million inhabitants has more than 25 telephones per hundred. In 1936, the total number of 'wire' communications, that is, of telephone conversations and telegrams per capita in Canada was 222, of which only 1 was a telegram. In the United States it was 211, 1 being a telegram, and in Great Britain and Northern Ireland it was 44, the number of telegrams sent per capita being a little greater than 1.

Meteorology in India

THE report on the Administration of the Meteorological Department of the Government of India in 1937-38 shows that certain undertakings that had been under consideration for a number of years were carried out. Of these the most important is considered to be the daily preparation of an afternoon synoptic weather chart at the Meteorological Office at Poona, which was begun on April 1, 1937. This has enabled that office to issue forecasts twice a day instead of only once. This afternoon synoptic chart is printed in the Indian Daily Weather Report, and adds greatly to the value of that report. Another important development was introduced on August 1, 1937, when the short-wave aeronautical wireless stations at Karachi and Calcutta began to issue regional broadcasts of synoptic data twice daily. The new Burma Meteorological Department followed this lead by beginning the broadcasting of data for stations in Burma from October 1, 1937. With the commencement by the Posts and Telegraphs Department of the construction of a short-wave wireless station at Poona, the time is approaching for the issue from headquarters of collective and regional synoptic issues. Further plans were made in accordance with recommendations made at a meteorological conference held in Delhi in December 1936. They included the reopening of a forecasting office at Delhi and the transfer of the Upper Air Office from Agra to Delhi. These plans were approved in principle by the Government of India, but sanction for putting them into effect had to be postponed owing to the unfavourable financial situation. Another new development was the introduction at the request of the Royal Indian Navy of an arrangement for broadcasting synoptic data and weather bulletins for the whole of the Indian waters from the Navy Wireless Station at Bombay, for the benefit of shipping. The new broadcasts are additional to those issued from the civil wireless stations at Bombay and Calcutta.

Osiris

VOL. 4, part 2 of *Osiris*, edited by Dr. G. Sarton, published in 1938, is a monograph on "Science, Technology and Society in Seventeenth Century England", by Robert K. Merton, and its content is

defined by the author as "an empirical examination of the genesis and development of some of the cultural values which underly the large-scale pursuit of science". The "Dictionary of National Biography" has been selected as the source of information of an occupational census and the data subjected to a tabulation process. On the basis of this information a further survey of discoveries based on Darmstaedter's "Handbuch zur Geschichte der Naturwissenschaften und Technik" was compiled. This indicated the particular interests which arose in different times in the period studied. The influence of religious movements such as Puritanism is considered. The influence of external factors is carefully examined. The whole study is very interesting and suggestive in many fields but suffers from the lack of a detailed table of contents, so that the intention of the work is not easy to grasp, and the author's conclusions are not easy to find in the mass of detail. Vol. 5 of *Osiris*, which now rejoices in a Latin title as *Commentationes de scientiarum et eruditionis historia rationeque volumen quintum Iulio Ruska oblatum*, is dated 1938, and is edited by Dr. Sarton assisted by Dr. Pogo. It contains some interesting and valuable papers on scientific incunabula (to which a recent volume of *Osiris* was devoted), on Arabic algebra (incidentally, the history of mathematics has occupied a prominent place in the journal so far), on Kopp, the historian of chemistry, on astronomy, on Michael Scot (a subject which has now been about worked to death), on animals in the Bible, and on other subjects. There is a biographical and bibliographical notice of Ruska and a portrait. These two volumes of *Osiris* maintain the high standard of scholarship of the publication, and are indispensable to students of the history of science.

Royal Cornwall Polytechnic Society

In its several ways the Royal Cornwall Polytechnic Society continues to stimulate interest in the traditions and archaeology of the county as well as in science. Lectures are given, prizes for essays awarded, excursions are made and much is done for meteorology by the maintenance of the Falmouth Observatory and the support of the Cornwall Rainfall Association. All these matters are referred to in the one hundred and fifth annual report, recently issued, which is accompanied by some of the original contributions to the Society. The Society was founded when the Cornish metalliferous mines were in full swing, and in a paper entitled "The Ancient Mining Districts of Cornwall" Mr. F. J. Stephens gives a review of the score or more of mines which existed within two miles of the coastline, in the parishes of Illogan, St. Agnes and Perranzabuloe. Another contribution, but in lighter vein, is an account of the opening of the railway to Falmouth in 1863, from which it was hoped the district would gain much by the re-opening of the port of Falmouth as a terminus for steamship lines, while in yet another Mr. E. Ohirwin treats of the dialect of Cornwall. As in other parts of Great Britain, the dialect "is speeding from the presence of compulsory instruction, the cinema, the motor coach, the daily paper and the thousands of visitors"

who flock to the district. As usual, Mr. W. T. Hooper gives a series of valuable meteorological notes, in which he shows that those discontented because perpetual sunshine is not to be enjoyed at Falmouth, have little about which to complain.

Japan Institute for Science of Labour

THE annual report of the director of the Japan Institute for Science of Labour for 1937 gives a brief account of the history of the Institute as well as of its divisions and functions (Tokyo: Japan Institute for Science of Labour, 1938. 70 sen). A programme of proposed investigations, including studies on nutrition and the prevention of industrial accidents and occupational disease, is also outlined which indicates how sadly warped the whole outlook of Japan has become under the demands of her policy of war and aggression. Brief notes are included on investigations completed in 1936-37, among which may be mentioned a study of dust in mail-cars and a survey of the labour conditions of railway postal workers. The first part of an investigation on gaseous metabolism in heavy muscular work has been completed, covering gaseous exchange in static effort, and a third report on occupational diseases of printers, especially lead poisoning, deals with the density of dust in the air and the window space in the printing shop. A statistical analysis has been made of the causes of death in different occupations, and other studies have included acute nicotine poisoning among land workers and water supply in an agricultural village.

The Lily Year-book

THE Royal Horticultural Society's Lily Year-book for 1938 (London: the Society's Office, Vincent Square, S.W.1. Pp. 181+35 plates. 5s. paper; 6s. cloth. 1938) contains an account by Messrs. A. B. Stout and W. M. Porterfield of "Seed Patterns and Incompatibilities in *Lilium candidum*". It is shown that incompatibilities may occur among sister plants of the same species. Such disabilities are physiological in nature, and are not to be confused with failures in hybridizing fertilizations. An ingenious method of estimating incompatibility by the examination of seeds has been used. The results are considered in relation to the practical promotion of fertility by late fertilization, when suitable stigmatic secretion is developed, and by artificial treatments of the stigma. The Year-book contains numerous papers about the horticultural treatment of lilies; Dr. Fred Stoker has a useful article upon the geographical origin and classification of the Carniolicum group of lilies; Mr. A. D. Cotton contributes a short biography of Père Armand David (1826-1900), the celebrated naturalist and explorer; and Mr. E. O. Clement describes various practices for the germination of lily seed in Ontario. The year's work upon lilies revealed by the volume indicates a lack of contributions of a fundamentally scientific nature. Reports of discussions at meetings of the Society's Lily Group, published in the present Year-book (pp. 42-79), and similar accounts in earlier

years, show that those whose interest in lilies is practical and aesthetic, need, and desire, the specialized help of the geneticist, the physiologist and the pathologist.

Scientia Genetica

WITH the object of stimulating the development of genetics in the Latin countries, a new journal, *Scientia Genetica*, is being launched under the direction of Prof. Carlo Jucci of the University of Pavia and with his colleague Prof. Adriano Buzzati-Traverso as its editor-in-chief. Though it is primarily intended to provide an appropriate medium for publication for geneticists in these particular countries, original papers from elsewhere will be welcomed so long as they are written in Italian, French, Spanish or Portuguese, and possess a strictly genetical interest. There is to be a special section for abstracts, reviews of recent books and for summaries of original papers dealing with animal and plant breeding (such papers will not be published in full). At the end of each year there will be given a complete bibliography of papers of genetical interest that have appeared in the scientific literature of the Latin countries, and from time to time there will be presented a critical review of some selected field. Geneticists will welcome this addition to the literature of their science. It undoubtedly supplies a need, and it may be expected to play a notable part in the inevitable advancement of genetics not only in the Latin countries but also in the world as a whole.

Beneficial Insects

IN 1922 the Ministry of Agriculture and Fisheries issued a small publication on "Beneficial Insects". It contained little-known information, written in a non-technical style, on those insects that are beneficial to the farmer, fruit-grower and gardener. During the sixteen years which have elapsed, this bulletin has passed through three editions and has been reprinted on five occasions. Knowledge of insects of this kind has greatly increased in the interval and the practical measures that can be taken to increase their usefulness have been extensively investigated. This new bulletin (No. 20; 1939) has been entirely re-written by Dr. W. R. Thompson and forms a useful non-technical introduction to the subject. It is obtainable from His Majesty's Stationery Office, or through any bookseller, price 9d. net.

Advanced Study at the University of Cambridge

THE University of Cambridge has recently published abstracts of ninety-one dissertations approved during the academic year 1937-38 for the Ph.D. (75), M.Sc. (11) and M.Litt (5) degrees. The abstracts are full enough (averaging about a page and a half) to give a fair idea of the substance of the dissertations. They may be roughly grouped as follows: the humanities 26, pure science 55, applied science 10. The actual distribution according to faculties is: divinity 2, moral science 2, classics 3, English 4, modern and medieval languages 6, history 3, economics and politics 3, archaeology and anthropo-

logy 2, geography 1, mineralogy and petrology 4, mathematics 8, physics 6, chemistry 14, botany and zoology 15, biochemistry and physiology 8, agriculture 3, engineering 7.

North Pacific Earthquake

AN earthquake of moderate intensity occurred on November 17, 1938, and its epicentre has been determined by the United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association as lat. 55° N., long. 158° W. It is estimated to have normal focal depth. This preliminary determination was made with the help of readings from the following stations: Georgetown, Fordham, Weston, Chicago, Ann Arbor, Ukiah, Victoria, San Juan, St. Louis, Tucson, Philadelphia, Williamstown, Butte, Bozeman, Honolulu, Manila, Sitka, Pasadena, College, Burlington, Huan-cayo and Kew. The epicentre is situated under the ocean bed to the south of the Alaska Peninsula, and is not far distant from the scene of the violent earthquake of November 10, which was lat. 56° N., long. 150° W.

National Physical Laboratory: Publications

THE demand for the first issue of the "National Physical Laboratory Abstracts", which covered papers contributed by the Laboratory to the scientific and technical press during the year 1938, has proved its value to industry and has justified the recent issue of a similar pamphlet for the year 1937. The abstracts of papers in the present issue cover sixty-seven pages and on the average an abstract occupies a little less than half a page. They are arranged in order of subject: engineering, metallurgy, electricity and heat and general physics abstracts occupying 7-11 pages each and other subjects less. Both author and subject indexes are provided. The pamphlet may be purchased directly from H.M. Stationery Office, price 1s.

Finney-Howell Research Fellowships

FINNEY-HOWELL RESEARCH FELLOWSHIPS have been renewed for the following: Dr. P. C. Aebersold, University of California, Berkeley; Margaret E. Boyland, Royal Cancer Hospital, London; Dr. Alma Howard, McGill University, Montreal; Dr. L. M. Joshel, Harvard University; Dr. L. W. Law, Jackson Laboratory for Cancer Research, Bar Harbor, Maine; Dr. H. Lisso, Johns Hopkins Hospital, Baltimore; Dr. C. S. McEuen, McGill University; Dr. W. O. Merkel, Union Memorial Hospital, Baltimore. Fellowships for 1939 have been awarded to the following: G. M. Badger, of Melbourne, Australia, to work at the Royal Cancer Hospital, London; Dr. A. Kirschbaum, to work at Yale University; Dr. J. L. Melnick, to work at Yale University; Dr. J. F. Menke, to work at Stanford University Hospital; Dr. J. L. Wood, to work at Harvard University; Dr. P. O. Zamecnik, to work under Dr. K. Linderstrom-Lang at the Carlsberg Laboratory, Copenhagen. Grants in aid have been awarded to Dr. R. D. Fowler and Dr. R. W.

Graham, jun., Johns Hopkins University, and Dr. G. O. Gey, Johns Hopkins Medical School. Applications for 1940 awards must reach the office of the Foundation (Medical and Chirurgical Faculty Building, 1211 Cathedral Street, Baltimore) by January 1, 1940.

A Large Sunspot

A LARGE sunspot of rapid development crossed the central meridian on April 18.1. When photographed at the Royal Observatory, Greenwich, on April 18, at 10 h. U.T., the spot had an area of 150 millionths of the sun's visible hemisphere; twenty-four hours later the spot, which had become of complex structure, had increased to 1,000 millionths. This is the largest spot seen during the past four months. Greenwich also reports a considerable magnetic disturbance recorded at Abinger as having begun suddenly on April 17 at 1^h 55^m. There would appear to be a definite association between the big sunspot and the terrestrial magnetic storm.

Announcements

M. JACQUES DUCLAUX, professor of general biology in the Collège de France, Paris, has been elected a free academician of the Paris Academy of Sciences, in succession to the late M. d'Ocagne.

DR. ALBERT SZENT-GYÖRGI, professor of medical chemistry at Szeged, Hungary, has been awarded the A. W. Hoffmann Memorial Medal by the German Chemical Society.

DR. T. MORAN, principal scientific officer at the Low Temperature Research Station, Cambridge, has been appointed director of research at the Laboratories at St. Albans of the Research Association of British Flour-Millers, in succession to Dr. E. A. Fisher. Dr. Moran will take up his duties on June 1.

COLONEL A. S. ANGWIN, deputy engineer-in-chief, has been appointed Engineer-in-Chief of the Post Office, on the retirement of Sir George Lee on May 31.

ON March 29, the Earl of Athlone, as president of the National Hospital for Nervous Diseases, Queen Square, formally accepted the Associated British Cinemas Laboratory for Biochemical Research and the Gaumont-British Laboratory for Histological Research.

A COURSE for those engaged in the training of mental defectives in occupation centres, institutions or mental hospitals and for home teachers has been arranged by the Central Association for Mental Welfare. Further information may be obtained from the Educational Secretary of the Association, 24 Buckingham Palace Road, London, S.W.1.

THE annual meeting of the U.S. National Academy of Sciences is to be held in Washington during April 24-25. The sessions for the presentation of scientific papers are open to the public. In the evening of April 24, the president of the Royal Society, Sir William Bragg, will deliver the second Pilgrim Trust

Lecture, which will be entitled "History in the Archives of the Royal Society".

THE Meyer Medal for distinguished services in plant introduction has been awarded by the American Genetic Association to Miss Kate O. Sessions, of San Diego, California. Miss Sessions, who is eighty-two years of age, has contributed greatly to the horticultural beauty of southern California through fifty years of active work spent there as a landscape gardener and horticulturist. The Meyer Medal is awarded periodically by the Council of the American Genetic Association.

A NATIONAL conference on the "Wider Aspects of Nutrition" will be held under the auspices of the British Medical Association in the B.M.A. House, Tavistock Square, London, W.C.1, during April 27-29. The inaugural address will be delivered by Sir Arthur Salter. The following sessions will be held: (1) Medical Aspects of Nutrition; (2) Means of Stimulating Production, (a) Home Agriculture, (b) Overseas Producers; (3) Means of Stimulating Consumption, (a) Family Allowances, Provision of Cheap or Free Milk or Meals in Necessitous Cases, (b) Education. On April 28, at 8.15, Prof. V. H. Mottram will deliver the Sir Charles Hastings Public Lecture entitled "Nutrition and the Public Health". Admission to the conference is by ticket obtainable from the secretary of the B.M.A.

THE following appointments and promotions in various branches of the Colonial Service have recently been made: T. F. Blood, inspector of produce, Nigeria; F. A. Leeds, inspector of plants and produce, Gold Coast; I. Sibson, inspector of plants and produce, Gold Coast; R. Johns (agricultural officer, Zanzibar), agricultural officer, Fiji; A. F. Nichols (assistant director of agriculture), director of agriculture, Seychelles; W. M. Robertson (conservator of forests, Sierra Leone), conservator of forests, Tanganyika Territory; F. B. Higgins (senior inspector of mines), chief inspector of mines, Gold Coast; R. L. Creery (veterinary officer), senior veterinary officer, Kenya; W. G. Emerson (veterinary officer), senior veterinary officer, Kenya; W. Fotheringham (veterinary research officer), senior veterinary research officer, Kenya.

WE have received from Messrs. Griffin and Tatlock, Ltd., Kemble Street, London, W.C.2, a copy of their new 1,150-page Catalogue No. 15 B of modern chemical apparatus. This has been entirely rewritten in the light of modern laboratory equipment and technique, and comprises a very wide range of apparatus for use in all branches of chemistry. It is planned in thirteen sections, in each of which the items are in alphabetical order, and there is a detailed general index. The apparatus is illustrated and in many cases there are adequate descriptive notes, so that the volume is much more than a mere catalogue of prices. In many cases the theory of the apparatus is briefly yet adequately described. This catalogue would be found of great value in any chemical laboratory.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 686.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

A New Type of 'X-Ray Microscope'

A STANDARD method of X-ray analysis consists in measuring the strength of the diffracted beams corresponding to a series of reflections around a crystal zone (for example, the reflections with indices $h0l$ around the b axis), and then forming a double Fourier series with the amplitudes F as coefficients.

$$\sum \sum F(h0l) \cos \left\{ \frac{2\pi h x}{a} + \frac{2\pi l z}{c} + \alpha(h0l) \right\}$$

The sum of this series gives the density of scattering matter at a point x, z when the contents of the unit cell are projected on the face (010). In the case of a centro-symmetrical projection $\alpha(h0l)$ is either 0 or π , and if there are sufficiently heavy atoms at the centre of symmetry, it is zero for all reflections. The present note describes a simple and rather striking optical method of effecting the summation for a case where $\alpha(h0l)$ is always zero.

FIG. 1.

Holes are drilled in a thin plate of brass, one for each reflection $h0l$. The area of the hole is proportional to $F(h0l)$ and the holes are arranged in the positions of cross-grating spectra. The plate represents, in fact, a section through the reciprocal lattice containing all $h0l$ reflections. The plate is placed between a pair of good lenses, of about 6-ft. focal length. A point source of monochromatic light (a

FIG. 2.

pin-hole in front of a mercury vapour lamp) is placed at the focus of one lens, and the image of the pin-hole at the focus of the other lens is viewed through a microscope. The diffraction of the light by the holes in the plate results in a very realistic image of the crystal structure being seen through the microscope. Each pair of holes $F(h0l)$ and $F(h0\bar{l})$ forms a set of parallel diffraction fringes, and these sets have the right amplitude, spacing and phase to build up the double Fourier series given above.

FIG. 3.

Fig. 1 shows the projection of diopside, $\text{CaMg}(\text{SiO}_3)_2$, on the plane (010). The largest circles represent superimposed Ca and Mg atoms at symmetry centres of the projection, these atoms being so heavy that $\alpha(h0l)$ is zero for all reflections. The intermediate circles are silicon, the smallest are oxygen. Fig. 2 is twice natural size and is from a contact print of a brass plate drilled with holes to correspond to the $h0l$ spectra given by the crystal (see Fig. 3b). Fig. 3 is a photograph of the diffraction image seen in the microscope when this plate is placed between the lenses as described above, and it will be seen that it is a faithful reproduction of the crystal structure shown in Fig. 1.

We are now searching for a device for dealing with the more general case of values of 0 or π for $\alpha(h0l)$, for example, a ready way of placing a film with a half-wave retardation over certain holes. If this can be found, the method may prove to be of practical use in crystal analysis.

Lattice Oscillations in Crystals

THE ions or molecules occupying the cells of a crystal lattice are in general optically anisotropic, and should also be capable of executing small angular oscillations about their positions of equilibrium. If the crystal is illuminated by monochromatic light of frequency ν , the local fluctuations in optical polarization produced by such oscillations should result in scattered radiations appearing with altered frequency, and theory indicates that these should exhibit peculiar polarization characters.

Taking an individual ion or molecule to be optically an ellipsoid, its polarizability along three mutually perpendicular directions being A, B, C respectively, it is clear that if the light-vector E in the incident beam is parallel to an axis A of the ellipsoid and its angular oscillations are also about the same axis, there would be no fluctuations in optical polarization and therefore no radiations of altered frequency. If, however, the ion or molecule oscillates about a second axis B with an angular amplitude θ and frequency ν^* the optical polarization would fluctuate with frequencies $\nu \pm \nu^*$; the corresponding scattered radiations would arise from a Hertzian dipole which is parallel to the third axis C of the ellipsoid and has the strength $\frac{1}{2}(C-A)\theta E$, where $\theta = (\hbar/2\pi^2 I \nu^*)$, I is the moment of inertia and $\hbar$ is Planck's constant. The scattered radiations would thus be of maximum intensity in the plane containing the oscillation axis and the incident light-vector and would vanish in the direction perpendicular to this plane. In other words, the displaced lines in the spectrum due to these oscillations in the lattice would disappear in just the direction in which the displaced lines arising from the symmetric internal vibrations of the ion or molecule would be of maximum intensity.

EFFECT OF ORIENTATION OF CRYSTAL ON LIGHT SCATTERING IN SODIUM NITRATE.

(a), (b), and (c) illustrate the foregoing remarks; they are spectra of the 4358 Å. radiation of the mercury arc, transversely scattered by a sodium nitrate crystal, the incident light being plane polarized. The three spectra correspond to three mutually perpendicular settings of the crystal; the directions of the incident light-vector and of observation of the scattered light are normal to each other and remain unaltered throughout. It will be noticed that in (a), in which the optic axis of the crystal is parallel to the direction of observation, the lattice lines (98 cm^{-1} and 185 cm^{-1}) have disappeared, while in (b) and (c) they appear strongly. On the other hand, the internal oscillations (1065 cm^{-1} and 1385 cm^{-1}) of the NO_3 ion appear strongly in (a) and (b), while in (c) they are very weak. The latter

result is to be expected, as (c) corresponds to the case in which the incident light-vector is along the optic axis of the crystal, and the polarizability of the NO_3 ions is a minimum in this direction.

Transmutation of Thorium by Neutrons

IN a previous letter we have proposed schemes for the disintegration of radioactive noble gases, formed by the bombardment of uranium with slow neutrons¹. We repeated these experiments, passing the active gases over absorbent carbon instead of through water, which resulted in appreciably higher activities. We were able to confirm our earlier measurements and found 33 minutes as a more accurate value for the longer caesium-period (instead of 80 minutes). It may be remarked that there is a satisfactory agreement between our results and those obtained by Hahn and Strassmann².

We have now studied the formation of radioactive noble gases by the splitting of thorium nuclei with neutrons in an analogous way. As this process requires fast neutrons, we used the following experimental arrangement. The neutrons were produced by the $(\text{Li} + \text{D})$ reaction. The neutron source was immersed in a concentrated solution of thorium nitrate. Thus, although the water slows down the neutrons, an appreciable part of those present in the liquid still have high energies. A fast stream of nitrogen was passed through the solution and, after being dried with phosphorus pentoxide, entered a U-shaped tube filled with active carbon and immersed in liquid nitrogen. The radio elements were extracted from the carbon with water containing caesium, rubidium, barium, strontium and lanthanum ions. This solution always contains thorium B and C originating from thoron absorbed by the active carbon. This fact made it necessary to carry out a lead precipitation before isolating the barium, and to purify as a perchlorate the caesium contained in the precipitate with antimony trichloride. The irradiations ranged from 5 minutes to 60 minutes.

Except for the 2-minute alkali period, our results were identical with those obtained in the investigation of uranium. We determined the same periods for rubidium (17 min.), barium (87 min.) and caesium (10 min. and 33 min.). Strontium was found to be inactive. It may be concluded that the splitting of uranium nuclei and of thorium nuclei leads to the same noble gases, and that the schemes suggested for uranium in our first communication hold for thorium too. As the time required for the preparation of the precipitates was longer in the case of thorium than it was in our investigation of uranium, it was impossible to search for the 2-min. alkali period.

Number of Neutrons Liberated in the Nuclear Fission of Uranium

RECENT experiments have shown that neutrons are liberated in the nuclear fission of uranium induced by slow neutron bombardment: secondary neutrons have been observed which show spatial¹, energetic² or temporal³ properties different from those which primary neutrons possess or may acquire. Such observations give no information on the mean number of neutrons produced per nucleus split; this number ν may be very small (less than 1) and the result of the experiment will still be positive.

We are now able to give information on the value of ν . Let us consider the curve representing the density distribution of neutrons slowed down in an aqueous solution surrounding a primary neutron source⁴; the area S of this curve is proportional to $Q\tau$, Q being the number of neutrons per second emitted by the source or formed in the solution, and τ the mean time a neutron spends in the solution before being captured. Assuming that the solution contains only nuclei which absorb neutrons according to the $1/v$ law (the only exception to this rule will presently be dealt with), τ is proportional to $1/\Sigma\sigma_i c_i$, where c_i is the concentration (atom grams per litre) of an absorbing nucleus, σ_i its cross-section for the capture of neutrons of velocity 1 and the index i is extended to all kinds of neutron-absorbing reactions attributable to nuclei present in the solution. Substituting the symbol A_i for $\sigma_i c_i$ and A_{tot} for ΣA_i , we have identically:

$$\frac{\Delta S}{S} = \frac{\Delta Q}{Q} + \frac{\Delta A_{tot}}{A_{tot}}, \quad (1)$$

neglecting all terms of higher orders, such as those containing $(\Delta Q)^2$, $\Delta Q \cdot \Delta A_{tot}$, etc.

Let the symbol Δ stand for the differences observed between the two solutions (uranyl and ammonium) used in our previous experiment¹. Neglecting ΔA_{tot} before A_{tot} introduces an ambiguity in the definition of A_{tot} (uranyl *vs.* ammonium value) which is numerically unimportant and can be reduced by adopting the arithmetical mean $(A_{tot}(\text{amm.}) + \Delta A_{tot})/2$.

In the quantity ΔA_{tot} the uranium nuclei are represented by several separate terms standing for the different modes of neutron capture (see below); let A_f be the term for the capture leading to fission. Every neutron has the probability A_f/A_{tot} of causing a fission and, since one individual fission process liberates ν neutrons on the average, the total number

ΔQ of neutrons thus created is $Q \cdot \frac{A_f}{A_{tot}} \cdot \nu$, and the equation (1) can be rewritten as follows:

$$\nu = \frac{\Delta S}{S} \cdot \frac{A_{tot}}{A_f} + \frac{\Delta A_{tot}}{A_f}. \quad (2)$$

Let us estimate the values of all quantities necessary to calculate ν according to this formula. The area variation $\Delta S/S$ can be read from the graph given in our previous letter with an error of less than 20 per cent (due to the uncertainties of inter- and extrapolation; in order to facilitate the latter, we added to the curves a further experimental point for $r = 29$ cm.). The value of A_{tot} for the ammonium solution can be easily calculated from the known concentrations and capture cross-sections (hydrogen, nitrogen and oxygen). A_f is equal to σ_f (1.6 in our experiment), multiplied by the value of σ_f given in a recent paper by Anderson *et al.*⁵. ΔA_{tot} contains a term expressing the small difference of the hydrogen

content between the two solutions; and three terms relative to uranium, namely, the fission term A_f , already dealt with, the thermal capture term A_{σ} which can be calculated by using a recently found value for σ_{σ} ⁶ and finally the resonance capture term A_r which requires some explanation.

Our reasoning assumed that all neutrons introduced into the solution spend practically all their life, and are absorbed, in the thermal state. This is true in so far as the $1/v$ law is valid for absorption of neutrons in all nuclei concerned; and, therefore, not wholly true for uranium, which shows a pronounced resonance capture of neutrons of about 25 volts⁶. A certain proportion of neutrons entering the solution is bound to come within this resonance band and to be absorbed by resonance; therefore, it will never reach the thermal state. This proportion depends on the width of the resonance band and on the concentration c_U ; its value in our system of symbols is equal to A_r/A_{tot} and was numerically determined by an experiment reported elsewhere⁶.

Putting all numerical values in the formula (2) (with 10^{-24} cm.² as the unit of cross-section), that is: $\Delta S/S = 0.05 \pm 0.01$; $A_{tot} = 36 \pm 3$; $A_f = 1.6 \times 2 = 3.2$; $\Delta A_{tot} = 8.7 \pm 1.4$ decomposable into $\Delta A_H = 1.2 \pm 0.1$; $A_{\sigma} = 1.6 \times (1.3 \pm 0.45) = 2.1 \pm 0.7$, $A_r = 6.4 \pm 1.1$ and $A_f = 3.2$, we find:

$$\nu = 3.5 \pm 0.7.$$

We were not able to allow for an error in A_f , since the value of σ_f given by Anderson *et al.* contains no indication of probable error. Any error in σ_f will affect $\nu - 1$ in an inversely proportional way; in any case ν will remain greater than 1.

The interest of the phenomenon discussed here as a means of producing a chain of nuclear reactions was already mentioned in our previous letter. Some further conclusions can now be drawn from the results reported here. Let us imagine a medium containing only uranium and nuclei the total neutron absorption of which, as compared to that of uranium, may be neglected (containing, for example, only some hydrogen for slowing down purposes). In such a medium, if $\frac{A_f}{A_{tot}} \cdot \nu > 1$ (A_{tot} includes now only

uranium terms), the fission chain will perpetuate itself and break up only after reaching the walls limiting the medium. Our experimental results show that this condition will most probably be satisfied

(the quantity $\frac{A_f}{A_{tot}} \cdot \nu - 1$, though positive, will be, however, small), especially if one keeps in view that the term A_r , because of the self-reversal of the resonance absorption line, increases much more slowly than the other uranium terms when the uranium content of the medium is increased.

Radiobromine

Don C. De Vault and W. F. Libby¹ and E. Segrè, R. S. Halford and G. T. Seaborg² have shown that the 4.5-hr. radiobromine transforms into the 18-min. isotope which is β -active, by the emission of soft γ -rays. Le Roux, Lu and Sugden³ find that this is the method of disintegration of at least 90 per cent of 4.5-hr. radiobromine. Segrè, Halford and Seaborg² predicted that the γ -rays would be soft, and a large proportion would be internally converted.

These considerations are in agreement with observations made in a Wilson chamber of the disintegration of 4.5-hr. radiobromine. Measurement of tracks starting from thin foils which had been activated with radiobromine, and from active ethyl bromide introduced as a vapour into the chamber, show homogeneous energy groups of electrons due to the K and L conversion of this γ -ray, superimposed on a background of the continuous β -ray spectrum of the β -active isotope.

In those experiments in which tracks start in the gas of the chamber, half the electrons produced by the internal conversion of the γ -rays in the K level are accompanied by short tracks starting from the same atom and due to the Auger conversion of the K X-rays of bromine. The existence of these X-rays was reported by Philip Abelson at the December meeting of the American Physical Society at Los Angeles. The Auger electrons accompanying L conversion would not be observed.

These experiments show that the γ -rays have an energy of 43,000 electron volts. The coefficient of internal conversion in the K shell is of the order of 0.30, and that in the L shell much smaller.

Since Le Roux, Lu and Sugden effected a 90 per cent separation of the isotopes, the loosening of the bond discussed by Segrè, Halford and Seaborg must be due to this low-energy γ -ray alone.

In even so brief a summary as this, I would like to make twofold acknowledgments. For advice and discussion on the physical side I must thank Prof. P. M. S. Blackett, Prof. J. D. Bernal and Dr. L. Simons; I wish also to thank Prof. S. Sugden for help and advice, especially on chemical matters.

Formation of Helium of Mass 3 in an Excited State

AN excited state of helium of mass 3 (^3He) has been previously suggested by me to explain a second low-energy group of neutrons from the deuterium-deuterium reaction¹. Since present theory does not predict such an excited state² in ^3He , it is important to establish definitely whether such a state actually exists. This note gives the results of some cloud chamber experiments which were made in order to investigate this point.

In the present experiments, the D-D reaction was studied with a cloud chamber filled with either methane or helium. The neutrons were detected by means of the recoil protons or recoil helium nuclei. The ranges of these recoil particles were measured

which were projected in the forward direction ($0-10^\circ$). Three series of experiments were made. In the first experiment methane was used in the cloud chamber and the neutrons were observed at 90° to the direction of the 0.9 Mv. deuterons. In the second experiment the conditions were the same except that helium was used in the cloud chamber. In the third experiment the neutrons were observed at an angle of 0° to the 0.5 Mv. deuterons. A summary of the results is given in the accompanying table.

Type of recoil	Deuteron energy (Mv.)	Angle of observation	Neutron energies (Mv.)	Relative intensity of recoil groups		Relative intensity of neutron groups	
				low energy	high energy	low energy	high energy
H	0.90	$90^\circ \pm 8^\circ$	1.5 : 2.8	0.28	1.00	0.17 $\pm$	1.00
He	0.90	$90^\circ \pm 15^\circ$	1.5 : 3.0	0.92	1.00	0.3-0.2	1.00
H	0.50	$0^\circ \pm 6^\circ$	1.25 : 3.55	0.19	1.00	0.13 $\pm$	1.00

In each of the experiments a second low-energy group of neutrons was observed as well as the high-energy group. A significant feature is the increase in the energy of the low-energy neutron group when the bombarding voltage was reduced to 0.5 Mv. and the neutrons were observed in the same direction as the deuterons ($0^\circ \pm 9^\circ$). In this case, although the maximum energy of the neutrons produced in the target is reduced from 4.07 Mv. to 3.55 Mv., the low-energy group of neutrons has more energy. This definitely shows that they are not produced by scattered neutrons. Furthermore, the increase in energy is just what one should expect from the reaction

The Q values of the reaction were calculated from the data obtained at 0.5 Mv. The disintegration values are $Q^0 = 3.32 \pm 0.04$ Mv. and $Q^1 = 1.48 \pm 0.04$ Mv. These agree within the experimental error with those I obtained previously with quite a different experimental arrangement. The relative intensities of the two neutron groups as given in the table were computed by means of the known relations between collision cross-section and energy, for neutrons³.

These experiments show that the ^3He nucleus is left in an excited state at 1.84 Mv. in approximately 15 per cent of the disintegrations. At the present time it is not clear what happens to the excited ^3He . Experiments on the gamma rays from this reaction seem to give too small an intensity⁴. However, the transition to the ground-state may be strongly forbidden as in the case of the 1.426 Mv. gamma ray of radium C', and so there may be a high internal conversion of the gamma rays. Another possibility is that the excited ^3He emits a positive electron with an energy of about 0.8 Mv.

A more complete description of these experiments will be published elsewhere.

A Cosmic Ray Burst of a Hundred Particles

NUCLEAR disintegrations caused by cosmic rays can be observed only rarely in the Wilson cloud

As can be seen clearly in the reproduction, the burst is accompanied by a number of separate small disintegrations. Within the field of vision, which was of 0.4 mm. in radius, four disintegrations with three tracks, one disintegration with four particles, three disintegrations each with five particles and two showers of heavy particles were found. There were thus ten disintegrations of total energy 50 Mev. within an area of 0.4 mm.², a disintegration density which is seventy times greater than is ordinarily found on these plates.

It should be noted that there are also many disintegrations outside of the field of vision of the microscope.

A more detailed account will appear in the *C.R. Acad. USSR*.

A. Jdanoff.

chamber. We have developed in recent years¹ a more effective method of observing these nuclear disintegrations. In this method photographic plates coated with thick emulsions (thickness ~50 μ) are exposed to the action of cosmic rays and then developed.

I have recently² made experiments at sea-level and at an altitude of 9,000 metres with such plates placed horizontally with their emulsions downwards, and I have found that the number of disintegrations and heavy particles per disintegration increases rapidly with increasing altitude. One case, which is reproduced herewith, is a burst of a hundred heavy particles. The two pictures are stereoscopic microphotographs taken with a magnification of 190. More tracks can be seen by stereoscopic examination of the original plate than on the reproduction. It can also be seen that all the particles diverge from one centre which is within the emulsion. The centre is quite large and contains many unresolved tracks. The black centre may be caused not only by heavy particles but also by the electron stream accompanying the burst. (Separate electron tracks cannot be seen as the emulsion is insensitive to them.)

In this burst there are twelve tracks of length equivalent to 18 cm. normal air situated within a cone of 30°. Assuming that these are proton tracks, the total energy calculated from the range is 40 Mev. In addition to these there are thirty tracks each with a range of 12 cm. (in normal air) within a cone of 70°. The appearance of the tracks at their ends suggests that they may be due to α -particles. If the tracks are due to protons their total energy is approximately 50 Mev. There are also between fifty and sixty particles lying in a cone of wide angle with ranges of approximately 5 cm. Assuming that these particles are protons, their total energy must be 80–90 Mev. Thus the total energy of the whole burst must be at least 200 Mev.

Optical Properties of Dental Enamel

It has been known for many years that dental enamel is birefringent; and its optical properties have been studied intensively by W. J. Schmidt and his pupils¹. In a recent paper², I have shown by X-ray examination that an enamel prism contains a multitude of regularly arranged crystallites of apatite, and have worked out in detail the orientation of these crystallites for human deciduous enamel. It was therefore felt to be of interest to determine whether the optical and X-ray results could be correlated.

The main feature of the structure suggested by X-rays is the presence in a single enamel prism of two groups of submicroscopic crystallites of hydroxy-apatite, the hexagonal axes of one group being inclined to the prism direction at about 5°, and those of the other group at about 40°. The intensity of the light transmitted by such an arrangement of crystallites, when the enamel is examined between crossed nicols, has been worked out; and it has been found that the calculated extinction phenomena, for both longitudinal and transverse sections of prisms, correspond closely with those actually observed by Schmidt, Keil and other workers.

The problem is essentially that of calculating the interference effects due to the superposition of two

differently oriented uniaxial crystal plates; a problem first attacked by Fresnel³ and discussed more recently by Schulz⁴. The formulae derived for the intensity of the transmitted beam may be applied directly to the case of a tooth section of known thickness, if the prisms are assumed to be parallel to each other, by making the thicknesses of the two crystal plates proportional to the numbers of crystal-lites belonging to the 5° and 40° groups referred to above.

The work forms part of an investigation being carried out for the Dental Disease Committee of the Medical Research Council, and will be published in full elsewhere.

Non-Euclidean Geometry in Microscopic Space

CONSIDERATIONS of Heitler, Nordheim and Teller¹, based on Heisenberg's uncertainty principle, show that Newtonian gravitation has only a macroscopic significance; further, in the theory of ultimate particles, it is necessary to introduce a finite length, a , of approximately 10^{-13} cm. (radius of electron or of light nuclei), which is not justified theoretically if we use Euclidean geometry or Einstein's gravitational curvature.

Consequently, it seems more convenient to use a non-Euclidean geometry, but one which is not connected with Einstein's gravitational theory; in the space occupied by the elementary particle, the square of the space-time interval is supposed to be defined by:

$$ds^2 = c^2 \left(1 - \frac{r^2}{a^2}\right) dt^2 - \frac{dr^2}{1 - r^2/a^2} - r^2(d\theta^2 + \sin^2 \theta d\phi^2) - c^2 r^2 d\tau^2 - d\sigma^2, \quad (1)$$

which is formally analogous with de Sitter's line element; the internal space is consequently spherical with a curvature $K = 1/a^2$, and the corpuscle is obviously stable, because the Einstein macroscopic relation $R = \kappa \rho$ between the world-curvature R , the density of matter ρ and the gravitational constant κ (which involves expanding space) is not verified.

Let the line element of the external space be defined by:

$$ds^2 = c^2 \left(1 - \frac{a^2}{r^2}\right) dt^2 - \frac{dr^2}{1 - a^2/r^2} - r^2(d\theta^2 + \sin^2 \theta d\phi^2); \quad (2)$$

therefore, there will be a nuclear attractive field, different from the Einstein or Newtonian field, which can be neglected if a tends to zero.

The spatial part of (1) represents a spherical or elliptic space² in which distance is not univocally defined; in the second case, a line element results from the Cayley relation:

$$\sigma = \frac{a}{2i} \log \chi, \quad (i = \sqrt{-1}) \quad (3)$$

where σ is the distance between two points A, B , χ the anharmonic ratio $AK/BK : AL/BL$, K and L the points of intersection of $\overline{AB}$ with the absolute

quadric³. The relation (3) is analogous to Schrödinger formula $S = \frac{h}{2\pi i} \log \psi$ between action function S and wave function ψ ; therefore, it is possible to quantize distance; χ is univocal and $\sigma = \sigma_0 + \pi n a$, where n is an integer; the quantum numbers are $\pm \frac{1}{2}$.

Metric notions are completely replaced by projective notions when we introduce for an angle V , Laguerre's formula:

$$V = \frac{1}{2i} \log \varphi \quad (i = \sqrt{-1}); \quad (4)$$

angular quantum numbers are spin quantum numbers $\pm \frac{1}{2}$; we specify that χ and φ have an immediate experimental significance, as ψ in quantum mechanics, while angles and distances lose their actual meaning.

Therefore, metric transformations T , which preserve V , are replaced by corresponding homographic transformations H which preserve the anharmonic ratio $\varphi = \frac{\lambda_2 - \lambda_1}{\lambda_3 - \lambda_2} \cdot \frac{\lambda - \lambda_2}{\lambda - \lambda_1}$; the projective parameter λ is changed by H in

$$\lambda' = \frac{\alpha\lambda + \beta}{\gamma\lambda + \delta}; \quad (5)$$

it is easy to prove that, in the usual cases, this transformation is identical with the unitary substitution of two variables of Van der Waerden⁴.

Temporary Poikilothermy in Birds

It appears to be well known to aviculturists and collectors that humming-birds are capable of a physiological state somewhat resembling hibernation in mammals, but of short duration; however, the fact seems not to have been recorded in the scientific literature. We propose to refer to this peculiar condition as 'torpidity'. The observations here recorded were made partly in the field in Ecuador, partly in the Zoological Society's Gardens at Regent's Park.

In complete torpidity, the birds are quite rigid, with head drawn back and pointed up, flattened plumage and closed eyes, and exhibit no perceptible respiratory movements. The condition is reversible, recovery in captivity taking 10-15 minutes, at high altitudes and low temperatures in Ecuador up to 30-35 minutes.

Partial torpidity is also observed. In captive birds this is characterized by violent breathing, ruffled plumage and the loss of the power of flight. Recovery from this state takes 4-5 minutes. Partially or completely torpid birds on being touched emit a peculiar expiratory whistle, which, it is suggested, may be due to deflation of the air-sacs.

Torpidity is promoted by numerous factors: (1) low temperature; (2) lack of food; (3) poor condition; (4) a diurnal effect, birds being much more susceptible at night; (5) a seasonal rhythm, captive birds having proved much more susceptible in

November–December than at the same night temperatures in August or March; (6) a size effect, large species in captivity being in general less susceptible than small; (7) a climatic effect, lower temperatures being required to induce torpidity in species from high altitudes, but the resultant torpidity then being more extreme, with longer recovery period; (8) a specific effect, susceptibility varying in species of similar size and habitat; (9) an individual effect, individuals of the same species showing different susceptibility (this may in part be due to temporary differences in condition).

Torpidity appears to be a temporary poikilothermy, rather similar to that already described for bats¹. In birds, one of us (O. S. W.) has noted a similar but less specialized condition in colies (*Colius*). Torpidity of a rather different nature has also been noted in swallows², but here recovery is only possible before complete torpidity is reached.

Torpidity in the fully specialized condition seen in humming-birds appears to be an adaptation promoting the survival of these very small birds in conditions which temporarily make the maintenance of normal body-temperature difficult or impossible. The fact, however, that it occurs also in a related family (colies), and scarcely, if at all, elsewhere among birds, indicates a general preadaptive proneness to the condition.

Temperature measurements of birds in different stages of torpidity will be undertaken with a thermocouple next winter, and will be incorporated with a fuller account of avian torpidity in general.

Segregation in Asexual (Apomictic) Offspring in *Rubus*

THE diploid species of *Rubus* we have examined always reproduce sexually. In the polyploid forms and species, however, reproduction may be (1) entirely sexual, (2) entirely non-sexual, apomictic, or (3) partly sexual and partly non-sexual.

The polyploids vary widely in the degree to which apomixis is developed, and a particular species used as female parent will show a variation in behaviour according to the species used as male in the pollination. The occurrence of segregation is not conclusive evidence of sexual reproduction, for we find that segregation occurs within the non-sexual offspring and has given rise to new and distinctive types, which in some cases breed true. For example, *R. nitidoides*, $2n = 28$, a species with comparatively small flowers and normal five-leaflet leaves, when crossed with *R. thyrsiger*, $2n = 28$, gave plants of three kinds, (1) a very small proportion of sexual hybrids, (2) a large proportion identical with the maternal parent *R. nitidoides*, and (3) a new true-breeding form with large flowers and seven-leaflet leaves, which shows no trace of the male parent. The dioecious species *R. vitifolius*, $2n = 56$, with three-lobed leaves, when crossed with the diploid *R. idaeus*, $2n = 14$, gives offspring all of sexual origin, and all are pentaploid, $2n = 35$. *R. vitifolius* crossed with the tetraploid form of *R. idaeus*, $2n = 28$,

however, gave a family consisting of plants of two kinds, with 42 and 56 chromosomes. The 42 chromosome plants are of sexual origin and have many of the characters of the male parent, such as hermaphrodite flowers and five-leaflet leaves. The 56 chromosome plants, on the other hand, show no trace of *R. idaeus*, and are evidently of apomictic origin. They all have three-lobed leaves and are identical with *R. vitifolius*; but approximately one half of the plants have female flowers and the other half male flowers. The progeny as a whole is dioecious like the female parental species. We therefore have segregation of characters even with an apomictic mode of reproduction. Evidently the apomictic embryo arises at a stage subsequent to the first division of meiosis, presumably by diploid parthenogenesis. This means that there are intermediate methods of reproduction which although superficially vegetative have certain of the properties of sexual reproduction, giving rise to genetical variation through crossing-over.

Incidentally, the results we have obtained with the American species *R. vitifolius* show that the conclusion of Gustafsson¹ that "all American species belonging to the *Rubus* subgenus *Eubatus* are sexual" is not of universal application.

The results are also significant in view of the difficult taxonomy of *Rubus*. They show not only how new forms and species can arise, but also how they are able to maintain themselves in Nature. Many of the species and micro-species of *Rubus* are evidently clones and sub-clones, produced by segregation and maintained by apomixis.

A Difference in Response of Normal and Tumour Tissue

PREVIOUS papers have reported the effect of respiratory stimulating factors (*RSF*) prepared from yeast on the respiration of liver, skin and yeast^{1,2,3,4}. The object of the research here reported was to investigate the effect of a crude sample of *RSF* on transplantable tumour tissue.

In the present experiments, crude *RSF* was prepared from Fleischmann's bakers' yeast (*Saccharomyces cerevisiae*) by a method reported by Cook, Kreke and Nutini⁴. The preparation used in these experiments corresponds to sample A in the above work. The crude *RSF* was prepared by extracting yeast successively with 95 per cent and 50 per cent alcohol, combining the extracts and concentrating *in vacuo*. The concentrated extract was redissolved in distilled water and autoclaved at 15 lb. pressure for 15 minutes. The pH was adjusted to 7.8.

Preliminary experiments showed that this crude extract in a concentration of 13.9 mgm./c.c. stimulated the respiration of mouse liver 160 per cent and of mouse skin 50 per cent.

Employing Warburg direct manometric technique, the effect of the *RSF* was tested on the respiration of transplants of a spindle-cell carcinoma of the mammary gland. The transplantable tumour (15091a) was obtained from the Roscoe B. Jackson

Memorial Laboratory and transplants were made in mice 7-8 months old. The age of the transplants used ranged from 14 to 17 days.

There was no stimulation of respiration of the tumour tissue noted when this *RSF* was added in a concentration of 13.9 mgm./c.c. to the Ringer-glucose-phosphate (0.02 per cent glucose) solution in which the tumour tissue was suspended. The average *Q_O*, for a series of fourteen determinations was 5.2 (limits, 4.1-6.8) with *RSF* and 5.3 (limits, 4.0-7.4) without *RSF*. Certain other cell-free tissue extracts which stimulate the respiration of normal tissues have failed to stimulate tumour respiration. For example, a cell-free extract prepared from tumour increased the oxygen uptake of liver but not of tumour. Spleen extract was the only one used in our laboratory which stimulated the respiration of tumorous tissue, which confirms the earlier observation of Bungeler¹.

This difference in response of normal and tumour tissue to the *RSF* preparation under investigation might be interpreted as indicating a qualitative difference between normal and tumour metabolism. At present there is insufficient evidence to show whether this is true; indeed, the bulk of previous evidence has led to the belief, in Boyland's words², that "in the mechanism of tumour respiration there is no known qualitative difference between normal and tumour tissue". This work does affirm that there is damage to the oxidative mechanism in malignant tissue as has been found by Dickens³ from measurements of the respiratory quotient.

The crude *RSF* has been fractionated by different methods, and experiments are now being conducted to test the effect of these fractions on normal and tumour tissue. It is not impossible that prolonged application of *RSF* to tumour tissue, either *in vitro* in tissue culture or by injection, will have a favourable effect. These possibilities, together with the use of further autogenous preparations, are being studied. The effects of *RSF* on other phases of normal and tumour metabolism are under investigation.

Nutritive Spheres in *Amoeba proteus* Y

THE impetus given to the investigation of cytoplasmic inclusions by the ultra- and electric-centrifuge technique used in the recent work of Bronté Gatenby and his pupils has raised once more the controversy concerning the exact nature of the nutritive spheres in *Amoeba proteus* Y.

Dr. Singh¹ confirms the findings of Sister Carmela Hayes² that the nutritive spheres contain glycogen. I would direct attention to one significant remark at the end of Sister Carmela's paper which indicates the possible explanation of discrepancies in

descriptions of the reactions of living organisms to various reagents, namely, her conclusion that the exact chemical composition of the nutritive sphere depends upon its physiological condition at the time of the experiment.

Dr. Singh does not wholly agree with those who maintain that I confused nutritive spheres with agametes. I hope to publish elsewhere my renewed investigations on the life-history of *A. proteus* Y. My purpose in writing this note is to direct attention to a method of demonstrating the presence of glycogen and of making very instructive permanent preparations of *A. proteus* Y, which may be useful for busy teachers.

The amoebae after being allowed to 'expand' are fixed in Bouin's fluid, washed in alcohol, stained in a 1 per cent solution of chlorazol black³ in alcohol, dehydrated in 'Cellosolve'⁴, cleared in xylol and mounted in Canada balsam.

The glycogen can easily be detected around the nutritive spheres by its red colour⁵. The interior of the sphere stains a pale green.

Since 90 per cent alcohol can be used as a fixative for *A. proteus* Y, the amoebae can be fixed and stained simultaneously by treatment with a 90 per cent alcoholic solution of chlorazol black, thus limiting the remaining operations to dehydration in 'Cellosolve' and making permanent 'in Euperal'.

Sea Island Cotton and the Lamarckian Theory

PROF. MACBRIDE¹ cites Sea Island cotton as an example of a strain evolved in response to a particular environment (in this case the sea islands of South Carolina) which only retains its distinctive characteristics under those particular conditions. He has, unfortunately, been misinformed. The perennial ancestors of Sea Island cotton were introduced from the West Indies into Carolina in the latter half of the eighteenth century and there selected for the annual habit. The annual types were sent to the West Indies about thirty-five years ago and have retained unchanged the annual habit and very high quality characteristic of the Carolina type. A Barbados stock has been cultivated on a small scale in Fiji for fifteen years and has maintained not only the general Sea Island characteristics, but also the distinctive superfine quality of the Barbados strain. In the U.S.S.R. and in Sind also American stocks have been grown for a number of years without reversion.

A Chemical Method of Assay of Insulin

In a recent communication¹, Vogelenzang suggests the possibility of an iodometric method for estimating the physiological potency of insulin preparations. A similar suggestion was previously made by Brand and Sandberg². Jensen, Schook and Sollers³, however, pointed out that the success of an iodometric titration of insulin is dependent upon the amount of impurities which will react with iodine. Since iodine reacts upon certain chemical groupings which are by no means confined solely to the insulin molecule, it is doubtful whether the physiological potency of insulin preparations can be reliably determined by iodometric titration. Blatherwick and associates⁴ have arrived at the same conclusion.

The protein nature of insulin⁵ makes it improbable that a simple chemical method of assay will ever become practicable.

Points from Foregoing Letters

W. L. BRAGG describes a direct method of converting the measurements of X-ray beams diffracted by a crystal into an optical image of the atomic arrangement as projected upon a given plane. Holes are drilled in a thin plate, arranged in the pattern of 'cross-spectra', and proportional in area to the amplitudes of the diffracted beams. If this plate is placed in front of the objective of a telescope focused on a point source of monochromatic light, the beam passing through the holes forms by interference an image of the crystal structure which can be seen through the eyepiece.

Photographs of spectra of light scattered by a crystal of sodium nitrate set successively in three mutually perpendicular directions to the incident monochromatic polarized light are submitted by Sir C. V. Raman and T. M. K. Nedungadi. They show that when the optic axis of the crystal is parallel to the direction of observation, the 'lattice lines' have disappeared; other lines which may be ascribed to the internal oscillations of the NO₃ ion appear strongly in this position and also in one of the positions perpendicular to it, but are very weak in the third position when the incident light-vector is along the optic axis.

It is stated by A. H. W. Aten, jun., C. J. Bakker and F. A. Heyn that radioactive noble gases arise from the bombardment of thorium with neutrons. At least one radioactive krypton and two radioactive xenons are formed, which are identical with those obtained from uranium irradiated with neutrons.

Discussing experimental results on the liberation of neutrons in the nuclear fission of uranium, H. von Halban, jun., F. Joliot and L. Kowarski estimate that an average of about 3.5 neutrons is liberated in every fission. They discuss the conditions of establishing a self-perpetuating reaction chain which seems to be theoretically possible.

R. E. Siday has observed in a Wilson chamber the K conversion electrons of γ -rays emitted when 4.5-hr. radiobromine transforms into the 18-min. isotope. The γ -rays appear to have 43,000 electron volts energy with a coefficient of internal conversion of roughly 0.3. The Auger electrons produced by the K X-rays accompanying the K conversion of these γ -rays were observed as short tracks starting at the origin of some of the γ -ray conversion tracks.

Cloud-chamber experiments are described by T. W. Bonner which show that there are two groups of neutrons from the nuclear reaction: $^1\text{H} + ^1\text{H} \rightarrow$

$^3\text{He} + \frac{1}{2}\text{n}$. The low-energy group is produced in about 15 per cent of the disintegrations. The interpretation of these experiments is that a low-energy neutron is emitted whenever an excited helium nucleus of mass 3 is formed.

Stereoscopic photomicrographs showing a cosmic ray burst of about a hundred particles on a photographic plate with thick emulsion exposed to the action of cosmic rays are submitted by A. Jdanoff. Assuming that the particles are protons, the energy of the burst would exceed 200 Mev.

The optical extinction phenomena, exhibited by the arrangement of hydroxyapatite crystallites in dental enamel suggested by X-ray examination, have been calculated by J. Thewlis; they correspond closely, for both longitudinal and transverse sections of prisms, with those actually observed.

J. Mariani presents an application of non-Euclidean geometry to microscopic space-time occupied by elementary particles as an explanation of their radius and spin.

J. S. Huxley, C. S. Webb and A. T. Best record the existence of a state of 'torpidity' or reversible poikilothermy in birds. Fully torpid humming-birds become completely rigid and apparently poikilothermous, with no perceptible respiratory movements. Recovery takes 10-35 minutes. Torpidity has been noted both in fresh-caught and captive humming-birds, and a similar but less specialized condition in colic (*Colinus*). It appears to be an adaptation promoting survival in unfavourable conditions.

M. B. Crane and P. T. Thomas report that diploid species of *Rubus* reproduce sexually; but in polyploid forms and species reproduction may be sexual, non-sexual (apomictic) or partly sexual and partly non-sexual, according to the species used as male in the pollination. They also report the occurrence of segregation within the apomictic progeny, and discuss these results in relation to the taxonomy of *Rubus*.

Mary J. Carroll finds that the respiratory stimulating factors obtained from Fleischmann's bakers' yeast, which stimulate the respiration of normal tissues, have no effect upon cancer tissue (spindle-cell carcinoma of the mammary gland). This difference in response may be due to a qualitative difference between normal and tumour tissue metabolism.

A method of demonstrating the presence of glycogen in *Amaba proteus* Y and of making useful permanent slides of this organism is described by Monica Taylor.

Research Items

Early Spread of Agriculture

H. J. E. PEAKS, having concluded that the cultivation of wheat (Emmer) first took place in Palestine (*Man*, March, 1939), now passes to consider the stages and directions of the diffusion of the cultivation of grain in the early world (*Man*, April, 1939). An early spread was to the south-west, where it is probable that the early Tasian civilization of the Nile cultivated grain, though there is no direct evidence; while their successors, the Badarians, were certainly cultivators. Both peoples were immigrants. From Palestine the cultivation of grain must have spread to Syria, where the people took to cultivating the inferior Einkorn, which apparently is associated with the Tell Halaf culture, extending from the neighbourhood of Aleppo to Arpachiyah on the outskirts of Nineveh. From this culture it may be assumed cultivation spread by way of Anatolia through the Troad to Thessaly, the Danube valley, the Rhine basin and ultimately to the lake villages of central Europe. From Palestine again, cultivation, passing along the Zagros range, appears early in Assyria, while in the early villages of the hills around Teheran, as early as Arpachiyah, it would seem that 'bread' wheat was produced by crossing. Thence it passed into Mesopotamia with the Al Ubaid culture, where it met the Emmer cultivation of Jemdet Nasr. From Persia, cultivation passed into Turkestan, where signs of wheat appear in a low level of Anau, and passing thence through Afghanistan it moved in two directions, on one hand appearing in the Indus civilization, on the other in the painted pottery culture of the early agricultural villages of China. The painted pottery culture of Tripolje of the south Russian 'black lands' has as yet produced no evidence, though it occurs in areas of derivative culture, reaching the Rhine and Switzerland. For western and northern Europe an origin is suggested, tracing it to a great maritime movement in the Early Minoan period which introduced agriculture along the coasts of western Europe and ultimately reached Denmark, which was also reached by bread wheat from the Ukraine through the Baltic.

Religion of the Serbian Gypsies

ALEXANDER PETROVIĆ, investigating the origin and character of the religion of the Serbian gypsies (*J. Gypsy-Lore Soc.*, Ser. 3, 18, 2-3; 1939), finds a clue in the gypsy language, differentiating the 'new' religion from the 'old', according as belief is that of those who do, or do not, speak Serb. The 'new' religion of the Serb-speaking gypsies has borrowed concepts from Serbian belief. Thus the *romani del*, by which the gypsy expresses everything that is above man, has come to be the equivalent of *Bog*, the Serbian popular concept of God as "an old man with white hair who lives above the clouds in heaven"; while *dži*, which to the gypsies originally meant the centre of everything, as, for example, the navel of the abdomen, or the heart of a fruit or a tree "most precious, most beautiful, most sweet", is used to translate the Serbian *duša* "the soul", which comes out of a man when he dies. *Kar*, however,

meaning both *penis*, and "man", or "male", in addition to its anatomical sense, in which a high or abnormal degree of development is thought to bring good luck in marriage and otherwise, is used of phallic emblems made of the protective blackthorn, or failing this of wood, which bring good luck when concealed in the roof of a house or in a bed, and are worshipped or addressed in prayer by women, asking for good luck. This emblem is also found among the Serbs, but for sorcery or a love spell. Old women alone know its use, and pass on the knowledge to one another. There is no connexion between the two beliefs, unless of a common Indo-European heritage; but the gypsy belief, in conjunction with the evidence of language, points to worship of the procreative principle as the original form of gypsy religion, formulated possibly in their original home in India, where the cult of the *lingam* is found.

A Spreading Factor in Snake Venoms

F. DURAN-RIVINALS (*J. Exp. Med.*, 69, 69; 1939) has carried out investigations to determine whether the venom of poisonous snakes contains a factor capable of increasing tissue and blood permeability. He found that the venom of various species of snakes differed considerably in the power to spread Indian ink through the skin and apparently did so independently of its toxicity. The spreading power was greatest in the Viperidae (rattlesnake) and relatively scanty in the venom of the Colubridae *proteroglyphus* (cobra). Extracts of the supralabial glands of harmless snakes contained only negligible amounts of the spreading factor. Rattlesnake venom heated at 65°-100° lost a large proportion of its toxicity but retained the ability to spread Indian ink. Antivenine serum inactivated both the toxic and spreading factors of venom.

Vertebrae in a Fossil Crossopterygian Fish

For some years the ancestors of the earliest amphibians (Stegocephalia) have been sought among the Devonian Crossopterygian fishes. The skull and limbs of Stegocephalia have been compared especially with those of the Crossopterygian *Eusthenopteron*, which is found well preserved in the Upper Devonian rocks of Saumeneau Bay, Province of Quebec, Canada. A newly described specimen of *Eusthenopteron* now permits satisfactory comparisons to be made also with the vertebrae (W. K. Gregory, H. Roodwell and F. G. Evans, *J. Paleontol.*, 13, No. 1, 126-129, Jan. 1939). In the earliest known Stegocephalia, each vertebral centrum consists of two successive bony rings, an intercentrum bearing the neural and haemal arches, and a pleurocentrum without arches (the 'ambolomerous' arrangement). It now appears that in *Eusthenopteron* the intercentrum occurs as a delicate bony ring consisting of separate right and left halves in contact above and below. This intercentrum is separated from the next by an equally wide vacant space, which is closed at the top by a very small bone. The alternating vacant space, therefore, was probably occupied by cartilage, and

if this became ossified it would form a pleurocentrum to complete a vertebra like that of the earliest Stegocephalia. The comparison is indeed interesting and may be significant.

Labradorite-Oranite

FELSPAR phenocrysts in the diabase-porphry of Mount Devon in Missouri contain large amounts of potash, and for this reason the mineral has been referred to oranite, an intergrowth of orthoclase and lime-rich plagioclase, while the rock itself has been distinguished from other diabasic rocks as devonite. Goldich and Muilenburg (*Amer. J. Sci.*, 237, 130; 1939) have made a detailed study of the rock and its minerals and they are able to show that the large phenocrysts represent labradorite which has been hydrothermally altered, with introduction of potash, to form sericite. It is pointed out that labradorite-oranites may exist as the result of normal crystallization from a magma, but that no good examples appear to be known. Chemical analysis alone is clearly not sufficient to establish the existence of oranite, unless it is definitely known that the mineral is unaltered. The authors reiterate their earlier conclusion that the use of the rock name 'devonite' should be discontinued. At its type locality the rock so-called is simply a hydrothermally altered diabase-porphry.

Structure of Iron Enneacarbonyl

ALTHOUGH some tentative structures have been proposed for the more complicated metal carbonyls, they have not been supported by any very convincing experimental evidence. The structure of $\text{Fe}_9(\text{CO})_9$ has now been determined by X-ray analysis by H. M. Powell and R. V. G. Ewens (*J. Chem. Soc.*, 286; 1939), and the result is quite different from that previously suggested. The molecular formula is $\text{Fe}_9(\text{CO})_9$. It is found that each iron atom is linked to three terminal carbonyl groups and the two iron atoms are joined by three carbonyl bridges (CO), $\text{Fe}(\text{CO})_3\text{Fe}(\text{CO})_3$. The ends of the molecule are formed by three $\text{Fe}-\text{C}\equiv\text{O}$ groups which are linear, but the three intermediate groups are not linear and function as $>\text{C}=\text{O}$, each carbon being attached to two iron atoms and attached to oxygen by a double bond. The two iron atoms are formally ferric and the substance might be expected to show a paramagnetism corresponding to two unpaired electrons. Actually it is diamagnetic. This is explained as due to the complete coupling of the electron spins (not necessarily by bond formation) owing to the close approach of the iron atoms, which are only 2.46 Å. apart.

The Structure of Benzene

LAST year's Bakerian Lecture by O. K. Ingold (*Proc. Roy. Soc.*, 169, 150) was devoted to recent work on the structure of benzene. Any solution to this problem must account for the great stability of benzene and for the approximately plane ring structure shown by X-rays and by electron diffraction. The electronic theory of valency explains chemical bonds in terms of the superposition of the wave functions of atoms, which may be expressed as the freedom of the electrons to exchange places. This freedom of exchange lowers the energy of the system and gives rise to binding forces. An extension

of the theory explains 'mesomerism'. When there are two differently bound forms of a molecule, the possibility of transition from one to the other is expressed by the superposition of two wave functions, and it may be shown that the mixed or 'mesomeric' state has a lower energy and a greater stability than either of the separate configurations. On this view, benzene is a mesomeric combination of

and has the full symmetry of the hexagon. Recent work has verified the symmetry by study of the infra-red and Raman spectra of benzene. In a molecule which has a centre of symmetry, there can be no lines common to the infra-red absorption and the Raman differences. The coincidences which had been reported for benzene vapour were found to be spurious, and due to liquid benzene in which the symmetry of the molecule is distorted by intermolecular forces. The vibrations of a benzene ring in which the symmetry of the molecule was modified by the substitution of deuterium for some of the hydrogen atoms were considered in detail, and found to agree well with the observed Raman and infra-red spectra.

Ozone in the Upper Atmosphere

AN account of observations of ozone in the upper atmosphere made in North-East Land (in latitude 80° 23' N.) at the base of the Oxford University Arctic Expedition, 1935-36, by R. A. Hamilton entitled "High Latitude Ozone Measurements", was read before the Royal Meteorological Society on March 15. The measurements involved the determination of the amount of absorption of ultra-violet light in the spectrum of the Pole Star, by examination with a photometer of the spectra obtained with a quartz spectrograph. The densities of the spectra for wave-lengths of 3290 Å. and 3092 Å. were compared with the same densities on an image on the plate of a source of light the intensity of which varied along the image in a known manner. The required constants for the actual computation of the amount of the ozone were obtained by carrying out a similar experiment at Oxford at night when the amount of ozone had been measured on the previous and following days by the standard method. Corrections had to be applied for the errors due to fogging of the plate by the light of the aurora borealis. The mean error of a determination was found to be of the order of magnitude of 30×10^{-8} cm., but the day-to-day fluctuations were much greater than this. The day-to-day fluctuations were, moreover, found to be very much larger than those observed in lower latitudes. A point of resemblance with what has been observed in all other latitudes was to be found in an autumnal decline in the amount of ozone. This continued throughout the winter, while there was a sudden rise in spring. A table of comparisons between the measurements made in January and February 1936 with similar measurements made by Dr. Tönnesberg at Tromsø (latitude 69° 50' N.) was shown. Observations were made on the same day at both places on only three occasions, but a large ozone figure was found on one of these occasions (January 17) at both places.

The State and Unemployment

THE report of the Commissioner for the Special Areas in England and Wales for the year ended September 30, 1938*, indicates that the activities of the Department have been devoted to continuing work previously begun and making extended efforts to attract new industries to the areas.

Very satisfactory progress appears to have been made with the trading estates at Team Valley and Treforest, and the Commissioner has also provided factories on other sites, including several which can accommodate many undertakings, such as the Solway Estate, Maryport, and the sites at Pallion, St. Helens, Auckland and Dowlais. Some sites were originally acquired for the clearance of industrial ruins, and at the end of September twenty factories were occupied or in preparation in certain districts outside the estates, where the problem of unemployment has been most intractable, including the Rhondda Valley, Dowlais, south-west Durham and Cleator, west Cumberland. In addition to the powers to provide factories and to offer inducements, the assistance which is available towards capital, either in the form of a loan or by taking up shares or debentures, has been of special value in establishing new industries. For this there are available the Nuffield Trust, the Special Areas Reconstruction Association and the Treasury Fund. The Commissioner considers that the time is too short to draw any final conclusions regarding the value of the provisions of the Special Areas (Amendment) Act, 1937, for the encouragement of new undertakings in the Special Areas, which have now been exercised for sixteen months. Even, however, if some help to the Special Areas is immediately forthcoming as a result of restrictions on the growth of London, he considers it would be a mistake to reduce the powers at present available for encouraging new industrial activity in these areas. They continue to present a serious working problem of a population in excess of the present employment capacity, which cannot be solved by short-term methods.

The report shows that between mid-1936 and mid-1937 the population of the Special Areas in England and Wales fell by 42,000 as compared with 38,000 in the preceding twelve months and 23,500 in 1934-5. The total fall in the three years was 3.6 per cent and this fall continues to be due wholly to migration from the Special Areas, although the natural increase in population, due to excess of births over deaths, is still steadily decreasing in rate, having fallen by 43 per cent in seven years, as compared with 25 per cent in the rest of the country. In the Durham and Tyneside Special Area the rate of decrease of population was not so great as in the previous year, but in the other two main Special Areas it was greater.

The Special Areas have been affected by the general trade recession to a slightly less degree than the rest of the country, the percentage of unemployment during the year increasing from 21.4 to 24.3, mainly in South Wales and Durham. Although the increase in the whole of Great Britain was two and one half times as great as in the Special Areas, the percentage

of unemployment in the latter remains nearly twice as high as it is for the country as a whole—24.3 as against 13.6. A striking feature of the present situation is the increase of 34 per cent in the number of men, aged 18-20 years, unemployed, between May, 1937 and May, 1938 as compared with a decrease of 42 per cent in this group between May, 1936 and May, 1937. This increase is attributed partly to a decline in transference. With regard to the prolonged unemployment which characterizes the Special Areas as compared with the rest of the country, although the position has improved since 1935, the proportion of long-unemployed men remains approximately as it was three years ago, three and one-half times as high as in the rest of the country.

The Commissioner points out that the main difficulty in solving the unemployment problem in the areas has been due to the fact that in the past the areas have been dependant largely on one or two heavy industries, such as coal-mining, iron and steel and shipbuilding. There has been comparatively little variety in the types of employment provided and the demand has been predominantly for male labour. A good deal of the new industrial development has been of the light industry type in which the proportion of female labour is higher, and accordingly it has not had quite the same effect in increasing the employment of men. The development of new industries has, however, also led to the provision of training facilities to assist unemployed persons to obtain work in their own districts in industries new to the locality.

The position of the local government services has also improved and when a number of hospital schemes have been completed, the health services should be substantially up to the level of the services in other parts of the country. Especially in the north-eastern area, progress has been made in clearing away the industrial ruins of past days. In regard to social work, the need for continuing the provision of holidays by the sea for children on the grounds of health is stressed, as well as for school camps and assisting the settlements. Once again special emphasis is laid on the importance of preventing demoralization among the young men, and of bringing them within range of useful occupation and opportunities of ordinary wage-earning employment. The Commissioner considers that the measures available to him under the Special Areas Act and the valuable training and transference facilities afforded by the Ministry of Labour are not wholly adequate to meet the need. In his view it would be reasonable in selected cases to require applications for unemployment assistance, as a condition of the receipt of a cash payment, to attend one of the instructional centres or physical fitness classes organized by the Ministry of Labour. Unless such an applicant could show good cause, he should be confronted with a choice between compliance with a reasonable condition if he is to continue to receive cash payments, and one form of assistance which would contain an element of deterrence. The Commissioner simultaneously, however, stresses the importance of further efforts to devise schemes to provide new

* Report of the Commissioner for the Special Areas in England and Wales for the Year ended 30th September 1938. (Cmd. 5306.) Pp. vii+120. (London: H.M. Stationery Office, 1938.) 2s. net.

openings for the able-bodied unemployed, particularly young men.

The Commissioner for the Special Areas in Scotland* also insists on the necessity for a long view. A boom in the heavy industries is little more than a temporary relief, and the object should be to change the unstable industrial equilibrium by introducing as many secondary industries as possible. He concludes that no solution which aims at getting the older men back into ordinary wage-earning employment can wholly succeed. Despite its inherent difficulty,

* Report of the Commissioner for the Special Areas in Scotland for the period 1st September 1937 to 30th September 1938. (Cmd. 5906.) Pp. viii+88. (London: H.M. Stationery Office, 1938.) 1s. 6d. net.

some form of sub-economic development must be provided. The absence of any serious attempt to co-ordinate the activities of the various social service organisations in Scotland is criticized, and the Commissioner considers that further expenditure from the Special Areas Fund would be fully justified if it welded into a strong national body the various organisations at present doing fine work in most difficult circumstances. In regard to industrial development, the Commissioner suggests that more might be done to help new and experimental processes, and that a scheme designed to foster new enterprise in the area should include encouragement of such processes, even if in the nature of things their ultimate success was bound to be problematical.

International Congress of Tropical and Sub-Tropical Agriculture

THE eighth International Congress of Tropical and Sub-Tropical Agriculture was held at Tripoli during March 13-17, under the presidency of Prof. Le Plae, honorary general director of agriculture to the Colonies' Ministry, Belgium, in the unavoidable absence of Prof. Franco Angelini, secretary-general of the International Federation of Technical Agriculturists (F.I.T.A.). Delegates from Italy, France, Belgium, Holland, Poland, Germany, Bulgaria and other countries attended the Congress, and Great Britain was represented by Sir John Russell, as chief Government delegate, and by Sir Arthur Hill.

The Congress was opened by H.E. Marshal Balbo, Governor-General of Libya, who also presided at the concluding meeting. At the opening meeting, papers were presented by Prof. Armando Mangini on "European Colonisation and Native Agriculture in Tropical and Sub-Tropical Countries", by Count Edmond de Warren on "Agricultural Production of the Warm Countries" and by Prof. Le Plae on the "Professional Preparation of Native Agriculturists through Compulsory Instruction". The Congress then broke up into five sections. The first dealt with the possibilities of agriculture in tropical and sub-tropical countries, Sir John Russell being one of the presidents of this section. In the second section papers were read on agricultural problems relating to ecology, meteorology, erosion, irrigation and dry culture; while the third section dealt with various economic problems such as credit, labour, co-operation and marketing.

The fourth section was in two parts, one devoted to vegetable products, of which Sir Arthur Hill was one of the presidents. Numerous papers dealing with cotton, sugar-cane, rubber, olives and vines in North Africa, citrus, etc., were presented, and also papers dealing with forestry. In the other subsection, papers relating to animal products were read.

The fifth section was devoted to insect and fungus pests of cultivated crops.

Visits were paid to the Agricultural and Zootechnical Experiment Station near Tripoli where fine new laboratories have just been completed; the grounds contain a very representative collection of citrus species and varieties, and of vines, almonds and other trees of economic value. The citrus, including grapefruit, were bearing large crops.

Of particular interest were the visits to the new villages of Crispi, Michele Bianchi and Oliveti, which have been recently built. Crispi, only some four months old, is situated in a seemingly desert plain and consists of some 333 farms with a civic centre where the church, town hall with cinema, hospital, school and co-operative store are arranged around a central square. The farms allotted to each colonist are 37-120 acres in extent according to the locality, part being irrigated for the growing of wheat, lucerne, cotton, etc., the rest being dry-farmed with olive and almond trees and vines.

Crispi with its new white houses in this sandy spot was not a prepossessing sight, but a visit to Bianchi and Oliveti, nearly three years old, was a revelation of the possibilities of irrigation and good cultivation, since at the start they were founded on sites as sandy and barren as Crispi.

At these two villages, the olive and almond trees were flourishing and beginning to bear, and the irrigated crops were in very good condition—a great tribute to the good work of the Italian colonists from the Venetian plain and to the foresight of the organizers of these remarkable developments. No doubt in Roman times much of this North African 'desert' country was fertile, else such magnificent cities as Leptis Magna and Sabratha would not have been founded.

The new colonist is provided with his house, sheds and farm on trust, together with the equipment and livestock. After a short time on a fixed salary, he is placed on a crop-sharing basis for about five years and in the sixth year he becomes full owner of the farm and assumes direct management. At the end of nine years, when he has paid one-third of his debt, the colonist becomes full owner of his farm. The whole debt is expected to be paid off before the end of the thirty-fifth year.

This eighth Congress was admirably organized by Dr. Gioacchino Dallari, colonial adviser of the Fascist Confederation of Land Workers, and his staff. The majority of delegates were conveyed from Genoa, Naples or Messina in the S.S. *Roma*, a fine cruiser of 30,000 tons which served as their headquarters during the Congress.

It was suggested that the Congress in 1941 might be held in England.

Localization of Activity in the Brain

IN his Ferrier Lecture to the Royal Society, Prof. E. D. Adrian (*Proc. Roy. Soc., B*, 126, 433; 1939) traces the development of the electro-physiological methods of investigation and analysis of the activities of the cerebral cortex from the discovery of the electrical excitability of the brain by Fritsch and Hitzig in 1870. This discovery led to Ferrier's classical work on cerebral localization, the main facts of which have never been seriously questioned, and, indirectly, to the modern method of study of cerebral function, the recording and analysis of the waves of electrical potential, which are the inevitable accompaniment of cortical activity.

Berger's observation that the electrical activity of the cortex could be detected through the unopened skull came at a time when the range of electrical technique was increasing enormously, and the result has been a great and sudden increase in the volume of work published on the subject. The great beauty of the method is that it allows a study of the activity of the whole cortex, and not merely in "the arrival and departure platforms"; but it has the inevitable difficulty of the interpretation of the records from an organ which, by its very nature, never responds twice in precisely the same way. Thus, the local electrical response, which has been shown to follow the arrival of sensory impulses, is related in size, not to the stimulus, but to the previous history of the cortical area on which it falls. In fact,

the mechanism of the various types of facilitation which are in constant evidence in the cortex is one of the most fascinating problems.

Some details of the spread of activity in the cortex can be studied in the response of the sleeping, or narcotized, brain to the arrival of a sensory message, but a simpler, because more easily controlled, method is the investigation of the response of the cortex to a direct electrical stimulus. Such a stimulus evokes a reaction locally, not unlike that in response to a sensory message. In the surrounding areas it has two distinct effects: the direct spread of the excited state and a diffuse general increase in excitability, which reveals itself, after repeated stimulation, in the wide spreading of waves of considerable electrical potential, very like those which occur in man during epileptiform convulsions.

It is evident that the cerebral cortex responds readily to sensory messages, and it is therefore difficult to define what is meant by the 'spontaneous' activity of the brain. It seems clear, however, that although the response is to some degree controlled by the character and size of the message reaching it, the final pattern of the cortical activity is determined by the structure of the particular region and by its history. However hopeless may seem the task of analysing the activity of the human brain, these new methods offer some hope, at least, of understanding the mechanisms which exist in it, and from which its behaviour is eventually synthesized.

The Spens Report and General Science

Discussion by the Association of Women Science Teachers

THE Association of Women Science Teachers held an extraordinary general meeting on March 4 at St. Paul's Girls' School, by kind permission of the Governors and the High Mistress, to consider: (1) the Spens Report in its relation to science in the curriculum; and (2) the Report on General Science, Part 2, recently published by the Science Masters' Association.

The Spens Report sees the value of "the natural sciences when vitally taught" and it emphasizes the need for general interest, but it indicates that this might require less time than a formal study. The idea that the wider study of science might require less time was questioned by the meeting, but members were in agreement that there is still room for pruning and taking stock of the topics which are included, so that the science teaching might instil the desire "to search for truth, goodness and beauty" and give some understanding of the part played in the modern world by the forces of science. Some felt that the emphasis on English subjects as the core of the curriculum might subordinate science, but all were agreed that all subjects had an important part to play in the teaching of English.

There was considerable variation in opinion as to the time which should be allowed to science, but it

was felt that the time suggested by the Spens Report is adequate for a general view, but where greater detail and depth of knowledge are desired, more time is necessary. There are, however, the 'pool periods' for which science specialists can make a claim. There was general agreement that specialization at an early age is not desirable. It was felt by many that the school child of to-day is over-taught, and that there is a definite need for leisure in school time so that there might be an opportunity for reading; for this to be of real value the school must possess a good library.

The Spens Report also emphasizes the need for good demonstrations as against excessive practical work on the part of the pupil. There was general agreement that, to produce such demonstrations, both time and good laboratory assistants are essential; it was also felt that demonstrations might be overdone at the expense of the pupil, who obtains satisfaction from the activity involved in practical work. Care is required to keep the balance between demonstration and individual work by the pupils.

The general feeling of the meeting on the Spens Report can be summed up in the words of a member, who said: "Here we have the core of something which is going to give the mass of our child population

something that will stay by them", and for this "we have to sacrifice things we think valuable". Surely the end which is desired makes this worth while.

In the discussion on general science which followed, the question of the teaching of general science by one mistress and as one subject, and not by individual specialists, was raised. Some members felt that in the two years preceding School Certificate the syllabus should be taught by specialists in the individual branches. The majority of the members present appeared to consider that more was gained when it is taught by one, and that freshness of outlook, saving of time and greater correlation between the branches might result.

Miss Casswell, headmistress of the Edgbaston High School for Girls, gave an interesting report on the minimum syllabus for general science, which is based on the minimum syllabus of the Association of Assistant Mistresses and of the Association of Women Science Teachers, and on the extended syllabus which is based on the Science Masters' Association's Report on General Science, Part 2. Both of these

new syllabuses have been drawn up by the Joint Matriculation Board of the Northern Universities. The minimum syllabus does not have a bias in any particular direction, and it tries to get a unity of science through a study of forms of energy, the material environment and the plants and animals of the environment. The syllabus is such that in ordinary circumstances there should be time for revision and for the introduction of other material which will give the individual teachers freedom of choice. The second paper naturally requires more time, and there would necessarily be opportunity for greater selection and deeper study of sections of the syllabus in which there might be greater interest, and this would involve effort to suit the work to the special circumstances and environment of the school.

Throughout the meeting it could be seen that there was a real and deep appreciation by science teachers of the need to make the teaching such that "it should reveal the influence of scientific thought and achievement in the evolution of our present-day civilisation, and that it should indicate its possibilities, for good and evil, in the future of the human race".

Petroleum and World Politics

THE importance of the geographical distribution of the heavy minerals around the North and South Atlantic Oceans was stressed in NATURE of January 28, p. 169. It is well to remember, however, that the world distribution of petroleum is also closely related both to the arts of peace and to the horrors of modern warfare. In the present temper of the world, any non-belligerent nation which possesses reserves of petroleum is in danger of finding itself involved in serious political complications. This is especially true of those States of South America which are believed to possess the world's largest reserves of petroleum. In this connection, some remarks of Dr. D. Rey Vercosi and Dr. Juan H. Caorsi of Montevideo, in a paper of recent date¹, seem worthy of wider attention.

The authors observe that it is the policy of the more advanced nations of the world to exploit for their own principal benefit the supplies of petroleum in the less-advanced countries of South America. Since 1936, also, it has become the policy of the United States, which is the largest producer as well as the largest consumer of petroleum, to conserve its own resources, which are calculated to be sufficient for about thirty years at the present rate of consumption, and to import large quantities of crude oil from foreign, mainly South American, sources. This attitude of the greater Powers is causing much searching of heart among South American peoples, who see their national resources being rapidly depleted and perhaps to some extent wasted elsewhere in the frantic rush of the modern world. Such stirrings of national spirit help to explain the recent happenings in Mexico and other States.

The authors place the world production of crude oil in 1937 at about two thousand million barrels, and give the following figures of production in the principal producing countries in thousands of barrels (each barrel = 42 gall.)

U.S.A. ..	1,278,000	Mexico ..	44,700
U.S.S.R. ..	800,000	Iraq ..	80,700
Venezuela ..	185,800	Colombia ..	20,200
Iran ..	78,100	Peru ..	17,700
Dutch Indies ..	54,900	Trinidad ..	15,000
Rumania ..	52,000	Argentina ..	15,900

They quote General Serrigny's recent estimate in round figures of exportation in tons from the four principal geographical producing regions:

North America ..	21,000,000
South America ..	28,000,000
East Mediterranean ..	12,000,000
Orient ..	14,000,000
Total ..	75,000,000

Of this total, about 33 million tons go to Europe.

The authors remark that since the necessities of a European war in which the United States might be involved would greatly increase the demand for petroleum and the non-belligerent countries would not diminish their consumption, it would be necessary to increase world production perhaps two or three times, and supposing that supplies from North America, the east Mediterranean and the Orient were for various reasons unobtainable or unreliable, on South America would fall from necessity or choice the principal charge of meeting the increased demand. The South American States, and especially Venezuela and Colombia, would thus be required to supply the demands of the belligerents.

It is clear that an international situation of great gravity might easily arise, and it is good to know that the younger and clearer minds in South America are already at work upon the problem. The authors urge the necessity of co-operation between the South American States themselves and collaboration in a spirit of peace and good will with the industrialized nations of the world for the general good of humanity.

J. D. FALCONER.

Seismology at Kew Observatory

THE most complete seismological equipment in the British Isles is at Kew Observatory, and thanks largely to the enterprise of its superintendent, Dr. F. J. W. Whipple, the performance of this has recently been vastly improved. Dr. A. W. Lee, the seismologist at Kew, has now written an account of the new installation (*Meteorological Office, Geophysical Memoirs No. 78, sixth number, 9. London: H.M. Stationery Office, 1939. 2s.*).

The three Galitzin seismographs, originally presented to Eskdalemuir Observatory by the late Sir Arthur Schuster, were, after transference to Kew, placed on a massive concrete pillar in the basement of the main building but isolated from it. These instruments were greatly influenced by the wind, and it was found by experiment with a Milne-Shaw instrument borrowed from the Science Museum, that the effect was not due to direct draughts on the instruments but to the rocking of the whole building and the surrounding subsoil by the wind; hence the entirely new building to house the seismographs, which was ready for occupation early in 1937. The two Wood-Anderson seismographs constructed at Kew (1933 and 1935) were transferred in February, the Galitzin horizontal pendulums in April, and the vertical Galitzin in September 1937.

The new building, which has two rooms at the same level, is situated about 100 yd. south-south-west of the main observatory building, and has its floor

5 ft. below the level of the surrounding paddock. The ceiling is covered by soil and turfed, the level of the turf being about 5 ft. above the surroundings. The whole is made to withstand the weather, and the temperature of the ventilated rooms is thermostatically controlled.

The south room, 20 ft. by 15 ft., contains the seismographs on concrete pillars built directly on the floor, and the north room, 10 ft. by 15 ft., contains the galvanometers and recording drum for the Galitzin pendulums on slate slabs cemented to concrete pillars. The timing is by a Hope Jones synchro-motor (No. 1901) standard clock which is arranged to give time breaks of 2 sec. at the minute and 4 sec. at the hour accurate to within a few tenths of a second, on recording paper fixed to an electrically driven drum. The rate is 15 mm. per minute. The small Wood-Anderson instruments have a static magnification of about 700:1 and the instruments at Kew are adjusted to have a free period of 2.5 sec. with a damping ratio of approximately 20:1. Both north-south and east-west components are made to register on the same drum in a similar manner to the three Galitzin instruments.

It is confidently expected that in addition to welcome minor improvements, the changes will have obtained for the Kew seismograms that freedom from wind effect and more uniform drum rate than with the separate clockwork drives which was so much desired.

The First Imperial Veterinary Conference

THE Imperial Agricultural Research Conference which was held in London in 1927 recommended that certain specialized imperial agricultural bureaux should be established, and as a result ten bureaux are now in operation. Two important events have since taken place. Following the Ottawa Conference of 1932, the Imperial Committee on Economic Consultation and Co-operation, in 1933, examined and reported on *inter alia* the work and functions of these bureaux; and in 1936 the British Commonwealth Scientific Conference met.

The First Imperial Veterinary Conference is one of the many important developments of the Imperial Agricultural Research Conference of 1927. It was held in London in August last and was attended by delegates from the United Kingdom, from each of the Dominions, and from Colonial Territories*.

The Conference was opened by Mr. F. L. McDougall, a former chairman of the Council of the Imperial Agricultural Bureau, who pointed out the economic importance of the livestock industry to the several territories of the British Empire, and directed attention to the results that have been achieved in the control of animal disease. The sessions of the Conference were devoted to consideration of the working of the Imperial Bureau of Animal Health and to discussion on certain disease subjects of outstanding interest. The deputy director read a report on the

work of the Bureau. At the present stage of its development, the maintenance of the indexing and abstracting services is the main activity. *Index Veterinarius*, issued half-yearly, is a classified subject and author catalogue dealing with about 10,000 references per annum. The *Veterinary Bulletin*, issued monthly, is devoted to abstracts, of which about 3,500 appear annually. The development of a review service is imminent. A special committee was appointed by the Conference to report on the Bureau.

At the sessions devoted to disease subjects, "Foot-and-Mouth Disease", "Gaseous Lymphadenitis of Sheep", "Virus Diseases of Animals", "Laryngotracheitis", "Infectious Bronchitis and Coryza of Poultry", "Blowflies of Sheep", "Fowl Paralysis", "Bovine Mastitis", "John's Disease" and "Chronic Bovine Haematuria" were discussed.

Resolutions were passed emphasising the importance of the Imperial Bureau of Animal Health and recommending certain developments in its activities, on the importance of work concerning a reliable diagnostic agent for John's disease, and on the danger of using certain prophylactic measures for the control of foot-and-mouth disease and some other virus diseases.

* Report of the First Imperial Veterinary Conference, 15th-18th August 1938. Pp. 97. (Weybridge: Imperial Bureau of Animal Health, 1938.) 5s.

Science News a Century Ago

Exploration of the White Nile by Steam Vessel

AMONG the papers read to the Royal Geographical Society on April 22, 1839, was one by A. T. Holroyd entitled "On the Practicability of Exploring the Sources of the White Nile with a Steam Vessel". In his recent journey to Sennar and Kordofan, said the author, his attention was directed to one of the great desiderata in African geography, namely, the exploring of the sources of the Bahr el Abyad. If a steam boat left Cairo in July, drawing not more than two feet of water, it might with care pass all cataracts between Cairo and Khartoum. "I mentioned the subject of passing the cataracts to Mr. Perring, an eminent civil engineer in the employ of Mohammed Ali Pasha who kindly made a drawing of a steamer calculated for a steam expedition." The proposal was to leave Cairo in July, get to Berber in September and remain there until the end of the rainy season. An express was to be sent ahead to Khartoum to prepare for the arrival of the boat. From that place, the steamer would proceed up the Bahr el Abyad and it would be probably found that six months would suffice to survey both branches of the river. The vessel would return to Berber and await the rising of the Nile before proceeding to Cairo.

Fossils and Shells from Canada

At a meeting of the Geological Society held on April 24, 1839, Lyell read some "Remarks on some Fossils and recent Shells collected by Capt. Bayfield, R.N., in Canada". Several eminent conchologists having observed that in the English crag there are certain shells which indicate a somewhat colder climate than that which prevails in our latitudes, and it having been supposed that a similar difference may be deduced, but with greater certainty, from shells found in the newer Pliocene strata in Scotland and Ireland, Lyell had been induced to examine with great care the collection sent home by Capt. Bayfield, which consisted partly of fossils procured from the most modern tertiary deposits bordering the Gulf of St. Lawrence, and partly of recent Testacea from the Gulf itself.

The Smithsonian Bequest

In a long communication on science, education and other matters to the *Athenaeum* of April 27, 1839, a United States correspondent said: "The topic now is the appropriation of Smithsonian's (English) bequest. The amount is half a million of dollars. Government have invited our distinguished men to offer plans for the proposed institution, and many have been given in. Some want a national university of the highest European order, in Washington on Jefferson's model. Others propose courses of lectures, and various other things. One of the most remarkable of these schemes is that of a German, who wishes for a grand national agricultural institute at the seat of government, of course, with the idea, I presume, that agriculture is the great interest of this nation, and yet one in which we are grossly deficient. . . . He would have a farm large enough for all experiments to be tried, and all systems exhibited."

James Smithsonian (1765-1829), F.R.S., at his death had left more than £100,000 to the United States for founding a Smithsonian Institution at Washington for the increase and diffusion of knowledge. The Institution was finally inaugurated in 1846.

M. GOLDHAUSEN: Interspecific hybrids in water-melons.

K. I. PANGALO: Living ancestors of cultivated water-melons.

F. E. RICHMONDS: (1) Stage-development in different biological groups of lettuce (*Lactuca sativa* var. *capitata*). (2) Change of the "sign of photoperiodic reaction" in turnips.

V. G. ALEXANDROV and O. G. ALEXANDROVA: Endosperm nucleus and its role in filling and ripening of grains of cereals.

V. J. RUDENSKAJA: Anatomical premises for breeding large-rooted forms of 'kok-saghyz'.

G. I. AZIMOV and A. D. ALTMAN: Various parts of the anterior lobe of the pituitary body and physiology of lactation.

A. V. RUMJANTSEV: Growth of embryonal tissue *in vitro* as influenced by an excess of chlorides (sodium, potassium, calcium).

A. A. WOITKOWITSCH: The action of the substance from various zones of the anterior hypophysis lobe in the chick.

Rome

National Academy of the Lincei (*Atti*, 23, 117-175; 1938).

G. ARMILLINI: Fundamental problems of the cosmogony and Newton's law (8).

G. SILVA: Keplerian motions and theory of the annual aberration of light.

Q. MAJORANA: (1) Further researches on the action of light on thin metallic films. (2) Action of periodically interrupted light on thin gold films.

G. GHERARDI: An observation on the linear complexes of spaces.

A. ROSENBLATT: Unequal single-valued functions in the unitary circle.

L. SOLAINI: Influence of internal orientation errors in photogrammetric restoring.

F. P. MAZZA and C. MIGLIARDI: Some *p*-amino-benzene sulphonyl- α -aminoacids and their derivatives.

C. ARNAUDI: Researches on the acidifying micro-organisms of ensilaged fodders.

A. CORRADINI: Attempt to reconstruct the general cycle of plasmodians in the vertebrate host.

G. MARTINO and A. ALIBRANDI: New observations on the conditional reflexes of blinking (for acoustic stimuli).

A. VATOVA: Hydrographic observations on the lakes of Italian East Africa.

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, April 24

VICTORIA INSTITUTE (at the Central Hall, Westminster, S.W.1), at 4.30.—Mrs. Walter Maunders: "The History of India, as Reflected in the Astronomy and Meteorology in the Hymns of the Rig Veda".

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A. King: "The Imperial College Expedition to Jan Mayen, 1938".

Tuesday, April 25

ST. MARY'S HOSPITAL, LONDON, W.2, at 5.—Prof. Wilfred Trotter, F.R.S.: "Has the Intellect a Function?"

Wednesday, April 26

UNIVERSITY COLLEGE, LONDON, at 5.—Dr. A. Hrdlička: "The Present Status of our Views on Human Evolution".*

Thursday, April 27

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Prof. P. M. S. Blackett, F.R.S.: "Cosmic Rays" (Kelvin Lecture).

Friday, April 28

UNIVERSITY COLLEGE, LONDON, at 5.—Dr. A. Hrdlička: "The Racial Fallacies and Realities of European Peoples".

ROYAL INSTITUTE, at 9.—Sir James Jeans, O.M., F.R.S.: "Tone Colour and Electrical Music".

Saturday, April 29

GILBERT WHITE FELLOWSHIP (at the Art-workers' Guild, 6 Queen Square, Southampton Row, W.C.1), at 2.30.—Annual General Meeting.

R. A. Smith: "New Light on Pre-historic Monuments" (Presidential Address).

U.S. NATIONAL ACADEMY OF SCIENCES, April 24-25. Annual Meeting to be held at Washington.

April 24, at 8.30: Sir William Bragg, Pres.R.S.: "History in the Archives of the Royal Society" (Pilgrim Trust Lecture).*

BRITISH MEDICAL ASSOCIATION, April 27-29. National Conference on "Wider Aspects of Nutrition".

April 28, at 8.15.—Prof. V. H. Mottram: "Nutrition and the Public Health" (Sir Charles Hastings Public Lecture).*

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

LECTURER IN CHEMISTRY in the Newport Technical College—The Director of Education, Education Offices, Charles Street, Newport, Mon. (April 28).

ASSISTANT LECTURER IN ENGINEERING SUBJECTS in the West Hartlepool Technical College—The Chief Education Officer, Education Offices, West Hartlepool (April 28).

LECTURER IN HYGIENE AND PUBLIC HEALTH in the Battersea Polytechnic, London, S.W.11—The Principal (April 29).

JUNIOR INVESTIGATOR OF STRENGTH OF MATERIALS to the British Non-Ferrous Metals Research Association, Hurton Street, London, N.W.1—The Secretary (May 1).

RESEARCH OFFICER for the Technical Advisory Committee of the North-East Development Board, 162 Northumberland Street, Newcastle-on-Tyne (May 1).

LECTURER IN MECHANICAL ENGINEERING AND PHYSICS and LECTURER IN MECHANICAL ENGINEERING AND MATHEMATICS in the Constantine Technical College—The Director of Education, Education Offices, Middlesbrough (May 6).

ASSISTANT LECTURER IN BOTANY in University College, Swansea—The Registrar (May 16).

No. 3626

Aeronautical Research in Australia

EARLY in 1937, the Australian Government invited Mr. H. E. Wimperis to advise on the inauguration of aeronautical research in the Australian Commonwealth. It could have made no better choice. Mr. Wimperis has been closely connected with aeronautical research practically from its beginnings in Great Britain. For twelve years until he retired in 1937 he was responsible, as director of scientific research, for the organization and development of research in the Air Ministry. Owing to his retirement he was free to apply his unrivalled experience to the problems of Australia. He spent six months in visiting the Royal Australian Air Force Stations in New South Wales, Victoria, and Western Australia, and the civil aerodromes in New South Wales, Victoria, Western Australia and Brisbane. He also visited the Munitions Supply Establishment at Maribyrnong, Victoria, and many engineering and industrial plants.

One of the principal recommendations made by Mr. Wimperis in his report* is that an engineering research establishment be organized for experimental work in aerodynamics, aircraft and automobile engines, and for the testing and development of aircraft instruments and other equipment. Mr. Wimperis estimates the initial capital cost of such an establishment to be £143,000, and the annual cost of its staff when completed to be of the order of £12,000 a year.

This recommendation has already been acted upon, and a start has been made in the building of the laboratory at Fishermen's Bend, a few miles from Melbourne. The laboratory is to be built close by the aerodrome belonging to the independent Commonwealth Aircraft Corporation,

which has agreed to give free use of its aerodrome to the laboratory and to co-operate fully with the research investigations. A short distance away are the works of the General Motors Company.

It is understood that the Commonwealth Government also intends to set up a Bureau of Standards at Sydney. The new Engineering Research Laboratory at Fishermen's Bend and the Bureau of Standards at Sydney will correspond together to the National Physical Laboratory in England. The aeronautical work at the new laboratory will be supervised by an Australian Aeronautical Research Committee; but the laboratory as a whole will be administered by the Council for Scientific and Industrial Research, the chief executive officer of which is Sir David Rivett.

Mr. Wimperis also recommends the establishment of a professorship of aeronautical engineering, and a readership in meteorology in Australian universities. Both these recommendations have already been given effect. A chair of aeronautical engineering has been established at the University of Sydney. The Commonwealth Government has made a grant of £20,000 for the building of an aerodynamics laboratory at the University, £12,000 for its equipment, and £3,000 a year for salaries and maintenance. The State Government has added £18,000 for building a hydrodynamics laboratory in conjunction with the aerodynamics laboratory. An assistant professorship of meteorology has been established at the University of Melbourne.

It may possibly be argued that the comparative remoteness of Australia, even in these days of rapid transport, the smallness of its population, and the relatively insignificant size of its industry, all combine to make the carrying out of aeronautical research both expensive and unnecessary, in view of the very large sums of money already

* Parliament of the Commonwealth of Australia. Report by H. E. Wimperis on the Inauguration of Aeronautical Research in Australia, dated 21st December 1937. Pp. 17. (Canberra: Government Printer, 1938) 1s.

devoted to the subject in other countries in Europe and America. Would it not be possible for Australia to get all the information it needs by studying the results of work in Great Britain and in America without attempting to duplicate it on what would appear in these countries to be an inadequate scale? Such views have been expressed, but we believe them to be entirely wrong. In the first place, no one can appreciate fully and apply the results of scientific investigations unless they themselves are engaged on similar work. It does not matter in the least that Australia may not be in a position for many years to contribute anything of first-class importance to the science of aeronautics. If no start is made, there never will be such contributions. Now that the start has been made, Australian contributions to the science will depend upon whether men of first-rate ability can be attracted to the country. In the meantime, the presence and active work of a trained staff will undoubtedly lead to a fuller comprehension and application of the results of work in other countries.

In the second place, Australia is committed to a policy of developing its manufacturing industries, as well as the older and more valuable industries of agriculture and mining. If Australia seeks, as it undoubtedly does, to attain a high state of efficiency in its manufacturing industries, it certainly needs a central institution of the first rank in engineering research. In the particular

case of the aeronautical industry, it is essential for the defence of Australia, and not merely of Australia but also of the British Commonwealth of Nations, that the manufacture of aircraft on a large scale should be undertaken in Australia. A start has been made and the industry is in the hands of capable and enthusiastic leaders. That it is bound to expand, and expand very greatly, in the near future is scarcely open to doubt, and its expansion must be facilitated by the new creation of a Government Aeronautical Research Laboratory. In aeronautics, as in every other branch of applied science, research and manufacture react on each other. Neither can be fully efficient unless it is in close contact with the other. Aircraft manufacture in Australia cannot exist in a healthy state if it merely relies on information and advice from other countries; nor will Australian aeronautical research be much more than academic and second rate if it is not carried out in the closest contact and with the enthusiastic support of Australian aircraft manufacturers.

The organization starts under the happiest auspices. The Australian Council for Scientific and Industrial Research, presided over by Sir George Julius, and administered by Sir David Rivett, has the complete confidence of the Australian Government, and scientific workers in Great Britain as well as those in Australia will feel that the development of aeronautical research in that continent is in safe hands.

The Modern Approach to Indian Problems

(1) Social Service in India:

an Introduction to some Social and Economic Problems of the Indian People. Written by Six Contributors. Edited by Sir Edward Blunt. Pp. xxiii+447+16 plates. (London: H.M. Stationery Office, 1938.) 10s. 6d. net.

(2) Health and Nutrition in India

By N. Gangulee. Pp. viii+337+13 plates. (London: Faber and Faber, Ltd., 1939.) 15s. net.

(1) **W**HATEVER may have been the ideas of the founders of the British Empire, the purpose always before the best of the modern administrators is to develop each part so as to give to its inhabitants the fullest and richest life possible for them. This purpose is particularly clearly shown in the volume called, appropriately enough, "Social Service in India" published by

H.M. Stationery Office, and edited by Sir Edward Blunt, with the collaboration of six colleagues, including some of the most distinguished Indian civil servants. The volume grew out of a proposal made by Sir Atul C. Chatterjee's Committee set up in 1936 to inquire into the system of probation for the Indian Civil Service: the proposal was that lectures should be given to the probationers on social welfare in India, and that a book should be prepared for use in connexion therewith. The first course was given in 1938 and the chapters were issued in typescript; they were then revised and expanded and are now printed in book form.

Contributors and editors alike have done their work well, and we know of no account of modern India so complete and concise as this. Sir Edward opens with two chapters on the environment and the people, showing, in the manner of the modern

geographer, how each has reacted on the other. Then follows a chapter by Mr. C. G. Cherevix-French on the rural community, giving a clear statement of its complex structure, of the *ryotwari* and the *zamindari* systems of land tenure and management, and of the land revenue and settlement problems.

Mr. R. G. Allan contributes two chapters on agriculture, the first giving a well-balanced account of the actual position, and the second showing the steps which the various departments are taking to effect improvements. These include the provision of better seed, better manures and implements, better methods of cultivation and of water supply, better livestock and better marketing facilities. There is also a section on the cultivation of fruit and vegetables, now recognized as of growing importance as sources of vitamins and mineral substances in the people's dietary. Cattle are of particular significance in the life of the village: usually the males are favoured as supplying power to the farmer, while the females have a less important position, receiving less food and of poorer quality, excepting only when they have special value for milk production. Broadly speaking, the poorest types are found in the areas around the head of the Bay of Bengal—regions of high rainfall and lateritic soils; the better types are found in the drier tracts of the Central Provinces, Bombay and northern India. Mr. Allan accepts the necessity for burning the farmyard manure, this being a cheaper fuel than coal or charcoal: but the peasant is being made to realize that green manures, composts and earth soaked with the urine of animals, are all good manures. Green manuring is found to be the most practicable, and it is now most common (1) before sugar-cane, where the ground was formerly left as open fallow, (2) before irrigated wheat, (3) before rice, if rain or irrigation permit of the establishment of a leguminous crop before transplanting begins. Night soil is but little used, as only very low castes will handle it.

Closely associated with agriculture come public health and nutrition, ably dealt with by Sir John Megaw. Famine and pestilence have in the past taken a terrific toll of Indian life: Sir John shows how they were gradually controlled, and describes in some detail the public health services of the Central Government and of the Provincial Governments. Systematic efforts are made in some provinces to bring medical aid within reach of every village. In Madras, 428 medical men receive a subsidy on condition that they reside in certain villages and provide medical relief for the sick poor. In the Punjab, 360 small dispensaries have been built, each in charge of a subsidized practitioner—these are in addition to the older hospitals and

dispensaries. Some £3,000,000 has been spent on hospitals in British India, and nearly 12,000 students are being trained in the medical schools and colleges. There are, however, nearly half a million villages in British India alone, exclusive of Burma and the Indian States, and they contain nearly 90 per cent of the total population of 270 millions. The birth-rate in British India is high; in 1935 it was 35 per mille (this included Burma) against 15 in England: the death-rate was 24 against 12 in England: the infant mortality-rate was 154 against 57 in England. The most significant fact brought out by these figures is that the annual number of births in British India and Burma averaged 4½ millions between 1881 and 1890, but was more than 9½ millions in 1935. This great growth of population is, of course, putting considerable pressure on the land, and Sir John recognizes that human nutrition is the most important and most difficult of all Indian problems. Experts differ as to whether the total food production in India is, or is not, adequate, but all agree that the great majority of the people are poorly nourished through lack of certain vitamins and mineral substances, and by reason of the poor biological value of much of the protein eaten. But this is no reason to think that the problems are insoluble. Accounts are given of the deficiency diseases that prove the lack of essential foodstuffs, and of the well-planned investigations on human nutrition now in hand by Dr. W. R. Aykroyd and others.

Sir George Anderson deals with the vexed question of education, and sets out clearly the disadvantages of a system which has undeniably turned out a considerable number of unemployed. An important chapter by Sir Frank Noyce deals with industrial labour and the many difficulties that have arisen in the development of a factory system in India. Finally, Mr. C. F. Strickland discusses co-operation, a method which, if it could but develop in India, would go far to solve many of the peasant's difficulties.

Altogether the volume can be strongly recommended, not only to those about to proceed to India, but also to all who are interested in knowing something of the way in which modern administrators tackle the problems that daily confront them there. We suggest to the editor the desirability of giving a short list of the more important of the many reports that have been issued on the various great problems discussed in the book, or alternatively, that they should be quoted as sources of fuller information should this be desired. Some of these reports are of special value but they run the risk of being overlooked, and few men have either time or the courage to attack, without guidance, the great mass of official literature that has now accumulated. Another improvement

would be the inclusion of an appendix summarizing the more important of the statistics discussed in the book.

(2) Prof. Gangulee's book deals entirely with health and nutrition in India, which he, too, regards as the most important problem there. He is unusually well equipped among Indian writers for his task: his early training under Tagore gave him a wide humanitarian outlook; his subsequent career in the United States, at Calcutta and at Rothamsted showed what was practicable in the way of agricultural improvement; his membership of the great Linlithgow Commission in 1926-28 furnished him with full details of the Indian problems; finally, his recent long months of reflection and writing have enabled him to put his ideas into shape.

In a significant dedication to Pandit Nehru, Prof. Gangulee quotes the old saying about India that "for every three mouths there are only two rice bowls" and so aligns himself with those who regard even the total production of food in India as inadequate, quite apart from the recognized inadequacy of vitamins and mineral substances. His suggested remedies are interesting. First and

foremost, to overcome the fatalism, even defeatism, which he finds so prominent in Indian life; then, the reorganization of the land system so as to abolish the tendencies to over-fragmentation of holdings in some regions, and over-large holdings in others; and the reorientation of agriculture so that human nutrition becomes its main purpose.

This question of the proper feeding of India is admittedly difficult, but it is now being faced courageously and we may still hope for a successful outcome of the many efforts now being made. One of the most hopeful features in the situation is the keen desire of the leaders of India, the Viceroy, the great social and political leaders, and the administrators, that the standard of life in the villages should be raised. It is now widely recognized that the prime purpose of Indian agriculture should be to produce food in the necessary quantity and of the proper quality, and that for this purpose special efforts must be made to bridge the present gap between the agricultural experiment station and the small cultivator, so as to bring the benefits of science within the reach of the villages of India.

E. J. RUSSELL.

Combinatory Topology

Topologie der Polyeder und kombinatorische Topologie der Komplexe

Von Prof. Dr. K. Reidemeister. (Mathematik und ihre Anwendungen in Monographien und Lehrbüchern, herausgegeben von E. Kamke, Band 17) Pp. ix+196. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1938.) 14.80 gold marks.

THE first systematic exposition of combinatory topology was made by Dehn and Heegaard in a section of the "Enzyklopädie der mathematischen Wissenschaften", in which the exact concepts involved are only developed as far as the third dimension. The extension of the theory to complexes of higher dimensions was fraught with considerable difficulties; and it was due to the work of M. A. H. Newman that the gap was finally bridged. In the section of the encyclopædia referred to above, he showed that combinatory topology was one of the most primitive branches of geometry, in which the concept of limiting values had as yet no place. In fact, as Prof. Reidemeister describes in detail in the present treatise, combinatory topology turns out to be a well-defined partial domain of the theory of polyhedra—a fact well calculated to demonstrate the elementary character of the subject and to justify Prof. Reidemeister in providing a new and systematic presentation of it.

In Euclidean geometry, a number of geometrical figures known as polygons or polyhedra—triangles, rectangles, cubes, etc.—are both familiar and indispensable. But the general concept of a two- or three-dimensional polyhedron has no part whatsoever in the definitions of these figures. Triangles and cubes are obtained directly from geometrical axioms; and even the more comprehensive class of convex polyhedra is treated as a special convex domain, as a section of a finite number of semi-spaces for example, and not as polyhedra having the additional property of convexity. Although, by virtue of numerous elementary examples, we may be familiar with the abstract idea of the polyhedron, an exact and unequivocal concept such as is essential for any systematic investigation, is lacking. Thus, at the outset, we are, as Prof. Reidemeister says, confronted with a decision the consequences of which present considerable difficulties for further developments.

By Prof. Reidemeister's fundamental definition, in which only the axioms of connexion and order of linear geometry and no continuous properties whatsoever, are assumed, a polyhedron P is an aggregate of points of a linear space R^n . It is in fact an extension of the definition of convex polyhedra given above. The totality of the polyhedra of an R^n is once more a polyhedron, and is,

moreover, the smallest aggregate-ring which contains the totality of the semi-spaces and linear sub-spaces of the R^n .

A polyhedron P can be obtained in two different ways; and the task which follows from Prof. Reidemeister's definition is a twofold one. On one hand, to obtain the connexion between the different methods of representation of P ; and on

the other, to obtain those properties of P which are independent of the method of representation, from a single representation. This task is accomplished by Prof. Reidemeister in two stages, and forms the substance of the present work, which does not assume much previous knowledge on the part of the reader, of either linear algebra or linear geometry.

The "Handbuch der Zoologie"

Handbuch Der Zoologie :

eine Naturgeschichte der Stämme des Tierreiches.
Gegründet von Prof. Dr. Willy Kükenthal.
Herausgegeben von Dr. Thilo Krumbach.

Band 4, Hälfte 2 : Insecta 2. Lieferung 9. Pp. 128.
16 gold marks.

Band 4, Hälfte 2 : Insecta 2 Lieferung 10.
Pp. 96. 12 gold marks.

Band 4, Hälfte 2 : Insecta 2. Lieferung 11.
Pp. 160. 20 gold marks.

Band 4, Hälfte 2 : Insecta 2. Lieferung 12.
Pp. 160. 20 gold marks.

Band 4, Hälfte 2 : Insecta 3. Lieferung 13.
Pp. 144+xiv. 20 gold marks.

Band 4, Hälfte 2 : Insecta 3. Bearbeitet von Dr.
Max Beier und Dr. Friedr. Hendel. Lieferung 14.
Pp. 312+xvi. 48 gold marks. (Berlin : Walter
de Gruyter und Co., 1938.)

THE parts of this publication now under review complete the three volumes devoted to the Insecta, which comprise 2,756 pages of text and additional pages, and 2,785 figures, all of high merit. The various orders, of which thirty-three are recognized, are dealt with in a remarkably uniform manner considering the different authors involved. Each starts with a short general account including a definition and a historical note. Then follows the morphology of imagoes, larvae and pupae, after which comes the detailed anatomy, with some reference to the physiology of the various systems, commencing with the integument and ending with the reproductive system. Problems of general interest such as the biology, phylogeny, geographical distribution, palaeontology, etc., precede the concluding and often most extensive part, the classification. In the latter, extensive and practical keys are provided. These are most useful since they cover the order as an entirety as it is now known and hence avoid the pitfalls of keys that are drawn up for a particular region where an order may be incompletely represented.

The whole of the first two *Lieferungen* here considered and the first sixteen pages of the third,

that is, *Lieferung* 11, are concerned with Diptera, the account of which had been commenced in *Lieferung* 8. It is by Dr. F. Hendel and Dr. Max Beier. There are 296 illustrations and while none of them is original, a large number are taken from the works of the former authority. It would, of course, have been impossible to include a complete list of all the literature of so large and important a group. The difficulty is met by giving a list of ten works each of which has an extensive bibliography. This is supplemented by a selected list of the more important works of the last twenty years, which occupies five and a half pages.

The remainder of *Lieferung* 11 and the first sixty-four pages of *Lieferung* 12 contain Dr. Max Beier's account of the Heteroptera. Of the 105 illustrations with which it is furnished none is original, a number being taken from the works of Handlirsch and of Weber. The last seven pages are devoted to a bibliography.

The same author's account of the Homoptera occupies the remainder of this *Lieferung*, the whole of the next and the first twelve pages of *Lieferung* 14, the last six of which contain the bibliography. Illustrating it are 317 figures; one photograph and one diagram are original, and of the remainder a number come directly or indirectly from the classical work of Weber.

At the end of *Lieferung* 13 are title-pages, list of contents, etc., for the volumes Insecta 1 and 2.

Lieferung 14 with its 312+xvi pages is by far the largest individual part. In a work like the present, the publication of which has extended over a period of years, it is inevitable that important works and even fundamental contributions to our knowledge of various orders should have been made during the interval: forty-four pages with thirty-one figures have wisely been devoted to remedying this. In such an extensive work also it is to be expected that slips and misprints should occur and these too, few in most orders, have been corrected. It is rather a surprise to find that in the Lepidoptera it should have been found necessary to provide a page and a half of corrections for 171 original pages; this rather suggests faulty

staff work somewhere. The greater part of *Lieferung* 14, 266 pages of it, is devoted to a closely printed index arranged in three columns. This is a most remarkable piece of work, for it contains many thousands of entries which, by means of contractions, signs and full cross references give ready access to the enormous mass of information in the books. To take an example chosen purely at random, under "Sternite" there are more than 100 separate entries referring to the different sternites, their occurrence in the larvae and the imagines of the various orders where they are mentioned. These entries in turn are cross-referenced.

In the table of contents in *Lieferung* 14 it is stated that *Insecta* 3 commences on page 1729 and it finishes on page 2756, that is 1028 pages. Yet on the covers of the parts, *Insecta* 3 does not appear until page 2301, and on the inside of the back cover of the past part it states that *Insecta* 3 contains "xvi + 1112 Seiten". Such discrepancies are difficult to excuse and provide unnecessary trouble when it comes to binding the volumes. So also will the fact that following the title-page for *Insecta* 2 we find in the table of contents a complete survey of *Insecta* 1 as well as *Insecta* 2 arranged continuously so that they cannot be separated.

By now this well-known general "Handbuch der Zoologie" has made a very definite place for itself in zoological libraries throughout the world. It is practically indispensable in the general library, for no other publication at present available can be regarded as a serious rival. The specialist library naturally depends upon the individual memoirs and researches in its own field appearing in scientific periodicals. But even here the "Handbuch" will prove of value since its full summaries of the fundamental work in each group up to date will furnish satisfactory stepping-off places. Indeed some specialists would do well to consult the volumes so as to orientate their particular studies to knowledge of a wider field and not get entirely lost in one small corner. It is the greater pity, therefore, that its price puts it beyond the reach of many who would wish to have more constant access to its pages. The three volumes devoted to *Insecta* have a total cost of Rm. 379 which, even allowing for a possible rebate of 25 per cent, represents at the present rate of exchange an outlay of more than £25 0s. 0d. This is more than the average worker in university or research station, or indeed a small general department, can contemplate spending on such a book, good though it may be.

Wireless Direction Finding

Wireless Direction Finding

By R. Keen. Third and enlarged edition. Pp. xi+803. (London: Hiffe and Sons, Ltd., 1938.) 25s. net.

WHEN the first edition of this book appeared in 1922, interest in wireless direction-finding was confined to a comparatively few individuals who were engaged either in the practice of the art for navigational purposes or in its application to a scientific study of the propagation of radio waves. Since the second edition appeared more than ten years ago (see review in *NATURE*, March 10, 1928), the scope and application of wireless direction-finding have increased considerably. Its use in connexion with marine navigation has become more widespread and has acquired greater reliability, while more recently it has become a very important aid to the navigation of aircraft. The appearance of the third edition, dealing in a comprehensive manner with the most up-to-date aspects of the subject, definitely establishes Keen's book as a standard work, which should be in the hands of all those engaged in the design, manufacture and installation of direction-finders, or in

the study and application of the results obtained therewith.

On the research side, this instrument continues to be a very useful tool in connexion with scientific investigations of the propagation of electric waves, including those unwanted waves of natural origin known as atmospherics. In a foreword to the edition under review, Mr. T. L. Eckersley stresses this aspect of the subject and directs attention to the efficient manner in which the scientific and technical sides of the art have advanced hand in hand.

In order to make room for new material, the author has had to delete the portions of the second edition dealing with the use of directive aerial systems for communication purposes only. Even so, the book has increased in size from less than 500 to more than eight hundred pages. After a brief historical introduction an explanation is given of the principles of the various types of directive aeriels and the manner in which they are influenced by electric waves. Detailed descriptions follow of the types of direction-finding apparatus used for shore, ship and aircraft installations, and of the various phenomena

encountered in these three spheres of application. The limitations imposed on the various types of instrument by vagaries in the propagation of waves are described in some detail, together with the manner in which these limitations have been overcome or reduced in importance. A chapter on systems of direction-finding which do not yet appear to have earned 'commercial' success includes the instrument giving a visual indication of bearing by the aid of a cathode ray tube. Recent

developments in connexion with this instrument indicate that it may soon be expected to emerge from its experimental shell, in which it has for so many years proved a most invaluable tool for the scientific investigator.

A well-arranged bibliography of selected papers is included in the book, and this will prove very useful to the student or research worker who wishes to delve deeper into the subject.

R. L. SMITH-ROSE.

Molluscs of the Great Barrier Reef

Great Barrier Reef Expedition, 1928-29
Scientific Reports, Vol. 5, No. 6: Mollusca,
Part 1. By Tom Iredale. Pp. 209-426 + 7 plates.
(London: British Museum (Natural History),
1939.) 15s.

THIS volume deals with the Lamellibranchia, excluding the Eulamellibranchia. The Barrier Reef Collection was augmented by dredgings around the Low Islands, with a few from the Queensland mainland. These regions the author names the Solanderian and Banksian divisions of the Australian fauna. A short history of reef exploration in the area, from Captain Cook to Hedley and his collaborators, is followed by a discussion of the criteria providing a basis for the classification of lamellibranchs. The author's scheme of classification is given, and the remainder of the book is devoted to a description of families, genera and species. More than two hundred species or sub-species are described and of these more than half are new. The six half-tone plates from drawings by Miss Joyce K. Allan and the photographs of oysters by Mr. Clutton are clear and adequate for identification of the shells. No index is provided, not even page references to families—an omission that may be rectified, perhaps, in the next part. A list of literature is also needed.

The study of this large class has been in the hands of three types of specialist, the geologist, the conchologist and the anatomist. Each has attempted to elucidate the evolution and relationships of the members of the Lamellibranchia from his own particular studies and is inclined to believe that the characters of a hinge, a gill or some other structure are sufficient for the purpose. The study of the dead shell, whether fossil or recent, has either tended to over-emphasize features which may be convergent, or, as Morley Davies pointed out (*Proc. Malac. Soc.*, p. 322; 1933) to divide orders and genera *horizontally* instead of *vertically*, so that their polyphyletic origin is masked.

We are, in fact, driven back to two important tenets in scientific philosophy. First, the specialists must pool their knowledge in order that a sound judgment can be made; no one of the three mentioned is competent to do it alone. Secondly, the features indicating affinity are likely to be those deep-seated characters that are little affected by the environment. Thus the conchologist has often been at fault because he has been too insistent on his own infallibility, the anatomist has rarely been also a geologist and conchologist and so has not obtained the full benefit of his anatomical studies. Moreover, the work on fossils and recent shells is far greater than that on the bodies of the animals themselves, and until this disproportion is corrected, the classification of any of the Molluscan classes must be regarded as unsatisfactory.

Mr. Iredale has clarified the issue considerably by attempting to combine the results of the geologists and conchologists with some anatomy. But his dogmatic and scornful attacks on other workers are unwise, since his own classification is not invulnerable, and in any case acerbity is dying out in scientific literature and may well be allowed to perish. He is to be commended for raising the anomalous Trigonias to ordinal rank, a position to which their deep anatomy also entitles them. Family rank for Watson's sub-families among the Pectiniformes is also sound, but the grouping of the Malletiidae with the Nuculidae can be questioned, since anatomically, especially as regards the pericardial complex, their relations are with the Solemyidae. Unfortunately, no Malletiids are described, so we do not know why the author arranged them thus.

Iredale is critical of the specialist in Europe who names the Australian fauna, and he stresses the importance of the local worker, who alone can study the variability of a species in its own home. He is quite right and the remedy is in his hands. Let him encourage Australian naturalists to carry on the work he has begun.

The Cycle of Weathering

By Prof. B. B. Polynov. Translated from the Russian by Alexander Muir. Pp. xii+220. (London: Thomas Murby and Co., 1937.) 10s. 6d. net.

THE science of weathering is fundamental in any study concerned with such a question as why the mineralogical composition of the surface material of the earth is as it is. It is therefore a fundamental science in the study of how geological deposits and soils came to have their present composition. Although this science is so fundamental, it possesses very few established facts. In Nature, weathering is exceedingly slow and very complex, with the consequence that until recently very few methods have been available for examining exactly what chemical processes are taking place. The science of weathering has thus been built up rather more on plausible guess-work than on established fact.

The author of this book, who is one of the leading Russian soil geologists, has not attempted to give a critical presentation of the subject in which the various rival theories are weighed and tested against known experimental data. The book is much more a monograph in which the author sets out to give a general survey of the field of weathering as he himself sees it. He discusses the types of weathering that can take place, and follows up in some detail the cycle of compounds which the commoner chemical elements pass through while in the earth's surface.

In the last chapter the author discusses the effect of topography and of the soil hydrological conditions on the rate at which weathering proceeds. He shows how, in a region having uniform climate and parent material, soils of quite different types would be expected, ranging from the most mature and leached soils on the divides to the most immature soils in the valleys. This effect constitutes what can be called the geomorphological limitation of the theory of the existence of climatic soil groups. This chapter is one of the most suggestive in the book, and the reviewer only regrets that it was not made longer so that more detailed illustrations could be given of the effect of topography. But if it serves as a stimulus for a fuller examination of this effect the book will have been more than justified. E. W. R.

Scoliodon (the Shark of the Indian Seas)

By Dr. E. M. Thillayampalam. (Indian Zoological Memoirs on Indian Animal Types, 2.) Second edition, revised and enlarged. Pp. xiv+126. (Lucknow: Lucknow Publishing House, 1938.) 2.8 rupees.

PROF. BAHL has now presented us with seven memoirs, each dealing with an Indian animal typical of some phylum and taught as a type of the same. The taxonomic position of each is shown, its anatomy and such parts of its physiology as are concerned with its habits in life. The classificatory position in relation to the rest of the Elasmobranchii is carefully considered, aided by forty-nine line illustrations, these leading up to the history of the genus *Scoliodon* and the consideration of the species.

The anatomical account which follows is interestingly written and excellently illustrated. We are

pleased to see modern views on locomotion, and we think the student would be helped by a more 'functional' tone throughout the anatomy. In particular, we should like to see a stronger treatment of the brain and cranial nerves, the broad functions of which apply to all the higher vertebrates.

Physiology of the Central Nervous System and Special Senses

By Prof. N. J. Vasifdar. Seventh edition, revised and enlarged. Pp. x+307+vii. (Bombay: Popular Book Depot; London: H. K. Lewis and Co., Ltd., 1938.) 10s. 6d. net.

A MEDICAL work which has passed through seven editions in less than thirty years does not require any further recommendation. It is sufficient to say that the present edition has been well brought up to date and will be found a valuable handbook by the practitioner and student alike.

The text is liberally interspersed with illustrations of the different types of nerve cells, tracts of white matter, transverse sections of the spinal cord, pons and mid-brain, the results of lesions at various parts of the central nervous system, and the structure and function of the special senses.

Fish Passes in Connection with Obstructions in Salmon Rivers:

being the Buckland Lectures for 1937. By T. E. Pryce-Tannatt. Pp. 108. (London: Edward Arnold and Co., 1938.) 3s. 6d. net.

THE subject chosen for the Buckland Lectures for 1937 by Dr. T. E. Pryce-Tannatt was appropriate, for Buckland himself was an inspector of salmon fisheries and was concerned with the question of obstructions in the courses of rivers. This book outlines the laws regarding obstructions, considers the obstructions in relation to the habits of the fish, and describes the types of fish passes in existence. The problems concerned with the choice of pass best suited for the varying circumstances are discussed, and thirty-two diagrams and photographs of the different kinds of obstructions and fish passes are given. It maintains the standard of this useful series of publications.

An Inorganic Chemistry

By Dr. H. G. Denham. Third edition. Pp. viii+694. (London: Edward Arnold and Co., 1939.) 12s. 6d. net.

THE main alterations in the new edition of Prof. Denham's book are concerned with the modern view of strong electrolytes and with valency. The last chapter has been extended so as to give a broad outline of the modern theory of valency. The book is of intermediate standard, and particular attention is given to the systematization made possible by the use of the Periodic System.

The possibility of predicting many properties of the compounds of the elements from those of the oxides is also used. The continued popularity of the book may be confidently expected in its new form.

Solar Variation and the Weather

By Dr. C. G. Abbot, Smithsonian Institution

WHILE he was visiting the United States at the end of last year, Sir Richard Gregory invited me to contribute to NATURE a general review of the results of the long campaign of the Smithsonian Institution on the variation of the sun, which was instituted by the late secretary, S. P. Langley. Thus far it has accomplished about 40,000 measurements of the solar constant of radiation, involving observations filling about 10,000 days, besides numerous and interesting side researches. A more detailed account of results is expected to appear in the April issue of the *Quarterly Journal of the Royal Meteorological Society*.

In 1903, by what now seems only a coincidence, a large drop occurred in our measurements at Washington of the solar constant of radiation, and simultaneously a considerable fall from mean temperature occurred generally over the north temperate zone. To test the possibility thus advanced that solar changes occur which govern weather, we began to make day-to-day observations of the solar constant at Mount Wilson Observatory in the year 1905. These continued during the summer and autumn months until 1920. The results, which treat of solar variation, of the transparency of the atmosphere, of the quantity of its precipitable water, of the coolness of sun-spots, of the brightness of the sky by day and by night, of the distribution of solar radiation in the different wave-lengths of the spectrum, of the distribution of radiation over the sun's disk, and which involved the invention of various instruments, including the silver-disk, water-stir, and water-flow pyrheliometers for measuring solar radiation in standard units, the pyranometer for measuring the brightness of the sky, the automatic recording balloon pyrheliometer, and others, are described in volumes 2, 3 and 4 of the *Annals of the Astrophysical Observatory* of the Smithsonian Institution. During these Mount Wilson years, I made expeditions to Mount Whitney, 14,500 ft. in altitude, and to Bassour, Algeria, to test whether similar results on the solar constant of radiation are found simultaneously at stations of different altitude and far separated. Also, in 1913 and 1914, automatic recording pyrheliometers were raised by sounding balloons. The most successful flight reached 25,000 metres, and brought back records which closely agreed with solar constant

values obtained at Mount Wilson and our other stations.

Up to 1919 our observations of the solar constant had all been made by the fundamental method of Langley. Briefly, it consists in measures of the intensity of sun rays at the station, supplemented by spectrobolometric determinations of the distribution of intensity in the solar spectrum. Both types of measurement were made simultaneously, and repeated about five times daily, beginning when the sun is not more than an hour high, and continuing until it approaches maximum elevation. After correcting for instrumental losses, the area included under the bolographic curve of the spectrum is corrected to be proportional to the pyrheliometer measurement of the total solar beam intensity. Then, by computation, each part of the spectral curve is raised to the intensity it would have outside the atmosphere. Then the area included under this computed extra-atmospheric curve, divided by the area of the corrected observed curve, is the multiplier to increase the pyrheliometer reading to what it would be outside the atmosphere. After reducing this to mean solar distance, we have the solar constant of radiation.

With the long computation involved, usually but one determination could be made by this method per day. Its accuracy, apart from instrumental and computing errors, depended on perfect uniformity of the transparency of the atmosphere for several hours. If the sky was clearing up, the result was too high; if growing hazy, the result was too low.

With these drawbacks, it is not remarkable that many meteorologists were not convinced that our results indicating solar variability were sound. They were inclined to think them merely accidental consequences of imperfect observation, or imperfectly uniform sky. Mr. H. H. Clayton, however, who has deserved specially well of meteorologists as editor of "World Weather Records", was at that time chief forecaster of the Argentine. He became convinced by Mount Wilson solar constant work, not only that the sun is really variable, but also that its variations are of first-rate consequence for meteorology.

To show the reasonableness of his views, I may remind readers that the accidental error of a mean diminishes with the square root of the number of observations. Mr. Clayton made use of this

principle. He collected all the solar constant values of the years 1913, 1914, 1915, and 1918, and placed them in six groups ranging from 1.89 to 2.01 calories, of which I abstract the highest and lowest as follows :

presence of volcanic dust, or some other unusual atmospheric condition might affect it, we have frequently checked its results by employing the fundamental method of Langley.

Now I come to state the outstanding results of

DEPARTURES FROM NORMAL TEMPERATURES (F.) AT BUENOS AIRES FOLLOWING DIFFERENT INTERVALS OF SOLAR RADIATION (MAY TO NOVEMBER)

Solar Constant (Cal. per min.)	Number of Days Observed	Days after Solar Observation															
		0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
2.00 $\pm$ 0.01	29	-2.2	-1.3	-0.9	-1.4	-1.3	-0.4	-0.4	+0.5	+2.7	+2.9	+3.6	+2.5	-0.2	+0.2	+0.4	+1.1
1.90 $\pm$ 0.01	30	+1.8	+1.8	+4.1	+2.3	-1.6	-1.8	-1.8	-2.7	-1.4	-0.9	-2.5	-0.9	+0.2	-0.5	+0.4	-0.5

The opposite trend of these values of temperature departures is obvious. Of sixteen pairs of values just given, the signs of twelve pairs are opposite. As the numbers of observations are so large, the accidental error of the mean values, approximately 2.00 and 1.90 calories, respectively, is only about one fifth as great as the average accidental error of the individual days. Hence the probability that we deal here actually with well-separated levels of solar radiation is strong. The marked opposition of the average marches of temperature departures, following the contrasted observing dates, certainly gives definite significance to these dates, and if it be not the variation of the sun, it is at least something of forecasting value.

These and other meteorological applications of Clayton's led us to wish to improve and render more continuous our solar constant programme. In 1918, therefore, we established a solar station at Calama in the nitrate desert of Chile, at a level of about 6,000 ft. From that time to the present we have endeavoured, so far as possible, to make one or more solar constant determinations on every fair day. While most of this work has been supported by the United States Government, large sums in aid have come from the income of the Hodgkins Fund of the Smithsonian Institution, from Mr. John A. Roebling, and from the National Geographic Society. At present we operate three observing stations: Monteruma, near Calama, Chile, altitude 9,000 ft.; Table Mountain, Southern California, altitude 7,500 ft.; Tyrone Station on Burro Mountain, New Mexico, altitude 8,000 ft.

In 1919 we noticed that the coefficients of atmospheric transmission for all wave-lengths of radiation could be empirically represented, to an excellent approximation, as specific functions of the brightness of the sky near the sun. This enabled us to multiply observations of the solar constant daily as the measurements were quickly made. Also, as the sky brightness could be almost instantaneously determined, the new method avoided errors due to changes in atmospheric transparency. In all recent years we have preferred this empirical 'new method', but fearing that

this long-continued daily recording of the intensity of the solar radiation. Solar variations are small but real. We may assign as the average amplitude for one combined rise and fall of the solar constant, 0.7 per cent. Such variations as this may be expected to occur about once in twenty days. That is, we may expect annually about twenty cases of rise and twenty cases of fall to give well-marked sequences of solar change averaging 0.7 per cent, and extending from three to six days during such a sequence. Rarely, however, solar changes of several times this amplitude may occur.

In order to set out the evidence quite clearly, I will refer to results published in a paper of mine three years ago. Having searched the record for the 12-year interval 1924-1935, I found 320 well-marked cases of solar change, about half of rise and half of fall. I divided these into monthly groups, so that there were about fourteen cases of each kind per month on the average. Some good months had as many as twenty, and only one test, that of falling radiation in February, was represented by less than ten dates.

For each of the 320 dates, I computed the departures from normal temperature at Washington and at three other cities for 16 days following the supposed solar change. Recalling that there were from ten to twenty cases of each kind for each month, it will be seen that by taking the mean results, I obtained fairly strong representations of the average march of departure from normal temperature which follows in each month of the year at Washington and at the other places, after a sequence of rise or of fall of solar radiation is observed to begin.

In every month these average marches of temperature departures showed opposite trends following, respectively, observed rise and observed fall of solar radiation. It would be more striking to show here a plot covering all months, but I content myself, in illustration, with giving merely the figures for October at Washington. Interested readers may plot them. The figures are adjusted to give zero average temperature departure after both rising and falling radiation, by adding

appropriate constants throughout to each of the lines of departures as originally computed. A third line gives the deviations which would be found if a curve representing 'falling' departures were folded over upon a curve representing 'rising' ones.

able conclusion than this. Solar changes exist, and are factors of prime importance governing day-to-day weather changes. Apparently if the sun's changes could be observed with accuracy from day to day, meteorologists would receive a new and important element, which might probably

THE AVERAGE TRENDS OF OCTOBER TEMPERATURE DEPARTURES (F.) FOLLOWING, FOR 16 DAYS RESPECTIVELY, RISING AND FALLING SOLAR RADIATION

Days after	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Rising	-1.0	-2.6	-3.0	-1.6	0.6	0.3	0.8	4.9	6.5	5.3	1.4	-0.7	-1.5	0.3	-1.4	-5.2	-3.7
Falling	2.2	1.9	1.2	-0.6	-0.7	1.9	-2.1	-4.6	-4.8	-3.8	-2.7	2.0	0.0	0.0	0.6	4.0	5.9
Folded discrepancy	+1.2	-0.7	-1.8	-2.2	+0.1	+2.2	-1.3	+0.3	+1.7	+1.5	-1.3	+1.3	-1.5	+0.3	-0.6	-1.2	+2.2

Number of signs of departures same for two groups 2

Range of departures following rising radiation " $6.5 - (-5.2) = +11.7$

Range of departures following falling radiation " $-4.6 - 5.9 = -10.5$

Arithmetical mean 'folded discrepancy' " ± 1.3

The range of temperature is so large that it is difficult to accept the conclusion that so great an effect is really caused by radiation changes of the order of 0.7 per cent. Hence I have tested the result in several ways. First, as shown in my paper, when comparing the earlier with the later years, the curves are very similar for the years 1924-30, as compared to the years 1931-35. Secondly, selecting 48 cases of unusually large change in the observed solar radiation, I found them followed on the average by temperature departures exhibiting features the same in phase, but of about twice the average amplitude, of those following usual observed solar changes. Thirdly, and most telling of all, I considered time next *preceding* each of the 320 selected dates. I computed for each of these cases the temperature departures of the *preceding* 16 days. Then I determined correlation coefficients between the march of temperatures for 16 days *preceding* and for 16 days *following* the cases of rising solar radiation and the cases of falling solar radiation. The result was highly significant, and is as follows:

Prior to solar change, $r = +11 \pm 6$ per cent.

After solar change, $r = -54 \pm 5$ per cent.

Thus there is no significant correlation of the trends of temperature for 16 days *preceding* rising and falling sequences of observed solar radiation, but *after* the solar change there is a negative correlation coefficient eleven times its probable error. Evidently the 320 dates were significant; but they were selected only because observation indicated that rise or fall in solar radiation began with them.

Similar results as regards opposition of trends and magnitude of their separations are found at each of the four temperature stations selected in different parts of the world. The effects are large, ranging from 10° to 20° F. I see no other reason-

enable them to predict details of weather for two weeks in advance. To attain the necessary accuracy and continuity of solar observation would require, I think, ten stations on high mountains in desert lands.

Long-range solar variations are also interesting. When we take monthly mean values, their accidental errors are reduced on the average by more than fourfold as compared with daily values, because from sixteen to twenty-five daily values enter into each monthly mean. Moreover, our three stations, separated by thousands of miles, agree fairly closely in their indications of the trend of solar variation over many years.

As we scan the curve of solar change since 1920, it appears to be irregular. But I have analysed it, searching for all the regular periodicities which it may contain. I have found twelve of them, ranging from 7 months to 274 months in length, and 274 months proves to be approximately the least common multiple of them all. In the case of half these periodicities, it was possible to derive them independently from two, or even three separate successive intervals, and to show satisfactorily that they persisted in approximately equal phases and amplitudes throughout the total interval of fifteen years. For the longer periods, exceeding thirty months, this check was not available. However, there was still evidence, by comparing individually several successive recurrences, that these longer supposed periodicities repeated in nearly the same phases and amplitudes.

On synthesizing these twelve periodicities, they retraced the observed trend of solar variation from 1920 to 1934 so exactly as to give an average monthly deviation from observation of only 0.2 per cent.

If, now, 274 months, or approximately 23 years, is really a master cycle in the sun, it may well be expected to reveal itself also in weather. It does

so. As noted by Wild, there is a 23-year periodicity in the temperature of that city which in his time was called St. Petersburg. Many other meteorologists have noted this cycle in other data. Hale found it in the magnetism of sunspots. The 11-year Wolf sunspot number cycles are of alternating unequal intensity. Tree-ring widths show it. It may even be discovered in the thicknesses of

92 years. These intervals correspond to double and quadruple the 23-year cycle. On this basis one may confidently predict, for example, that the great drought of the past ten years in the western United States is now broken, but will recur in considerable severity beginning 1975, and will recur with the excessive severity of the one just past beginning about 2021.

varves deposited by rivers and lakes in former geological ages.

For some stations, and notably for the precipitation, as at Nagpur in India, or at Peoria in Illinois, the principal secular features repeat themselves at intervals of 23 years so unmistakably in approximately equal phases and forms, that predictions based thereon covering years in advance are fairly well verified. More important is the recurrence of severe drought conditions at intervals of 46 years, and recurring still more severely every

In this connexion I will close by quoting from some correspondence of the past five years, illustrated by a graph showing the similarity of precipitation at Bismarck, North Dakota, in recent years, with that of 46 years before.

Under dates of January 1, 1934, January 1, 1935, March 14, 1936, February 6, 1937, and January 4, 1938, a farmer in South Dakota asked me to predict for him in each case a year in advance the trend of precipitation, and sometimes also of temperature. That area has suffered greatly from

drought in recent years. With strongly expressed cautionary statements as to the insecurity of such predictions, I have given him, year by year, the following indications.

1934: "There will be more precipitation in Minnesota and the Dakotas in 1934 than in 1933, but it will be in the latter half of 1934 that the relief will come."

1935: "One could hardly expect normal rainfall in South Dakota in 1935."

1936: "Precipitation far below normal, but with some improvement in the autumn. As regards temperature, the year 1936 followed almost exactly the pattern of temperature 46 years ago, i.e., 1890. If 1936 should follow 1890, it should show a very cold winter (as indeed has occurred), followed by normal temperature in spring and the early part of the summer."

1937: "A good precipitation in the spring or early summer of 1937, followed by a dry autumn and winter, recovery in the spring of 1938."

1938: "Normal precipitation during the first six months of 1938, with some (but not excessive) let-down for the remainder of the year, and for the first five months of 1939. Then a short dry spell in the middle of 1939, but precipitation normal or above normal after November 1939 for considerable time."

In January 1938, my correspondent said: "Because of the accuracy of your former predictions of weather conditions for the Dakotas, I am again soliciting your predictions for the coming season. I have much confidence in your ability to predict, therefore please do your best once more."

These forecasts were made by studying the departures from normal conditions at Bismarck, North Dakota, 46 years previously. How well they were fulfilled is to be estimated by examining the accompanying graph.

Use of Isotopes in Biology

THE discovery both of artificial radioactive elements and heavy non-radioactive isotopes, together with methods of concentration of the latter, has opened up new methods of examining the reactions and movements of substances in the body.

The isotopic indicator most frequently used in biological research is radioactive phosphorus (^{32}P) which may be prepared by the bombardment of carbon disulphide by neutrons from a radium-beryllium source. The sulphur atom takes up a neutron and gives out a proton, forming heavy, unstable, radioactive phosphorus (half-life period 14 days):

The phosphorus is then oxidized to phosphate. Stronger preparations may be obtained by bombarding red phosphorus with deuterium ions using a cyclotron:

For use, a small amount of the labelled sodium phosphate is added to ordinary sodium phosphate solution, and by this means the path of the phosphorus in the body can be traced. Estimations are carried out by observing the decay, at a given time, using a Geiger counter, and comparing directly with the decay of a similar standard at the same time, thus avoiding corrections for the rate of decay due to lapse of time. Thus if it is desired to determine the radioactive phosphorus content of the bone of an animal to which a labelled phosphate solution has been administered

(and hence determine any exchange in the phosphate of the bone), a known weight of bone ash from the animal is placed under the Geiger counter and the strength observed. This is compared directly with the same weight of calcium phosphate, precipitated together with the labelled phosphate from a known weight of solution. This method has placed an extremely delicate method of estimation in the hands of the experimenter and has the great advantage that it is not necessary to purify the substance carefully from non-radioactive elements.

Of the non-radioactive elements, deuterium (^2H) has been isolated in a state of purity; while heavy oxygen (^{18}O) and heavy nitrogen (^{15}N) have been concentrated sufficiently to make their use as indicators possible.

Heavy hydrogen and oxygen may be accurately estimated by conversion to water, and, after careful purification, determination of the density of the latter. Heavy nitrogen is determined by the mass-spectrograph. This method may also be used for the determination of heavy oxygen: it has the advantage that very careful purification is unnecessary.

It may be objected that the use of isotopes as indicators in the living body may disturb the normal conditions. Actually, the proportion of radioactive phosphorus which it is necessary to use is extremely small, and the radiation from it may be comparable with that from the potassium which is already present in the body, and on decaying it is converted to a sulphur atom. Heavy

non-radioactive isotopes are also already present in small proportions in the body, and the use of a slightly greater concentration as an indicator should not be objectionable. In the case of deuterium, it may be best to avoid the use of concentrated preparations.

A joint meeting of the Chemical Society and the Physiological Society on February 9 last took the form of a discussion on the use of isotopes in biology, which was opened by Prof. G. von Hevesy, of the Institute of Theoretical Physics, Copenhagen.

Among examples of the use of radioactive phosphorus, Prof. Hevesy described the results of experiments in which labelled sodium phosphate was injected intravenously; blood samples of known volume taken at intervals showed a very rapid decrease at first, followed by a slow decrease, in the labelled phosphate. This was found to be taken up by the bones and organs of the body, but chiefly by the former. It can be shown, by shaking up solid calcium phosphate with labelled phosphate solution, that there is a rapid exchange between the phosphate ions and the phosphate in the solid, the rate depending on the concentrations of the ions and the surface area of the solid. In the case of the body, the weight of the solid phosphate in the bones is very great compared with the inorganic phosphate in the blood, and most of the labelled phosphate will exchange with ordinary phosphate on the surface of the bones. As phosphate is lost by excretion through the kidneys and bowels, the uptake of labelled phosphate by the bones will cease, and finally, when the labelled phosphate in the blood is nearly removed, there will be a slow exchange of labelled phosphate back from the bones to the blood. Thus it may be possible to detect labelled phosphate several weeks after administration. Examination of the separate organs of the body enables the passage of the phosphate to be followed, and similarly examination of sections of bone shows that the rate of exchange of phosphate varies with different bones. In the case of growing bone such as the teeth of rats, the greater activity is found in the tooth formed after the addition of the labelled phosphate; the part formed before the addition, however, also shows some activity, indicating that exchange of phosphate takes place at the same time as new growth.

Phosphorus atoms in an organic molecule such as lecithin do not exchange with labelled sodium phosphate. Thus, if active lecithin is found, it indicates that the lecithin molecule has been synthesized after the administration of the labelled sodium phosphate (in the presence of suitable enzymes) and thus a distinction can be made between old and new molecules. This method may be used, for example, to find the place of

formation of the phosphatides in the yolk of hens' eggs. By killing a hen five hours after an injection of labelled phosphate, it was found that the liver and plasma phosphatide were very active (the former more than the latter) compared with that in the ovary and yolk; thus the phosphatide molecules formed during the last five hours do not originate in the ovary, but are taken by the ovary from the plasma and used in the building up of the yolk. It was also found that after the egg had left the ovary no labelled phosphatide was formed in it. This was shown by examination of labelled phosphate (the egg, after leaving the ovary, remains in the oviduct about 20 hours).

The use of radioactive sodium phosphate has also been of great help in a study of the formation of (goat) milk. Samples of blood and milk taken at intervals after administration of labelled phosphate were examined for the activity of the phosphate in the blood and the various phosphorus compounds in the milk. It was found that after three to four hours the milk inorganic phosphate was replaced by the active phosphate of the plasma; while if heavy water was injected at the same time as the active phosphate, after one hour water samples prepared from blood and milk had the same density, the difference in the rates being due to the fact that water molecules diffuse through the membranes at a greater rate than phosphate ions. From the rate at which the casein phosphorus becomes active, compared with the active inorganic phosphorus in the milk, it was estimated that the time of formation of casein in the gland cells was about one hour.

The fact that a few hours after addition of the labelled phosphate the milk phosphatides are only slightly active compared with the inorganic phosphate, indicates that the latter cannot be produced from the former, thus contradicting the view that the fats and inorganic phosphate are produced by the breaking up, in the milk gland, of the phosphatides of the blood. The investigation of problems of milk secretion was also referred to by Dr. S. K. Kon.

Labelled sodium phosphate has also been used in a study of the movements of phosphate in plants. Maize and sunflowers grown first in a culture solution were then transferred to a second solution containing labelled phosphate. The leaves which grew while the plant was in the second solution were examined for activity and compared with the leaves which grew in the first (inactive) solution. It was found that, after four days, the lower leaves had 80 per cent of the activity of the upper leaves, showing that a rapid replacement of phosphate took place. Similar experiments have been carried out using heavy nitrogen as indicator.

The use of deuterium as an indicator was discussed by Prof. H. S. Raper and Dr. W. E. van Heyningen. The former referred to the work of Cavanagh and Raper, in which fats labelled with deuterium were fed to animals and a study made of the rate of formation of the deuterium labelled lipins in the liver and kidney; the latter gave an account of the work of Schoenheimer and Rittenberg *et al.* on deuterium as an indicator in the study of intermediary metabolism, and referred especially to the uses and limitations of the method.

The use of heavy oxygen as an indicator was discussed by Dr. J. N. E. Day. He referred to the work of Aten and Hevesy, who examined the possibility of exchange of oxygen in sulphate, with other oxygen atoms present in the body, by injecting heavy sodium sulphate into rabbits, and concluded that there was little or no exchange. Reference was also made to the work of Day and Sheel on the use of heavy oxygen in animal

respiration, in which the heaviness of the expired carbon dioxide was determined.

Radioactive sodium was dealt with by Dr. B. G. Maegraith, who mentioned experiments in which active sodium chloride had been injected into rabbits, and the distribution of the active sodium investigated. He suggested that this might be used to estimate the extracellular fluid content of the rabbit.

Dr. W. D. Armstrong described experiments dealing with the exchange of phosphorus of the enamel of teeth and the blood using radioactive phosphorus. A very slow exchange was noticed, indicating, not the formation of new molecules, but exchange of phosphate between enamel and blood. Mr. C. H. Collie referred to work of Collie and Morgan showing that radioactive sulphur can be used as an indicator.

Dr. D. Roaf described a method of producing radioactive phosphorus by irradiation of trioresyl phosphate with slow neutrons.

Obituary Notices

Prof. Franz Werner

PROF. FRANZ WERNER'S death, which took place in Vienna on February 18 after a short illness at the age of seventy-two years, came as a shock to his numerous herpetological friends and colleagues the world over. Born in 1867, Franz obtained his doctorate at the University of Vienna in 1890 at the early age of twenty-three years, was appointed assistant in the First Zoological Institute of the University, later rising to be professor there, and had a distinguished record as a teacher until 1933, when he became emeritus professor. For more than fifty years, almost up to his death, he was zealously engaged in zoological researches, being in the foremost ranks of European herpetologists and a recipient of many honours. He was a corresponding member of the Vienna Academy of Sciences, an honorary doctor of the University of Athens, an honorary member of the American Society of Ichthyologists and Herpetologists, and a member of numerous other scientific societies.

Prof. Werner was a prolific writer, having more than a hundred papers, including some voluminous works, to his credit, the list including not only papers on Amphibia and Reptilia, in which he was principally interested, but also titles on Orthoptera and scorpions. Interested at first in morphological problems, he became more and more devoted to faunal exploration and herpetological taxonomy as the years went by. He undertook many travels for the sake of such study, and made valuable contributions to our knowledge of the fauna of Greece and the Aegean Islands (1902, 1912, 1927, 1930, 1933, 1935, 1936, 1937), Algeria and Morocco (1914, 1929, 1931), Asia Minor

(1902, 1903, 1905, 1929), Persia (1903, 1917, 1929, 1936), South and West Africa (1902, 1913, 1915), Anglo-Egyptian Sudan (1914, 1919, 1924), Guatemala (1903), the Andes (1916), China (1903, 1924), etc. His contributions on Chamaeleontidae (1911), Eublepharidae, Uroplatidae, Pygopodidae (1912) and Reptilia Loricata (1933) in "Das Tierreich"; on Amphibia and Reptilia in Brehm's "Tierleben" (1913); and on Amphibia (excluding Anura) in Kükenthal's "Handbuch der Zoologie" (1930-31) are models of deep learning and lucid expression, and will make him familiar to younger generations of herpetologists even when the charm of his personality is long forgotten.

He was a patient, enthusiastic and indefatigable worker for herpetology. B. C. MAHENDRA.

Dr. E. H. Hankin

THE death on March 29 of Ernest Hanbury Hankin at the age of seventy-four years removes one who in the early days of the development of bacteriology did much to forward its practical applications. The son of a clergyman, he was educated at Merchant Taylors' School, at University College, London, and at St. John's College, Cambridge, of which he was a scholar and later a fellow, obtaining the M.A. and Sc.D. degrees. He also studied at St. Bartholomew's Hospital for a time, but did not proceed to a medical qualification, and worked in Koch's laboratory in Berlin and in the Pasteur Institute, Paris. He then accepted an appointment as chemical examiner, analyst and bacteriologist to the North-West Provinces and Oudh, India, and spent his professional

life at Agra. Dr. Hankin's earlier researches before proceeding to India were mainly concerned with the germicidal action of proteins of blood-serum and of cells, so-called 'alexins', upon which he published several papers in the *Proceedings of the Royal Society*, *Journal of Pathology and Bacteriology* and *Centralblatt für Bakteriologie*.

In India, Hankin soon took up the study of cholera, isolated the cholera vibrio from contaminated well- and river-water, and so early as 1894 insisted that the disease was a microbial one and not a 'miasm'. He studied methods for destroying microbes, particularly the cholera vibrio, in the contaminated water of wells, first by means of excess of lime, and afterwards with permanganate of potash, and his method of "pinking" wells continued in use until the introduction of chlorination. In connexion with cholera, he noted that the waters of the Jumna and Ganges possessed a natural germicidal action upon the vibrio, which was not removed by filtration but was destroyed by boiling, but in spite of much work on the subject, he was unable to discover the nature of the germicidal agent. This was not elucidated until many years later through the work of Twort and of d'Hérelle upon the filterable lytic agent that destroys bacteria, the bacteriophage. Hankin also published several papers dealing with plague, the plague bacillus, and the relation of insects and rats to its spread.

Besides his bacteriological work, Dr. Hankin's other pursuits included observations upon the problems of flight, studied mathematically, experimentally with kites, and by observations on the flight of birds, which were embodied in a small work "Animal Flight". He also published "Methods of Design in Mahomedan Art", an analysis of geometric patterns, especially of those that adorn the Taj Mahal.

R. T. HEWLETT.

Prof. Ettore Pais

WE regret to record the death of Prof. Ettore Pais which took place recently in Rome at the age of eighty-three years. Prof. Pais was a historian of international reputation, widely known as one of the foremost authorities on the history, laws and customs of ancient Rome and the early history of the peoples of the Italian peninsula generally.

Ettore Pais was born in 1856 and educated at the University of Florence, afterwards studying under Mommsen in Berlin. His first appointment on his return to Italy was as curator of the museum at Cagliari. Afterwards he occupied the chair of ancient history in the University of Palermo. In 1906 he was appointed to the University of Rome, after holding professorial chairs at Pisa and Naples. In Rome the researches in archaeology and the early history of Roman rule, which he had initiated when in Sardinia, Sicily and southern Italy in his earlier years, came to full fruition. During his twenty-five years tenure of his chair, his lectures and writings on the epigraphy, antiquities and prehistory of Italy and on the history of Rome up to the Punic wars came to be recognized as of standard authority, more

especially for the insight displayed in his brilliant interpretations of the results of the excavations of Roman and Etruscan antiquities.

Among the honours which Pais received were honorary doctorates of the Universities of Oxford, Paris and Chicago, membership of the Institut de France, and in 1922 elevation to the rank of senator.

Miss Ella C. Sykes

WE regret to record the death of Miss Ella Constance Sykes, which took place in London on March 23. Miss Sykes, who was educated at Lady Margaret Hall, Oxford, had been secretary of the Royal Asiatic Society (1920-26), and was a member of the Royal Geographical and Central Asian Societies, at whose meetings she was well known as a traveller with first-hand and intimate knowledge of the land and peoples of Persia in the earlier years of the century. She accompanied her brother, Major (afterwards Brigadier-General Sir) Percy Molesworth Sykes, on journeys of geographical and archaeological interest, made when he was seconded from the British Army in India to the consular service and was Consul-General in Kerman. On one occasion she and her brother rode on horseback from the Caspian to India, and in 1915 they travelled together in Chinese Turkestan and the Pamirs. Her experiences in Persia were embodied in "Through Persia on a Side-saddle" and in "Persia and her People". She was also joint author with her brother of "Through Deserts and Oases of Central Asia". Miss Sykes visited Canada to investigate the question of the employment of educated women there on behalf of the Colonial Intelligence League. "A Home-Help in Canada" records her experiences.

WE regret to announce the following deaths:

Dr. J. Anderson, formerly lecturer in bee-keeping in the North of Scotland College of Agriculture, aged sixty-six years.

Prof. W. Cramp, professor of engineering in the University of Birmingham, on April 20, aged sixty-three years.

Mr. E. W. Fraser-Smith, secretary and treasurer of the North East Coast Institution of Engineers and Shipbuilders since 1911, on April 5.

Mr. H. J. George, University lecturer in chemistry in the University of Oxford, on April 19.

Prof. F. N. Guild, emeritus professor of geology and mineralogy in the University of Arizona, on March 12, aged sixty-eight years.

Captain H. M. S. Laidlaw, known for his work on hydrography and in re-surveying small islands in the South Seas, on April 16, aged fifty-two years.

The Rev. W. J. O'Leary, S.J., director of River-view Observatory since 1929, known for his work in seismology and astronomy, aged seventy years.

Sir William Ramsay, emeritus professor of humanity in the University of Aberdeen, formerly professor of classical archaeology and art in the University of Oxford, on April 20, aged eighty-eight years.

News and Views

Sale of Food and Drugs

THE annual report of the Ministry of Health for 1937-1938 contains some very interesting information relating to the results of the examination of samples of food and drugs by public analysts in England and Wales. In all, 151,370 samples of food and drugs were examined, and of these the surprisingly high number of 8,401 or 5 per cent were reported against. The distribution of the adulteration among the counties and towns is amusing, but the differences in sampling probably makes the comparison of the different areas inconclusive. Oxfordshire and West Suffolk lead the English counties with 24.2 and 25.8 per cent of adulterated samples respectively, and the city of Oxford does little to redeem this with 12.5 per cent, which is high among the boroughs. These figures may well be compared with 8.4 per cent in Cambridgeshire and 5.1 per cent in Cambridge itself. The metropolitan boroughs show a quite low rate of adulteration, the worst being Shoreditch, with 11.1 per cent.

Of the common foodstuffs, 7 per cent of the samples of milk were unsatisfactory, one even containing formaldehyde, an adulterant also found in two samples of cream. Some remarkable cheeses have been exposed for sale; one, a cooking cheese, consisted practically of crude casein and water, and others sold under fancy names were found to be made of fat not derived from milk at all! The unsatisfactory jams and marmalades showed among other things the presence of pieces of glass, and other samples were deficient in fruit or soluble solids. Many samples of canned fish were contaminated with lead or tin, and the latter metal was also found in tinned fruits, vegetables and soups. A number of samples of beer were found also to contain lead, but the most remarkable beverage was a 'non-alcoholic' raisin wine, which yielded 17 per cent of alcohol. The chief errors found in the drugs examined were of the nature of deficiencies, namely, tinctures of iodine without sufficient iodine or potassium iodide, and mercurial ointments without, in one instance, any mercury.

Exhibition of Archaeological Finds from Afghanistan

AN exhibition of antiquities of both archaeological and artistic interest from the Swat Valley and Afghanistan in the Indian Section of the Victoria and Albert Museum, South Kensington, opened on April 25. These antiquities are the material results of an archaeological expedition to the Swat Valley and Trans-Oxiana in 1938, which was supported by the Museum and the Royal Geographical Society, and was led by Mr. Evert Barger. An account of the expedition was given by Mr. Barger before the Royal Society of Arts on November 30 (see *NATURE*, 142, 1029, 1046; 1938). The object of the expedition,

as was then stated, was to study the development of the Græco-Buddhist art which flourished in these regions from the first century B.C. until the fifth century of our era. The importance of this investigation lies in the fact that it followed up the route by which Indian cultural influence penetrated to central Asia and eventually to China; but although the Swat Valley had been visited by Sir Aurel Stein in 1926 no excavations had been carried out previously. The finds now exhibited reveal a remarkable local hybrid culture, caused by the meeting of Græco-Roman and Indian influences. Especially notable are a large number of very fine carvings in grey schist, illustrating scenes in the life of Buddha. An outstanding specimen is a seated Buddha, of which the drapery and head-dress are markedly Greek. This came from Amaluk, a ruined monastery in the hills, 4,000 ft. above the valley. Another carving shows Buddha being asked to preach the law. Several small plaster heads of Buddhas and Bodhisattvas, and specimens of ironwork, including door-hinges and a monastery bell, come from Swat. In the region across the Oxus, the ancient Bactria, no excavations were made; but coins, seals and fragments of pottery, found on the sites of ancient cities, are shown. Little is known of the ceramics of this area. Three Hellenistic column bases of stone, seen and photographed at Kunduz, are the first Greek structural remains to be found in Afghanistan and constitute the expedition's most important discovery.

Cultural Contacts with India

It may be recalled that at the meeting of the Royal Society of Arts at which Mr. Barger described the results of his archaeological investigations of the evidences the spread of Indian cultural influence to the Oxus and beyond, when Lord Zetland, Secretary of State for India, was in the chair, attention was directed in the discussion which followed to the importance of the study in Britain of the culture and archaeology of India as an influence making for closer contact between Great Britain and India. Lord Zetland, when presiding at the twenty-ninth annual meeting of the India Society at Burlington House on April 24, took advantage of the occasion again to emphasize the importance of such cultural contacts. Pointing out that politics was not the only link between Great Britain and India, he referred to the invitation which he himself had tendered to Sir Leonard Woolley, when Lord Linlithgow, as Viceroy, had intimated that he would welcome the visit to India of an archaeologist of world-wide distinction. This intimation was evidence of the interest taken by the Viceroy in the archaeological problems of India. In the result Sir Leonard Woolley had produced a report of the highest interest, which contained suggestions for the future work of the Archaeological Department. Lord Zetland went on to say that

although we were living in times of financial stress, when it was impossible to devote as much money as could be wished to work of this character, he was not without hope that the outcome of Sir Leonard's visit would be greatly to the advantage of the cause of Indian archaeological exploration and research. His concluding remarks were especially noteworthy: "As a people", he said, "we should surely stand condemned if, when judgment was passed on us at the bar of history, it should be said of us that we had neglected in our long contact with India those cultural values, which alone raised man above the level of the animal world and were an index of his achievement in the domain of the spirit."

Neanderthal Man in Central Asia

AN announcement of a discovery in the Uzbek republic of the U.S.S.R. of very considerable interest is announced by the Russia To-day Press Service. The skeleton and other traces of man of palaeolithic age have been found in a cave some twelve miles north-west of the town of Baisun. Stone implements found on the site are said to fix the date of the stratum, in which the discovery was made, as late Mousterian. Prof. Gerasimov, the well-known Russian archaeologist, has succeeded in restoring the skull, and a commission has been appointed, which will make a special study of the reconstructed relic. These remains are the first indisputable signs of palaeolithic man to be found in central Asia, and previously no traces of the Mousterian culture had been known to occur there. The skull, it is stated, was found lying under a single stratum, close to the wall of the cave, while the remainder of the skeleton lay scattered beside it. The remains are those of a child of about eight years of age; and as it is in a fair state of preservation, it is possible to decide that it differs markedly in structure from the human skeleton of to-day. The contour of the skull, particularly, is said to recall that of the anthropoid ape—a statement which, at first sight, seems to conflict with the further comment that it is said to refute the racial theory that present-day man developed independently of Neanderthal man. The trend of recent discovery, it may be pointed out, would certainly not necessarily be widely at variance with modernistic tendencies in a skull of such a facies, but until further details are to hand judgment one way or the other is obviously premature.

Introduction of Screw Propulsion

At a meeting of the Newcomen Society held at the Science Museum on April 19, in a paper entitled "The First Twenty Years of Screw Propulsion 1838-58", Engineer Captain E. C. Smith gave some interesting information regarding the early inventors of screw propellers, Sir Francis Pettit Smith, John Ericsson, George Lowe, George Blaxland and Bennet Woodcroft, whose names were most closely associated in the minds of their contemporaries with the early trials of sea-going screw-driven vessels and the adoption of the screw-propeller on a wide scale. It was appropriate, Capt. Smith said, that the subject

should be dealt with at a meeting at the Science Museum, for Bennet Woodcroft was the virtual founder of that institution, while Smith was for some fourteen years the curator under Woodcroft. Both these pioneers were buried in Brompton Cemetery, and their tombstones mention their participation in the introduction of the screw. Ericsson's work began with his patent of July 1836, the building of the little *Francois B. Ogden* and then the slightly larger *Robert F. Stockton*. Soon after the trials of the latter in the Thames in 1839, she was sailed to America; Ericsson soon followed her and it was in the United States that his main work in connexion with screw propulsion was done, his most notable vessel being the U.S.S. *Princeton*, built in 1841-43. She was the first screw-driven warship ever launched. By 1850, about a hundred and fifty American vessels had been fitted with the screw. The most important work in England was done by Smith, but of this Capt. Smith is to deal with in a future paper. In an appendix to the paper prepared by Dr. H. W. Dickinson, Mr. A. A. Gomme and Mr. E. W. White, a review was given of the various law cases which arose out of the patents and over which a vast amount of time, energy and money were wasted.

Acquisitions at the British Museum (Natural History)

THE trustees of the Museum have purchased for the Department of Geology the terminal section of a tail-sheath of an extinct giant armadillo (*Hoplophorus* sp.) discovered in the Pleistocene deposits of Santa Fé, Argentine. The giant armadillos had a solid bony shell and armour of the same type on the head and tail. When danger threatened, they withdrew their limbs into the shell, closed the head end by means of the bony casque, and lashed the club-like tail from side to side so as to ward off attack from the rear. Some genera had massive horny spikes on the end of the tail, but in *Hoplophorus* the tail was covered with scales. The Department of Mineralogy has acquired a superb specimen of cheerylite from Tsumeb in South-West Africa, and an extremely beautiful specimen with bright yellow plates of wulfenite (lead molybdate) on a glistening white ground of calcite crystals from Arizona. The Department has also purchased from the widow of the late Dr. A. E. H. Tutton a collection of the salts, chiefly double sulphates and selenates of the alkalis (potassium, rubidium, caesium, etc.), utilized by Dr. Tutton in his researches on the relation between physical properties and chemical composition in isomorphous series of compounds. An important addition to the departmental library is a first edition of the "Speculum Lapidum" by Camillus Leonardus, physician to Caesar Borgia, to whom the book is dedicated. It is a fine example of the printing press of Sessa in Venice. The book was one of the most widely read 'lapidaries' of the time, and its editions ran from the first in Latin in 1502 (forty-four years before Agricola's "De Natura Fossilium") to an English edition in 1750, bridging the gap between medieval and modern mineralogy. The late Frederick Adams of Jersey has bequeathed to the Department

of Botany a collection of 23,000 microscope slides of diatoms, together with catalogues, books and pamphlets, and the microscope with which he worked. For many years past Mr. Adams acquired whatever diatom collections came on the market, and thus accumulated the largest collection in private hands.

British Museum Excavations in Northern Syria

SOME further details of finds of the British Museum archaeological expeditions to northern Syria under Sir Leonard Woolley and Mr. M. E. L. Mallowan in 1938 are given in the official summaries (*Brit. Museum Quarterly*, 13, 1; 1939). The most important objects found within the palace at Atchana, in the opinion of Sir Leonard Woolley, are the clay tablets inscribed in cuneiform in the Akkadian language, from which it has been possible to learn not only the name of the place—Alalakh—but also the names of several of its rulers. One of these was contemporary with Saushtatar, a king of Mitanni, already known as a leading potentate in western Asia in the middle of the fifteenth century B.C. Among the small objects the most interesting is a steatite roundel engraved on both surfaces with formal patterns surrounding a middle ring, which encloses characters of the Hittite hieroglyphic writing. At Tall Brak Mr. Mallowan found the great palace to be a building of Naram Sin of Agade, bricks being stamped with his name, and tablets being found of the Agade period of about 2500 B.C. The south-west corner of the palace proved to be built over the ruins of a great mud-brick tower, probably part of a temple, belonging to the Ismet Nisar period, more than five hundred years earlier. It rested on a clay platform, under which was buried a great number of votive objects. Most of them were in underground chambers, which had been visited by robbers in antiquity. Apart from a large collection of beads, there were many amulets of two principal kinds, the first being stamp seals in the form of animals, or animal heads, and secondly little stone 'idols' found in large numbers, which though classed as amulets, are of unknown significance. They vary little in style; but some show as many as three pairs of eyes side by side, while one or two seem to portray mother and child. Many sherds of prehistoric painted ware were found, especially of the Tell Halaf style.

Recent Earthquakes

AN earthquake giving rise to large amplitudes on seismograms is reported by European observatories to have taken place on April 18, the initial waves being received about 6h. 36m. G.C.T. and the tremors lasting about three hours. The shock was well recorded at Stonyhurst, near Blackburn; at Kew, where it was received at 36m. 22s.; at Uccle, where it was received at 36m. 31s.; and at Zurich, where it was received at 36m. 18s. A very prominent feature of the seismograms at the latter three observatories was the *S_pP_sS* or *SKS* wave, which is a pulse starting at the epicentre as a transverse wave, being transformed at the earth's core to a longitudinal wave, continuing thus to the other side of the core

where it is again changed back to a transverse wave. It is received as a transverse wave at the observatory. The epicentral distance of the shock from Uccle is calculated from the arrival times of the various pulses to be approximately 105°, which is consonant with an epicentre in Chile, though the azimuth has been difficult to determine, and confirmation or otherwise is awaited from the American observatories.

Two earth tremors are reported from Barbados to have been felt about 1.45 p.m. on April 20. At St. Kitts, several shocks were felt, though no damage is reported from the vicinity of either area. Tremors in the West Indies are by no means uncommon, and it will be recalled that the earthquake swarm which occurred in 1934 and 1935 in Montserrat led to the dispatch of an expedition to that island, and to consequent valuable reports by Mr. A. G. Macgregor and Dr. C. F. Powell. In September 1938 the Wiechert seismograph and eight Jagger shock recorders set up at the time of the expedition were still in operation on the island under the care of Mr. Kelsick. Then from August until November 1937 about forty shocks were reported from Dominica. The Royal Society afterwards nominated a West Indies Seismological Committee, which contemplated sending an expedition to this latter island. The shocks, however, diminished in frequency, and it is now wondered whether or not the centre of seismic activity in the islands has again changed.

Long-Distance Automatic Telephony

AS improvements were made in manually operated switchboards, the trend of telephony has always been to substitute automatic devices for human labour. So much progress was made in this direction that it soon became obvious that even in large cities it would be possible to eliminate almost all the operators by the substitution of electrically controlled machinery. In the *Revue Générale de l'Electricité* of March 11, M. R. Dreyfus discusses the prospects of long-distance automatic telephony and points out that in small countries like Switzerland and Holland automatic inter-urban working is already in process of realization. It has now been developed to the extent of eliminating the operator at the exchange of the subscriber initiating a trunk call. By simply using his dial the subscriber puts himself in touch with any other subscriber in the same country. M. Dreyfus thinks it quite likely that automatic operation will now be developed for international calls. The International Consulting Committee for Long Distance Telephone Communication (the C.C.I.T.), which was formed by international delegates at a conference in Paris in 1923, has now taken up the problem. It is stated that within a few years a subscriber in Paris will be able merely by dialling to put himself through to a subscriber in New York.

Factory Lighting

THE spinning and twisting of real silk threads for the hosiery and silk weaving trade involves the processing of threads as small as two-thousandths of an

inch in diameter. The throwsters, that is, the operators who twist silk fibres into raw silk or raw silk into thread, find that they can work much better and much more quickly when the threads are brilliantly illuminated by the light from electric discharge lamps. To avoid eye strain, the Factories Act which came into force in July 1938 has emphasized the necessity for adequate lighting in such cases. We learn from an article on factory lighting which appeared in the *Electrician* of March 24, that G. H. Heath and Co. of Macclesfield and an associated company, British Crepe, Ltd., said to be the largest firm of silk throwsters in Great Britain, after experimenting with many kinds of lighting, have recently adopted as standard throughout their factories the electric discharge lamps made by Siemens Electric Lamps and Supplies, Ltd., with very successful results. In one case a room at the factory was lighted by discharge lamps consuming a total of 4.7 kw. and giving approximately 13-15 foot candles, whereas with gas-filled electric lamps the same room would have required 14.5 kw., that is, more than three times as much, and would only have given a lighting intensity of 7-8 foot candles. The sizes of the Siemens "QH" lamps installed are 80 w. and 125 w., according to the size and height of the rooms. The economy effected in running costs is very noticeable.

Compulsory Illumination in Factories

In a special leaflet (Form 282) dated March 1939, the Factory Department of the Home Office reminds the owners of factories that the Departmental Committee appointed to deal with the subject has issued its fourth report (H.M. Stationery Office. 1s. 1d.) It recommends certain minimum standards of illumination below which work in factories should not be done regularly, and further recommends that these standards should be made legally compulsory next July. Tables of lighting practice suitable for many industrial processes can be obtained from the Illuminating Engineering Society, 32 Victoria Street, S.W.1. Another similar table is issued by the Electric Lamp Manufacturers Association, at Savoy Hill, W.C.1. The Secretary of State directs attention to a memorandum of the Air Raid Precautions Department, dealing with a general scheme of lighting restrictions to be enforced in the event of war. Occupiers of factories are recommended to obtain and study this memorandum, but naturally it deals more particularly with the screening of windows and roof lights in order to prevent the emission of light from buildings. It is in no way inconsistent with the requirement of adequate and suitable lighting within the building. Information and advice on general lines are usually obtainable from the gas or electricity undertaking supplying the factory.

Progress in Horticultural Science

VOL. 7 of *Scientific Horticulture*, the journal of the Horticultural Education Association (from the Hon. Editor, Mr. R. T. Pearl, S.E. Agric. Coll., Wye, Kent. 4s. net.; 4s. 6d. by post, February 1939)

contains a well-balanced collection of papers for gardeners, both practical and professional. There are papers upon commercial horticulture in Eire, Devon, Lancashire and Bedfordshire, and articles upon the practical control of slugs by the use of 'Meta fuel', by S. G. Jary, and the horticultural work of the Land Settlement Association, by H. Fairbank. Messrs. H. G. H. Kearns and H. Martin contribute an account of the physical properties and practical use of combined insecticidal and fungicidal washes for use upon expanded blossom and foliage. They conclude that oil emulsions afford the most promising basis for combined direct and protective sprays, and practical instructions are given for their use upon various tree fruits and soft fruits. Interesting possibilities of the controlled nutrition of horticultural crops by growth in nutrient solutions are envisaged by Messrs. S. R. Mullard and R. H. Stoughton. Though the huge increases in yield claimed for the method in California were not realized in England, growth of gladioli was superior to that from soil-grown corms. Lela V. Barton summarizes the work of the Boyce-Thompson Institute, New York, upon germination and dormancy in seeds. Effective pre-treatments for dormant seeds and for the after-ripening of certain species, are condensed into three tables of great practical utility. Epicoity dormancy, where the radicle begins growth but not the plumule, can be broken by keeping rooted seeds at a cool temperature, usually between 40° and 50° F. for a few weeks. A series of papers by members of the staff of the East Malling Research Station, or the occasion of the Association's annual conference in September 1938, is also included in the volume.

Radio Meteorology in the United States

THE growth of aviation has resulted in an urgent and intensive demand for accurate weather forecasting not only at ground-level but also at all heights now utilized by aircraft. Methods previously employed for determining aerological data in the atmosphere have utilized kites, sounding balloons or aeroplanes to carry special instruments recording the temperature, pressure and humidity at various altitudes. A mimeographed report entitled "The Radio-Telemeter and its Importance to Aviation", by R. W. Knight has recently been circulated by the U.S. Civil Aeronautics Authority. This report discusses the general problem of determining aerological data by radio sounding balloons, to which are attached transmitters emitting signals carrying the indications of the meteorological instruments. A somewhat detailed description is then given of the apparatus developed for this purpose by the Blue Hill Observatory of Harvard University. Illustrations are given of the complete radio transmitter, with the associated instruments for determining temperature, pressure and humidity. At the ground station, the signals are received on a simple pen-writing recorder, from which the aerological information can be observed while the balloon flight is in progress. A specimen record indicates that heights up to 72,000 ft. (14 miles) can be obtained by this type of apparatus. The U.S.

authorities maintain a network of teletypewriter communication facilities for disseminating the weather data to other meteorological stations, while radio broadcasting is used for the benefit of airmen. Plans are in hand for extending to other parts of the United States this application of radio methods to aerological observations.

Value of an Auxiliary Language

A PAPER by M. Talmey on the auxiliary language question, in which the value of an auxiliary language as an agency for world peace is discussed, has been reprinted from the *Modern Language Journal* of December 1938. Dr. Talmey discusses the basic requirements of an auxiliary language, particularly the importance of being more expressive than the natural languages and strictly neutral. It must also be as suitable for the expression of all ideas as the most efficient natural languages are. He discusses the development of Esperanto in the United States and the reasons for its failure, and then describes the origin and development of a new international system known as 'Arulo' or 'Gloro', which aims at removing the ambiguity which characterizes most modern languages. In this system the main parts of speech are recognisable by characteristic endings, of which there are eighteen, six occurring very rarely. He suggests that the fitness of a language for translation is the best criterion of its efficiency.

The School Health Services

A BOOKLET entitled "The School Health Services: their Initiation, Growth and Character" has been issued by the National Union of Teachers, Hamilton House, Mabledon Place, London, W.C.1. It is a review by the Union designed to show how the school health services came into being, how they have developed, and what part the National Union has taken in their initiation, conduct and progress. Provision of meals, medical and dental inspection and treatment, physical education and school camps are some of the subjects dealt with, and finally recommendations are put forward which it is considered would improve the services. The memorandum is primarily intended for the information of members of the Union, but has been issued to the public in the hope that it may prove of use to those concerned with the health and fitness of the children of the nation.

Oxford Science

THE second quarterly issue of this publication maintains the high standard and interest of the first number. There are two articles on the teaching of chemistry at Oxford, one by an undergraduate, the other by Dr. J. H. Wolfenden, the former deliberately critical and even fault-finding, the latter an admirable exposition and defence of the unique system of training that has been in force at Oxford during the past seventeen years. The possibilities of science as an education are discussed by Dr. J. Z. Young. He advocates means of making scientific courses more

valuable as a part of general education so that whoever takes them may in some sense be educated and not, as too often at present, merely filled with plain facts. There are two articles on popular lines. Dr. A. H. Cooke of the Clarendon Laboratory gives a short account of the technique used there in attaining low temperatures and discusses briefly the more important results that have been obtained; Prof. J. H. Burn discusses the phrase 'suffering from blood-pressure' in a paper which will be read with interest by all and with relief by some. In "Correspondence" the Nuffield professor of clinical medicine criticizes some of the suggestions about the medical curriculum made by one of the medical tutors in an article in the first issue. There are also reviews of scientific books and short accounts of the activities of the scientific and medical undergraduate societies.

History of Cholera in Poland

In his inaugural thesis (*Thèse de Paris*, 1938, No. 739) Dr. Kac Hirs, a native of Warsaw, gives an interesting account of the history of cholera in his country, in which there were six epidemics of the disease between 1831 and 1902, the last of which persisted until 1915. The study of cholera epidemics in Poland as in the rest of Europe shows that they start in the East and then follow as a rule one of two routes, namely, (1) by land, passing through Astrakhan and Russia, or (2) by sea, when they are conveyed by pilgrims coming from Mecca who had landed at Odessa. Since the first epidemic in 1831 all the countries in Western Europe have taken a lively interest in the behaviour of cholera in Poland and have actively collaborated with the Government of that country in a campaign against the disease.

Progress in Photochemistry

THE third report of the Committee on Photochemistry (Reprint and Circular Series of the National Research Council, No. 108, July 1938) contains eleven review articles dealing with various aspects of recent photochemical research written by seven different authors. Each is provided with a bibliography. There is a long table of quantum yields which gives a very useful review of this part of the subject. The report strikes a good balance between theory and experimental methods.

Large Sunspots

Two new large groups of sunspots have recently appeared. Particulars from the Royal Observatory, Greenwich, are as follows, the areas being measured on April 21 and expressed in millionths of the sun's visible hemisphere.

Date on Disk	Central Meridian		
	Passage U.T.	Latitude	Area
April 20-May 2	April 20.1	27° N.	1060
April 20-May 2	April 20.6	16° S.	1350

Chromospheric activity in the region of the first group was noted on April 21, an extensive bright eruption beginning at 9^h 3^m and lasting for about half an hour.

The Night Sky in May

THE duration of night (sunset to sunrise) on May 1 in the latitude of London is 9.3 hours, decreasing to 7.8 by June 1. The moon is full on May 3 at 15.3^h, and new on May 19 at 4.4^h. A total eclipse of the moon, invisible from Great Britain, occurs on May 3. On May 5, the bright star β Scorpii (mag. 2.9) is occulted by the moon, the disappearance as seen from Greenwich taking place at 3^h 34.5^m at position angle 164° from the north point. Lunar conjunctions with the planets occur as follows: on May 9^d 10^h with Mars; on May 14^d 23^h with Jupiter; on May 16^d 21^h with both Venus and Saturn; on May 17^d 14^h with Mercury. Venus, Jupiter and Saturn are morning stars. Mars rises about an hour after midnight at the beginning of the month and just before midnight at the end. Mercury is not visible either as a morning or evening star. On May 12 at about 3^h 45^m it is worth looking at Jupiter when satellites I, II and IV present a curious arrangement on the east side of the planet. A corrected ephemeris for Comet Pons Winnecke (1939 c) is given in I.A.U. Circular No. 758. On May 17, the ephemeris places the comet 6° greater in declination than the star β Boötis. No ephemeris is available here for the bright comet, Comet Haase, discovered on April 18 in the constellation of Andromeda. Solar activity is sufficiently high to warrant a look-out to be kept for auroras. (All times are given in Universal Time; add 1^h to convert to Summer Time.)

Announcements

THE first superintendent of the new Engineering Research Establishment in Australia (see p. 697) is Mr. L. P. Coombes, formerly senior scientific assistant of the Royal Aircraft Establishment, Farnborough, where he was in charge of the aeroplane experimental tank.

PROF. GUSTAVE ROUSSY, professor of pathological anatomy in the University of Paris, has been elected a free academician of the Paris Academy of Sciences in succession to the late Paul Halbrönnner.

THE Makdougall-Brisbane Prize of the Royal Society of Edinburgh for the period 1934-1938 has been awarded to Prof. D. M. S. Watson, for his paper published in the *Transactions* of the Society, within the period, entitled "On *Rhamphodopsis*, a Ptyctodont from the Middle Old Red Sandstone of Scotland", and for his many distinguished contributions to the science of vertebrate paleontology.

THE International Congress of the Latin Federation of Eugenics will be held at Bucharest next September under the presidency of Prof. C. Parhon, when the subjects for discussion, among others, will be: (1) prophylaxis of hereditary diseases, (2) heredity and liability to infections, (3) inheritance of intellectual aptitudes, and (4) heredity and endocrinology.

THE annual Congress of the Royal Institute of Public Health and Hygiene will be held at Hastings

on May 23-27 under the presidency of the Right Hon. Walter Elliot, Minister of Health. The Congress will consist of five sections, in which the following subjects will be discussed: Section I, State medicine and industrial hygiene; Section II, women and children and the public health; Section III, tuberculosis; Section IV, rheumatism and allied diseases; Section V, nutrition and physical education.

FARMERS and all interested in agriculture in its practical, technical, or educational aspects are invited to visit the Rothamsted and Woburn plots at any convenient time between the beginning of May and the end of October. Mr. H. V. Garner and Capt. E. H. Gregory will be in charge of the demonstrations. There is ample material at each farm to occupy a full day, and therefore visitors should arrange to see them on separate days. The director, Sir John Russell, will be happy to arrange full details with organizations of farmers, farm workers and others wishing to accept this invitation; small groups of farmers are specially welcomed. Further information can be obtained from the Secretary, Rothamsted Experimental Station, Harpenden.

A NATIONAL conference on Maternity and Child Welfare will be held at the British Medical Association House, Tavistock Square, W.C.1, on June 27-29 under the presidency of Mr. Walter Elliott, the Minister of Health, when the following subjects will be discussed: safety in childbirth for mother and child; encouragement of breast-feeding; the nursery school, nursery class and the day nursery; the child in relation to foster mother and the daily minder; parents with a physically defective child, and propaganda on the maternity and child welfare movement. Further information can be obtained from the Secretary, National Association of Maternity and Child Welfare Centres, Carnegie House, Piccadilly, W.1.

WE have received an annotated catalogue of works on chemistry, pure and applied, No. 857, from Messrs. Henry Sotherton, Ltd., 2-5 Sackville Street, London, W.1. This contains a large number of interesting items, and in most cases each work has a note of bibliographical, biographical or scientific interest. The catalogue is one of considerable interest and is valuable for the large amount of accurate information it contains.

RECENT statistics show that infantile mortality in Germany, though continually falling, is greater than that in some other countries including the United States.

WE regret that in the issue of NATURE of February 25, p. 329, it was stated incorrectly that Prof. Helmuth Scheel had been appointed president and Prof. Theodor Vahlen vice-president of the Prussian Academy of Sciences; Prof. Vahlen has been appointed president and Prof. Heymann vice-president, with Prof. Scheel as director of the Academy.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 727.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Surface Transport in Liquid Helium II

IN our previous communications¹ on the 'transfer' of liquid helium II by a surface film above the liquid level, we stressed the similarity of this 'transfer' with the so-called transport phenomena in the free liquid, and suggested that the latter might be due to a process similar to the transfer above the liquid level. Later experiments on the formation of this film² seemed further to strengthen the conception that there existed a similar surface transport below the liquid level, and we have recently made two observations which seem to corroborate this hypothesis:

(a) A small Dewar vessel (see Fig. 1) containing a heating coil was suspended by a thread in a bath of liquid helium II. When no heat was supplied, the levels of the liquid both inside and outside the vessel adjusted themselves to the same height L_1 , owing to the 'transfer' through the film on the interconnecting glass surface. When, however, a current was passed through the heating coil, the level of the liquid inside the vessel rose above the outside level and took up an equilibrium position L_2 . By increasing the connecting surface between the vessel and bath by a number of wires, differences between inside and outside levels up to 5 mm. could be obtained. This clearly shows that there exists a 'transfer' of helium from a colder to a hotter place when a temperature

Fig. 1.

Fig. 2.

gradient is imposed. On further increasing the heat supplied, however, the evaporation from the vessel became the predominant factor and the inside level fell below that of the bath.

This effect is quite analogous to the 'fountain phenomenon' in the bulk liquid, discovered by Allen and Jones³. However, in the present case the transfer of liquid must be carried out through the surface film above the liquid level, which shows that there exists a flow of helium against a temperature gradient, even if the two containers are not connected by free liquid. One may conclude therefore that the 'fountain phenomenon' in the bulk liquid is probably also due to a surface transfer, though in this case along the surface below the liquid level. This hypothesis is further strengthened by the fact that the 'fountain phenomenon' is more pronounced when tubes containing fine powder are used to connect the two volumes of liquid rather than a straight capillary, for which the available surface is comparatively small⁴.

(b) A Dewar vessel (see Fig. 2) was closed at the top and had a hole at the lower end which was constricted by a plug, *P*, of fine emery powder. It contained a phosphor-bronze thermometer, *T*, and was suspended in a bath of liquid helium II. When the Dewar vessel was lifted out of the bath, the liquid ran rapidly out of the vessel through *P* and fell into the bath, and at the same time the temperature of the inside liquid was noticed to rise by about 0.01° . On lowering the vessel so that now liquid ran from the bath into the vessel, the liquid inside was cooled by a similar amount.

This mechano-caloric effect is evidently the reverse of the 'fountain phenomenon', for whereas the latter means that the setting up of a temperature difference results in a flow of liquid helium II, the mechano-caloric effect shows that a flow of liquid helium II is accompanied by a development of heat (or cold). Such a caloric effect has actually been postulated by Tissa⁵ for a flow of liquid helium II through capillaries. It seems to us, however, that the anomalous phenomena of liquid helium II are not so much caused by capillary flow as by a transport along solid surfaces; and these results seem to indicate that the heat content of those atoms transported by surface flow must be lower than average. The hypothesis that the transport phenomena in the bulk liquid are due (at least primarily) to a surface transport similar to the 'transfer' above the liquid level seems also to agree with observations by Allen and Misener⁶ and H. London⁷, as well as with theoretical considerations of F. London⁸.

A more detailed discussion of this tentative explanation with regard to these and other results will be given elsewhere.

A New Refraction Method for Obtaining Photographic Records of Concentration Gradients

WHEN a concentration gradient in a vertical column of solution, for example, an ultracentrifuge cell, is investigated by a refraction method, it is desirable to obtain a diagram relating the refractive index gradient with height in the column of solution. The two data, the height and the corresponding gradient, are in the different methods registered along the same vertical axis or along one vertical and one horizontal axis.

Using the scale method described by Lamm¹, which at the present time is far the most accurate procedure, we get the two data registered along the same vertical axis. This makes it necessary to compute the scale photographs before the shape of the curve and the exact positions of the maxima can be obtained. In the Toepler *Schlieren* method², where the two data are still registered along the same vertical axis, we can measure the positions of

the maxima directly on the plate, but only a rough estimation of the shape of the curve is possible. The method worked out by Philpot³ gives the height along a vertical axis and the gradient along a horizontal axis. The curve is in this case obtained as the boundary between dark and white on the plate. The shape of the curve may be seen directly on the plate, and the position of the maxima can be measured in a comparator. The method to be described in this communication gives the height along the horizontal axis and the gradient along the vertical axis. On the plate the curve appears as a rather narrow dark line (Fig. 1).

Fig. 1.

PHOTOGRAPHIC RECORD OF SEDIMENTATION IN DILUTE HORSE SERUM SHOWING THE ALBUMIN AND THE MAIN GLOBULIN COMPONENT.

Centrifugal force, 350,000 times gravity; time after reaching full speed, 50 min. Reference points and their distance (cm.) from axis of rotation are at foot of record.

Optical arrangements (Fig. 2). The light from a automobile head-lamp bulb with horizontal filament *A*, passes through a spherical lens, *B*, placed at its focal distance from the lamp, and a cylindrical lens *C*, with vertical axis, which concentrates the light on the centrifuge cell, *F*. *E* is a slit inclined at an angle to the vertical axis. The projection of the different points of the slit on a horizontal axis is focused on the photographic plate, *I*, by means of the cylindrical lens with vertical axis, *G*, and the spherical lens, *H*. Vertically the lens *H* still focuses the lamp *A* on to *I*. Conjugate foci are marked *a*, *a'* or *b*, *b'*.

If there is no deviation of light in the centrifuge cell, a horizontal straight line, *OX*, is obtained on the plate. The length, *X*, of this line corresponds to the cell-height, *h*, and the angle, θ , in the following manner:

$$X = h.m.\tan \theta, \quad (1)$$

where *m* is an enlarging factor equal to the ratio between the focal distances of the lenses *H* and *G*.

If light is deviated by an angle δ (Fig. 2) at certain height in the cell, the corresponding point of the line *OX* is displaced a distance *Z*, proportional to δ and the focal distance *f* of the lens *H*. We thus obtain the equation:

$$Z = f.\delta \quad (2)$$

The angle δ depends upon several conditions; for example, cell deformation, compression of the liquid sedimentation of low-molecular and high-molecular substances. In order to obtain the effect caused by the sedimentation of the high-molecular substance under investigation, two similar runs are made: the reference run, with pure solvent in the cell, as well

as the normal run. A diagram with the differences, Z_2 , between every two corresponding Z_1 -values as ordinate and the position in the cell as abscissa gives the desired curve. Z_2 , according to Lamm¹, is related to the cell thickness, a , and the refractive index gradient, dn/dx , as follows:

$$Z_2 = a \cdot f \cdot dn/dx \quad (3)$$

As the slit angle θ does not enter into equation 3, it is possible to alter the sensitivity by changing θ . When there is a small gradient, θ is also reduced and the ratio between ordinate and abscissa scales becomes larger. For a large gradient the image is made as broad as possible by making θ large.

Fig. 2.

DIAGRAM OF OPTICAL ARRANGEMENT.

To obtain absolute Z_1 values, the position of the undeviated straight line OX must be recorded. In the ultracentrifuge practice this is easily arranged. The balancing cell in the rotor is provided with two index holes at distances from the axis of rotation that are smaller and greater respectively than that of the solution cell. The light passing the index holes is recorded on the plate as two points, called reference points (Fig. 1). For the calculations an enlarged image of the photograph is projected on to millimetre paper and a line is drawn in the middle of the curve. The position of the plate is adjusted to give the reference points at the same place on the millimetre paper in both the reference run and the normal run.

The optical arrangements are made in such a way that both the new method and the scale method can be used on the same run. The first use of the method has therefore been to get immediate information on the general shape of the sedimentation curve and for choosing scale distances in the scale exposures. In preliminary experiments the sedimentation constants and the concentrations of the sedimenting substances calculated according to the new method and the scale method have been found to agree satisfactorily.

In comparing this new procedure with Philpot's method there are two points worth considering. The fact that a line and not a boundary between dark and white is obtained on the photographic plate permits more exact recording of the sedimentation curve than is possible with Philpot's method. Quite recently this disadvantage in Philpot's method has been overcome by Svensson⁴. With his arrangement a line is obtained, but it is still an open question whether a modification gives enough light intensity for use in the ultracentrifuge.

Furthermore, the use of the reference points makes it possible to obtain with the aid of a reference run a well-defined base-line. On the other hand, the possibility of changing the sensitivity is more adequate in Philpot's method than in the new one.

A more detailed description of the method and its accuracy will in the near future be given elsewhere.

Deposition of Protein Multilayers

SEVERAL workers^{1,2} have built up multilayers from proteins spread at the water-air interface, using some modification of Blodgett's technique³, and drying the wet slide between each dip. It has sometimes been assumed that this procedure deposits a monolayer of protein on the slide at each movement of the piston and that the thickness of the resultant multilayer is a simple multiple of the thickness of the surface film of the protein on water, also that this thickness is a measure of the lengths of the side chains in the protein.

The area and presumably also the mean thickness of a protein film are dependent upon the piston pressure employed. At 30 dynes the area is about half the area at 10 dynes, and multilayers which we have deposited at high pressure have shown interference colours when only 40 layers thick, indicating that an average thickness of about 20 Å. per layer can be obtained (see ref. 2) instead of the 10 Å. that has been obtained by some other workers¹.

Mitchell⁴ found that surface films of proteins go into solution readily and come out on clean portions of the surface if the pressure is near the collapse point. In his experiments, using the spreading technique of Gorter and Grendel⁵, he found collapse points between 7.5 and 15 dynes for various proteins. The same effect has been found with egg albumin spread from the dry powder on distilled water with piston pressures as low as 10 dynes, the lowest at which we have been able to build up multilayers.

The wet slide on withdrawal after dipping contains water between the two upper layers of protein, as can be demonstrated by measuring the potential. Deposition of stable multilayers can readily be achieved on gauzes both of stretched silk and of metals. Using a 'slide' of stretched silk in electrolytic contact with the trough at its lower edge, the potential was measured with an ionized air electrode at the exposed surface of the partly withdrawn slide, at the air-liquid surface in direct proximity to the slide, and at a remote part of the trough. In one experiment, at 17 dynes, the undisturbed egg albumin had a potential of 310 mv.; near the slide, where the albumin had presumably been stretched, the potential was 270 mv.; and on the upper edge of the wet slide, 210 mv. The low value indicates that the protein had been considerably stretched as it went on to the 'slide', but that it had approximately the same orientation as on the water surface. There is no reason to assume that the hydrophilic

groups have turned over and that the water adheres on top of the film; in fact a small bubble of water can often be moved about within its protein sack by tilting the slide. If protein has dissolved in the substrate, some will be in solution in the water on the slide and will remain after drying, contributing to the mean thickness of the protein in the multilayer. This factor will contribute a large error if the dissolved protein is adsorbed beneath the surface layer.

The deposition ratio (the decrease in water surface covered by the protein divided by the area of the slide covered) was measured with egg albumin spread from a powder at piston pressures of 10 and 17 dynes. With new substrates of distilled water deposition ratios of 1.0 were sometimes obtained; but after a few minutes, especially if the surface was disturbed by dipping, the deposition ratio fell and values as low as 0.6 were sometimes obtained. At the same time, the protein commenced to go into solution and came out in the piston oil and on the clean surfaces of the trough. Low deposition ratios and solution of the film were always obtained at higher piston pressures.

It would seem advisable to have some slow mechanical dipping device and to empty and clean the trough between each dip while the film is drying in order to get deposition ratios of 1.0 and no contamination from dissolved proteins. If these precautions are not observed, no valid estimate of the thickness of a surface layer of protein at a given pressure can be obtained from measurements on multilayers.

Viscosity of Liquids

As a result of a detailed consideration of the mechanism of viscosity of liquids, Fig. 1 was obtained. It is a graph of the logarithm of viscosity of the *n*-paraffin hydrocarbons from *n*-butane to *n*-octadecane (represented by the figures opposite the respective points), against the function T_B/T , or the absolute boiling temperature/absolute temperature of measurement.

It may be seen from the graph that:

(1) A 'specific viscosity curve' is obtained for a family of compounds irrespective of the position of the compound in the family, provided it is not among the first few members.

(2) The function T_B/T thus becomes a fundamental basis for comparing a dynamic property such as viscosity when the effects of constitution are to be studied. It has been pointed out¹ that the reduced

temperature T/T_c and the function $\frac{T - T_f}{T_c - T_f}$, in

which T_c is the critical temperature and T_f is the freezing temperature², failed to yield results of any value when dealing with viscosity.

(3) It is generally accepted that in $\eta = Ae^{B/T}$,

Fig. 1.

B is invariant with temperature for such liquids. This statement cannot be proved rigorously unless a liquid is examined over the entire range of temperature in which it exists as such.

In this graph, none of the liquids has been examined since the literature generally reports the results at temperatures between 0° and 100° C. Since *n*-butane boils around 0° C. and *n*-octadecane is solid at that temperature, it may be seen that this graph actually represents the viscosity of any one of the *n*-paraffins over the entire range in which it exists as a liquid. The line is not straight and, therefore

Fig. 2.

or all these members B is variable with temperature. It probably follows that for all liquids B is a function of temperature, and that the difference between associated and non-associated liquids with regard to γ is entirely a matter of degree.

For other families of compounds similar lines exist, but a better rendering of these curves is obtained by plotting the function η_B/η_T against T/T_B , as shown in Fig. 2.

The results of 137 liquids have been plotted representing *n*-paraffins (12), *iso*-paraffins (15), acyclic aldehydes (7), *cyclo*-hexene, alkyl halides (25), alcohols (11), acetaldehyde, ketones (4), anhydrides (2), diethyl-ether, carboxylic acids (5), water, cyclic compounds (30), elements (12) and inorganic compounds (10), resulting in the following conclusions:

(1) All the normal or unassociated liquids fall in a fan-shaped manner in the shaded portion of the graph. In this area, also, fall such compounds as the carboxylic acids which are known not to change appreciably the degree of association on rise of temperature and in fact evaporate to a great extent in the dimer form. Thus the shaded portion contains all compounds which are either unassociated, or if associated, have a small coefficient for the increase of association with a fall in temperature.

(2) The upper portion of the graph contains associated liquids. It is remarkable that water changes its degree of association very slowly, as the evidence of the plot tends to show, when compared with tri-nethyl carbinol.

(3) The lower portion of the graph is characteristic of liquid metals. Mercury shows the regularity of the points on the curve.

A full description of the work and the results obtained has been prepared for publication and will appear in the literature later in this year.

Surface Tension and Lindemann Frequency

ANDRADE¹ has derived the expression $\eta = \frac{4}{3} \frac{m}{\sigma}$

for the viscosity (η) of a liquid at its melting point in terms of the molecular mass (m), the Lindemann frequency (ν) and the mean molecular distance (σ). This simple relation has been amply substantiated by experimental results and has given us an insight into the mechanism of viscosity in liquids. But so far as we are aware, no equally elegant explanation of the phenomenon of surface tension in liquids has been put forward.

Let us assume that at the melting point the energy per unit area of the surface is given by the total energy of the molecules in a surface layer of unit area, each molecule vibrating with a frequency equal to the Lindemann frequency. Considering that the oscillation is simple harmonic with an amplitude a , it follows on the basis of the assumptions that the surface tension

$$\gamma = \Sigma \frac{1}{2} m a^2 (2\pi\nu)^2 = \frac{2\pi^2 a^2}{\sigma^3} m \nu^2.$$

Assuming, after Lindemann and others, that at the melting point a/σ is constant, we obtain

$$\nu = k \sqrt{\frac{\gamma}{m}},$$

a relation dimensionally correct. Calculating the Lindemann frequency both for elements and compounds from the relation $\nu = 2.80 \times 10^{12} \sqrt{T_m/MV^{2/3}}$ where T_m is the melting point, and M and V refer to the atomic weight and the atomic volume respectively in the case of elements, and to the molecular weight and the molecular volume respectively in the case of compounds², and dividing the frequency so obtained by $\sqrt{\gamma/m}$, we find that the value of k in the case of forty-six substances examined, of which twenty-four are elements, ranges between 1 and 3.5, with a mean value of 2.34. The variation of surface tension with temperature can thus be explained on the same lines as that of viscosity.

Details will be published elsewhere.

Influence of Electrical Conductivity of Surroundings on the Natural Wave-length of an Antenna

THE free end of an antenna fed by an oscillator is connected to a metal plate under which is placed a basin of water. The conductivity of the water is changed by adding known weights of various salts. The solution is earthed and the distance between the plate and the solution is kept constant.

It has been found that the natural wave-length of the antenna increases with this conductivity up to a definite limit and then becomes constant for greater concentrations. This definite concentration marks the limit between the dielectric and the conductive state of the solution. The increase of the natural wave-length for small concentrations can be attributed to the fact that the dielectric constant of the solution increases with concentration.

Experiments are now being carried out for different wave-lengths and different electrolytes. The effect of this conductivity on the resistance of the antenna is also being investigated.

Hydrolytic De-amination of Amino-Acids

Virtanen and Erkama¹ discovered recently in *B. fluorescens liquefaciens* an enzyme which causes hydrolysis of aspartic acid into malic acid and ammonia. This, however, is not the first example of hydrolytic de-amination of amino-acids. In a series of papers², we have been able to show that in aqueous solution, amino-acids are hydrolysed under the

influence of ultra-violet light to give the corresponding hydroxy-acids:

Here again, a certain resemblance exists between enzymatic and photochemical processes.

This photolysis of amino-acids is a general reaction. It is the primary process in absence of oxygen and precedes, therefore, the well-known photo-oxidation of amino-acids² into the corresponding aldehydes:

Histidin, for example, is reported by Szendrő³ to give imidazol-acetaldehyde, on irradiation. We have been able to show that here, too, ammonia and a hydroxy-acid are formed primarily; the presence of the latter one is easily demonstrated by the colour reaction with 2,7 dihydroxy-naphthalene⁴. The reaction velocity is high: 115 c.c. of a 1 per cent aqueous solution of (-)-histidin, irradiated for two hours in the apparatus, described previously, gave 18.4 c.c. of N/10 ammonia, corresponding to a 25 per cent decomposition of histidin in the above sense. In presence of oxygen only, the hydroxy-acid is degraded into imidazol-acetaldehyde.

The histamin-like biological effects of an irradiated histidin solution⁵ are due to imidazol-acetaldehyde according to Szendrő³, and there is no need to assume a photolytic degradation of histidin into histamin proper. As imidazol-acetaldehyde resembles histamin physiologically, the possibility has to be kept in mind that the 'histamin-precursor' identified by Barsoum and Smirk⁶ with histamin on the basis of their biological resemblance is also imidazol-acetaldehyde.

It would be worth while to test the biological effects of imidazol-hydroxy-propionic acid.

Sulphonamide Drugs and Pneumococcus Capsular Polysaccharides

THE remarkable curative effects on certain types of bacterial infection of drugs of the sulphonamide group¹ immediately opens up a new field of research into the mode of action of these drugs. In a bacteriological examination of organisms isolated from the peritoneal cavity during a course of treatment of an experimental pneumococcal infection in mice by 'M and B 693' (2-[p-aminobenzenesulphonamido]-pyridine), Whitby² reported that the "capsules became swollen and crenated and eventually disappeared". Hence it might seem that the drug has a direct destructive action on the pneumococcus polysaccharide-capsular material. It is well known that the capsule is a defence mechanism of virulent bacteria and, for example, in pneumococcal infections, is probably the decisive factor in determining

the fate of the bacteria in the host. Any destructive action on capsular material by sulphonamide drugs would be comparable to the effects of the polysaccharide-splitting enzymes studied by Avery, Dubos and others³. In this work it has been clearly demonstrated that denudation of the organism of its capsule leaves the cell exposed to the phagocytic action of the body and usually the attack of pneumonia is repelled.

We have thought it of interest to ascertain whether solutions of sulphonamide drugs have any destructive action *in vitro* on purified capsular polysaccharides from Type I and Type II pneumococcus. Accordingly dilute solutions of the polysaccharides were separately incubated in physiological saline during several days at body temperature, with saturated solutions of sulphonamide, sulphonilamide (supplied by the Glaxo Laboratories, Ltd.) and 'M and B 693' (supplied by Messrs. May and Baker, Ltd.). The solutions were systematically examined for changes in specific rotation, increase in reducing power, change in viscosity and for loss in precipitin reactivity with homologous immune antisera.

We could clearly demonstrate that under the above conditions the drugs have no chemical action on the specific polysaccharides. It is likely, therefore, that the action of the drugs *in vivo* is not one of capsule destruction but one of capsule inhibition. Whilst this work was in progress, a recent investigation by McIntosh and Whitby⁴ has thrown considerable light on the problem. These authors favour the idea that the mode of action of the drugs is in some measure bound up with the inactivation of the bacterial enzymes responsible for the food requirements of the organisms. In support and extension of these findings it is of interest to recall the work carried out in this department and elsewhere⁵ on polysaccharide synthesis by bacteria. In the cases studied here it has been found that polysaccharide production is extremely capricious, for not only must the organisms have their appropriate food supply but a highly specific 'accessory growth factor', albeit in minute quantity, must also be available. It is possible that *in vivo* sulphonamide drugs can render unavailable to the organism the necessary 'accessory growth factor' and thus inhibit capsule formation; the body would then be able to rid itself of the invading bacteria by phagocytic action.

This tentative explanation would account for differences observed in the mode of action of various drugs on different groups of organisms, since 'accessory growth factors' are sharply specific for each group. A search in peptone broth or in blood for such growth-substances responsible for capsule production in the pneumococcus group, for example, might well prove a profitable study.

Sulphanilamide Therapy in Pneumonia

NICOTINIC acid has been found to be especially important as a supplement to sulphanilamide therapy of pneumonia. In a series of cases, it has been noted that there frequently occurs in victims of pneumonia treated with sulphanilamide, a black-dotted, heavy furring of the tongue akin to black-tongue. At the same time, consolidation of the lung fails to resolve though the temperature be normal and toxic effects cleared.

Administration of nicotinic acid in doses of 10-100 mgm. results in rapid clearing of the tongue, generally from behind forward. At the same time, the consolidation of the lung resolves.

Though no pathological studies have been made, it appears probable that the failure of resolution in these cases is due to changes in the mucous membrane of the bronchial tree of the same character as affects the tongue.

An interesting light is thrown on the mechanism of action of sulphanilamide by the change of typing of the pneumococci in cases treated with the drug. Following therapy, it will frequently be found that the pneumococci lose their typing reactions and cannot be typed. Characteristic typing reactions are usually restored to the organisms after animal passage.

"Animal Language"

THERE is a point in the review of "Animal Language" in NATURE of February 25 on which I should like to comment. The reviewer writes: "At times, Dr. Huxley expresses his views with considerable confidence. 'What is the point of a rattlesnake's rattling? The answer is really very simple. The snake doesn't want to strike unless it has to. It might very easily get trodden on . . . The rattle is a warning to the intruder to keep away. . . . In the same sort of way those who install burglar alarms in their houses put up a notice to that effect outside.' This may be so, but whether it is an established truth or simply an *ad hoc* hypothesis we are given no real evidence to decide."

In the first place, "Animal Language" was not designed as a scientific monograph, but as a popular book addressed to the general public, so that citations of evidence would have been out of place. In passing, in compiling it I was astonished at the lack of any coherent body of scientific information on the comparative aspect either of sound-production or of hearing: here is a fruitful field for anybody with time and knowledge.

As regards the point concerning the rattlesnake, Jadow, in the "Cambridge Natural History", writes: "The rattle is decidedly useful to the snake as an instrument of warning off any approaching possible enemy, since no snake likes to bite unless in self-defence or in order to kill its prey." The "Encyclopædia Britannica" (eleventh edition) expresses a similar idea. So does that eminent authority, Dr. Thomas Barbour, in his book "Reptiles and Amphibians" (1926), but in considerably greater detail, and with the specific suggestion that the bison is the enemy to be warned off.

Ditmars, in his "Reptiles of the World" (1910), is one of the few authorities to express scepticism as to

the rattle's warning function—though he goes on to make the far more speculative statement that it may serve as a mating call, an assertion which, as Barbour points out, must be erroneous as snakes cannot hear.

The whole question of what constitutes "evidence" for the presumed function of an allæsthetic character, whether concerned with warning, threat, or display, is a very interesting one. I have recently¹ briefly discussed this question. It seems clear that there are different degrees of probability, culminating in proof only when the experimental method has been applied, but that the 'old-fashioned' Darwinian view of presuming an adaptive function from general study of the structure and habits of the animal in question gives a reasonable probability and puts the onus of disproof on opponents.

Ditmars indulges in one fallacy that is so common that I cannot refrain from commenting upon it. He wishes to deny the warning function of the rattle because "many species of harmless and poisonous snakes without a rattle, vibrate their tail when angered". It should surely be obvious by this time that the lack of a character or organ in one type does not preclude its being adaptively functional in another. Numerous examples of this point in regard to threat and warning characters in birds have recently been given by me². Not only this, but in this particular case the evidence adduced by Ditmars strengthens the case for the warning function of the rattle, by making it clear that tail-vibration *per se* is a warning device, presumably rendering the snakes more conspicuous without impairing their capacity to strike. In some cases it may produce auditory as well as visual effects, by rustling dry leaves on the ground. The rattle is a further auditory specialization of this widespread generalized activity.

Production of Intercellular Hormones

IN the investigation of metabolic controlling factors (intercellular hormones) appearing in the suspending fluid when cell aggregates are subjected to lethal ultra-violet¹, X-rays², and other external agents, it seems to us of particular interest to determine whether such substances are released by living cells into the intercellular fluids or are simply dead-cell disintegration products. To study this question, suspensions of yeast in isotonic salt solution were irradiated with lethal ultra-violet for periods from 9 to 24 hours under such conditions that the full irradiation period was required to kill 90 per cent of the cells. Samples taken out at regular intervals were filtered through Berkefeld filters, and the growth potencies of the filtrates compared with those of filtrates from control suspensions allowed to stand for equal periods without irradiation. The extent of killing was determined by methylene blue staining and by plating. Maximum production of growth factors (intercellular wound hormones) preceded maximum rate of killing and occurred while most of the cells were still living.

As an alternative method, carbon dioxide and oxygen were bubbled through yeast suspensions for 24- and 48-hour periods, and the growth potencies

of the filtrates from these suspensions compared with those from controls allowed to stand for equivalent periods. Less than one per cent of the cells stained in any of these suspensions. Nevertheless, the filtrates from the suspensions exposed to carbon dioxide averaged one and one-half times as potent as the control filtrates, and four to seven times as potent as the filtrates from suspensions exposed to oxygen.

Full details will be published elsewhere.

Cytochrome Oxidase in Flowering Plants

In 1925, Keilin¹ described for the first time the absorption spectrum of cytochrome visible in the living tissues of flowering plants. We have been able to prepare from germinating seeds and other tissues of monocotyledons and dicotyledons an insoluble residue showing the complete cytochrome spectrum.

This residue behaves in the same way as the cytochrome oxidase preparations from animal tissues. Shaking the suspension in air causes the bands of cytochrome to disappear, succinate will cause the bands to appear; re-oxidation is prevented by cyanide and azide. If cytochrome c (from ox heart) is added to the preparation it is rapidly reduced in presence of succinate and immediately oxidized by shaking in air. In the accompanying graph are shown manometric measurements of the oxygen uptake of the preparation in presence of cytochrome c, succinate and p-phenylenediamine. The enzyme suspension was prepared by grinding cotyledons from germinating *Phaseolus* seeds in twice their weight of water; the greater part of the solid material was removed by a low-speed centrifuge and the opalescent fluid was spun down on a high-speed centrifuge. The slightly brownish residue was suspended in about three

volumes of water. This preparation showed a cytochrome spectrum one twentieth the intensity of that in bakers' yeast. In each experiment shown 37.5 mgm. dry weight were used in 2.2 c.c. of fluid at pH 7.4. The Q_{10} with p-phenylenediamine as cytochrome c was 20; with succinate and cytochrome c, 10.8. Tests for catechol oxidase were negative.

These results show that the cytochrome spectrum seen in plant tissues is associated with the insoluble enzyme systems which characterize yeast and animal tissues. This now proves the presence of a true cytochrome oxidase in the higher plants and a respiratory mechanism identical with that found in yeast and animals. It is not possible to state exactly how much of the oxygen taken up in the respiration of plants is by means of the cytochrome system, but in some tissues the intensity of the spectrum when compared with that of yeast is parallel with the rate of respiration. These observations are a confirmation of the general presence of the cytochrome system in aerobic organisms as originally discovered by Keilin.

Spectroscopic Power of a Human Eye due to Injury

THE case reported here of a structure resulting from an injury to an eye, conferring on the owner the power of spectroscopically analysing light, is possibly unique.

Mr. J. M. Rowe, of Adelaide, suffered, at eighteen years of age (he is now fifty-two years old), an injury to his right eye due to the impact of a stone-chip which cut through the cornea and iris, but did not apparently, penetrate further. Natural healing took place with development of a scar on the cornea the protuberant part of which was afterwards removed with a pair of surgical scissors. The pupil of the eye was left, however, displaced from its central position downwards and inwards; also it is no longer round but distinctly elliptical in shape with its long axis in the direction of the displacement. Eyesight with this eye is quite normal—Mr. Rowe has been an excellent rifle-shot—except for the fact that bright sources of light show spectral colours. Mr. Rowe has been aware of this for some years, but only recently informed me of this peculiarity of vision.

Tests made showed that the effect is due to the existence of a periodic structure in the eye of the nature of a diffraction grating. It is definitely not a prism effect since: (1) the spectrum is seen on either side of the bright source; (2) the blue is on the inside the red on the outside of these images; (3) the angle made by the direction of the blue light with that of the source is approximately half that made by the red part of the coloured image. Rough measurements of these angles was made by asking Mr. Rowe to indicate the positions of the several images on a metre rule held at a measured distance from the eye. The blue—or violet—inner edge of the coloured images was approximately four and a half centimetres distant from the central source, a single filament galvanometer lamp; the red outer edge about 7 centimetres, when the metre rule was held at a distance of one metre from the eye. This makes the first-order diffraction angle about $2\frac{1}{2}^\circ$ for the blue and about 4° for the red light, corresponding to spacing in the elements which constitute the grating.

f 1,000–1,300 'lines' per centimetre. The direction in which the rule had to be placed in order that all three images fell upon it was about 15° from the vertical and, roughly at least, perpendicular to the direction in which lay the major axis of the displacedupil.

A sodium lamp gave first-order (uncoloured) images in positions agreeing well with the above. Second-order images were seen only when a 'Pointote' arc-lamp was substituted for the filament lamp, the brightness of the spectrum causing Mr. Rowe to exclaim: "Oh! It's beautiful."

Dr. Tostevin, an eye-specialist, kindly made an examination of Mr. Rowe's eye with the aid of a slit-lamp. He states that the injury has resulted in thickening of the cornea to the iris, and that the cells of the cornea where the scar exists have lost their nuclei and are elongated in a definite direction. There is no injury to the lens.

Should any reader of NATURE suggest a reason for more accurate or other observations, Mr. Rowe has estimated his willingness to submit to them.

Commemoration of the Cell Theory

THE hundredth anniversary of the discovery of the cell by Th. Schwann is being commemorated this year in many countries. There seems, however, to be a mistake about the date of this great discovery. Schwann's "Mikroskopische Untersuchungen" bears the date 1839; but the first two—and I think the most important—parts of the book had already appeared in 1838. The edition must have been very small, for I have seen only one copy of them during the last twenty years. Schwann placed the 1838 edition before the Paris Academy of Sciences. At all events we are, I think, late in our commemoration.

A few years ago, by the way, I made a similar blunder. I published in my "Facsimile Edition" a reprint of the first edition of Galvani's famous work which had appeared in 1792. But I discovered too late that this work had already been published as a paper a year earlier in the 'Commentari' of the Academy of Bologna. My reprint was in reality only that of the first edition of the *separate* work.

Points from Foregoing Letters

J. G. Daunt and K. Mendelssohn find that a 'transfer' of liquid helium II takes place along a solid surface when a temperature gradient is kept up. They also observe that a flow of liquid helium II through a powder plug is accompanied by a caloric effect. These results seem to support the idea that the transport phenomena in liquid helium II are mainly due to surface flow.

A new method for obtaining photographic records of refractive index gradients in a column of solution is described by Kjell J. I. Andersson. The refraction methods now used in ultracentrifugal practice are briefly discussed and the new procedure compared with an analogous method described by Philpot.

Several factors are presented by R. B. Dean, O. Maty and E. Stenhagen which may invalidate the assumption that the thickness of multilayers of protein is a measure of the thickness of a surface layer of the protein on water. Conditions for avoiding these errors are set forth and the orientation of the layers of protein on the slide is also considered.

A. H. Nissan and L. V. W. Clark state that a reasonable basis of comparison for studying the viscosity of liquids has been found so that an homologous series, for example, the *n*-paraffins, yields a solitary curve for all its members, with the exception of the first few, independent of molecular weight. It is generally accepted that in $\eta = Ae^{B/T}$, *B* is invariant with temperature for unassociated liquids. Evidence is given that *B* is a function of temperature even in the case of *n*-paraffins. From an examination of a large number of liquids it is possible to classify them into three groups with regard to viscosity: normal, associated and metallic.

Assuming that, at the melting point the energy per unit area of a liquid surface is given by the total energy of the molecules in a surface layer of unit area, each molecule vibrating with a frequency equal to the Lindemann frequency, L. Sibaiya and S. Rama Rao arrive at a simple formula connecting

the surface tension of a liquid with the molecular mass and the Lindemann frequency. The values obtained in the case of forty-five substances investigated were found to be of the right order of magnitude.

The natural radio wave-length of an antenna is found by R. Nakhla to increase with the electrical conductivity of the surroundings up to a definite limit and then to become constant.

Ch. Weizmann, E. Bergmann and Y. Hirschberg point out that the enzymatic hydrolytic de-amination of amino-acids, recently discovered by Virtanen and Erkama, parallels the analogous photochemical process, which is more general. The behaviour of histidin is quoted as an example.

M. Stacey and Miss E. Schluchterer find that certain drugs of the sulphonamide group have no chemical action *in vitro* on specific capsular polysaccharides from Types I and II pneumococcus. The tentative theory is advanced that sulphonamide drugs are active *in vitro* since they can render unavailable to the invading bacteria highly essential 'accessory growth factors' which are responsible for capsule formation; deprived of their protective mechanism, the organisms fall prey to the phagocytic action of the body and the infection is aborted.

John R. Loofbourow and Sister Ceelia Marie Dwyer have found evidence that living cells produce growth factors ('intercellular wound hormones') as a physiological response to injury in the fact that the production of such factors precedes the killing of yeast by lethal ultra-violet and occurs in suspensions of living cells aerated with carbon dioxide.

A preparation from various tissues of flowering plants showing the complete cytochrome spectrum has been obtained by R. Hill and Miss K. Bhagvat. The cytochrome is associated with cytochrome oxidase and succinic dehydrogenase showing the presence of a respiratory mechanism in the plant identical with that characteristic of animals.

Research Items

Socio-political Grouping in the Great Basin, U.S.A.

IN 1935 the University of California, and in 1936 the Bureau of American Ethnology, instituted an ethnographic reconnaissance of the Western Shoshoni and their Paiute and Ute neighbours of the Great Basin area, under Julian H. Steward. In a study of their socio-political groups (*Bull.* 20, Bur. Amer. Ethnol., 1939), it is shown what are the sociological patterns among these simple hunters and collectors, and the factors which produce them are analysed. Most of the Basin Plateau peoples live at bare subsistence level, and their culture is meagre in content and simple in structure. Problems of daily existence dominate their activities and limit and condition their institutions. Population density depended directly upon the quantity of plant and animal food which the hunting or gathering devices known in the area allowed to be procured. This, therefore, determined in each region the size, nature and permanency of the population aggregate, which in turn determined the social structure and political controls. Generally exigencies of existence allowed little latitude for variation; but where ecology permitted such latitude; warfare, festivals, ceremonies, etc., became determinants of sociological patterns. Hence among the Western Shoshoni and Paiute it was physically impossible for families to remain long in one place or in permanent association. The outstanding sociological unit, therefore, was the biological family and the small winter village.

Carbohydrate Metabolism and Muscular Work

F. C. Courtice, C. G. Douglas and J. G. Priestley (*Proc. Roy. Soc., B*, 127, 41; 1939) have studied in detail the respiratory exchange and quotient and the sugar, lactic acid and carbon dioxide combining power of the blood in two subjects during the period after prolonged moderate muscular work (a ten-mile walk at a speed of 4½ miles per hour). During rest after work there is a reduction in the glucose tolerance, which is very like that following a low-carbohydrate, high-fat diet, and is also associated with a low respiratory quotient and ketonuria. It appears, therefore, that the low R.Q. after exercise is to be attributed to a diminution in the ratio of carbohydrate to fat oxidized. There was no evidence that the reduced tolerance to glucose was accompanied by a change in the sensitivity of the tissues to insulin, since the response of the blood sugar to intravenous insulin was the same whether after exercise or after a low-carbohydrate, high-fat diet. The administration of insulin is followed by a prolonged but slight increase of the respiratory quotient, suggesting an increased oxidation of carbohydrate, and it is tempting to assign the similar rise in quotient which occurs during exercise to the same cause. The injection of insulin is, however, accompanied by a large fall of blood sugar, and such falls do not occur during exercise. It is probable that other endocrine secretions, for example, adrenaline, play a considerable part in the control of carbohydrate metabolism during exercise. Administration of adrenaline causes an increase in the oxygen consumption, hypergly-

cæmia and certain characteristic changes in the lactic acid of the blood. If insulin and adrenaline are injected together, they neutralize one another in as far as their effects on the blood sugar are concerned but the changes in the blood lactic acid are the same as if adrenaline alone were injected.

Habits, Distribution and Anatomy of *Ophelia clathensis*

IN 1935, I. P. McGuire described a new polychaet worm from the sands near Millport under the name of *Ophelia clathensis* which had escaped recognition until that time, sometimes possibly because it had been taken for the young of another species. R. S. Brown (*Proc. Roy. Soc. Edinburgh*; 1938) has given a full account of the habits, distribution and anatomy of this form, thus establishing completely its identity and specific distinctness. The adult reaches a length of 15 mm. in the male and 18 mm. in the female or rarely slightly larger than this, so it is not a large worm. It has twenty-five segments, all save the last being setigerous, and 8-10 pairs of gills. The body wall is semi-transparent so that the animal is a pinkish colour due to the colour of the haemoglobin-containing blood showing through. It is found just below high water neap tides, and in spite of its recent discovery may be present up to 273 per square metre.

Effect of Apple Diet on Intestinal Flora

G. M. Daak, R. Johnson and L. R. Dragstedt (*J. Inf. Dis.*, 64, 52; 1939) have made a comparative study of the bacterial flora of the duodenum, ileum and caecum of three *Macaca mulata* when these monkeys were on a control and a raw apple diet. Surgical fistulae were made in the three levels of bowel to simplify the removal of specimens under physiological conditions. The bacteriological examination included the determination of the relative number of *Bact. coli*, the predominant organism, and the numbers of *L. acidophilus* in the caecum. Dysentery bacilli were looked for as the monkey is a susceptible host to bacillary dysentery. A search was also made for *Bact. necrophilum*, which has been associated with ulcerative processes in the bowel of man and animals, but with negative results in both cases. No essential differences were found in the flora of monkeys on a control diet as compared with the apple diet. The authors conclude that any therapeutic effect that raw apple diet may have is not by virtue of any change which occurs in the bacterial flora of the bowel. Hydrogen ion determinations were made and there was no radical shift in the pH of the caecum which would account for inhibitory effects or bacterial growth.

Phenology of 1938

THE Phenological Report, 1938, by Major H. C. Gunton (*Quar. J. Meteor. Soc.*, 65, No. 279; 1939) is the forty-eighth annual report of this kind. For meteorological reasons the period with which it is concerned, namely, December 1937-November 1938, is one of exceptional suitability for the study of the

sections of wild life to abnormal conditions. The change from winter to summer in the British Isles, instead of taking place in its usual rhythmical manner, spring being made up of short bursts of warmth, sometimes equal to that of summer, followed by abrupt wintry retrogressions due to sudden incursions of cold air from the Arctic, seemed on this occasion likely to be a sudden one, winter holding sway in February and summer from the beginning of March onwards. In actual fact, however, the exceptional warmth of March did not persist beyond that month, and there were long cold and dry periods in April and May, with frequent night frosts. These conditions caused much damage to blossom and foliage, and the report instances cases where song thrushes and blackbirds deserted the young birds in their nests in the drought, when insects must have been unusually scarce. The weather continued very abnormal even after May, for there were notably severe midsummer gales, and very stormy weather again in October, which resulted in an early fall of the leaves, which had already suffered damage. In November came the second spell of unseasonable summer warmth, which was as remarkable as that of March except in its duration. It is not surprising that butterflies and moths were on the whole scarce throughout the year, but there were some exceptions, among them the silver ground carpet moth and the chalk hill blue butterfly. Red admirals, moreover, were observed in large numbers in September and October, and even as late as November. The early fall of the leaves made the autumn a poor one for grouse, but the November warmth caused numerous abnormal second flowerings of shrubs and trees.

The Weddell and Ross Seas

THE Weddell Sea and the Ross Sea, the two great bights on the opposite sides of the Antarctic continent, have different relations with the Southern Ocean. These contrasts are indicated by G. E. R. Deacon in a paper on the "Antarctic Voyages of R.R.S. *Discovery II* and R.R.S. *William Scoresby* 1935-37" in the *Geographical Journal* of March. In the south-west of the Weddell Sea freezing is intense in winter; this raises the salinity of the surface layers by the salts left when the ice is formed. Thus the surface waters sink rapidly and, as a bottom current, spread over the whole Southern Ocean and northwards into the Atlantic, Indian and Pacific Oceans. Bottom temperatures and salinities at great depths show a continuous increase towards the east and the oxygen content a continuous decrease. The increase in temperature is due to mixing with the deep Southern Ocean water subsequent to sinking from the cold surface, and the decreased oxygen content is due also to distance from surface origin. It is thus clear that the Weddell Sea is the chief supplier of the cold bottom water. The Ross Sea has comparable surface conditions but a submarine ridge between Cape Adare and King Edward Land cuts off the bottom waters from the Southern Ocean. This basin, south of the ridge, is filled with very cold saline water that cannot escape. Thus the Ross Sea has little influence on oceanic circulation in general.

Analysis of Ethylene Oxide - Carbon Dioxide Mixtures

A MIXTURE of carbon dioxide (90 per cent) and ethylene oxide is now largely used as a fumigant. The analysis of this mixture has caused some

difficulties and J. R. Branham and M. Shepherd (*J. Res. Nat. Bur. Stand.*, 22; February 1939) have now described a simple and accurate method with a reproducibility of 0.05 per cent. Ethylene oxide is rapidly and quantitatively absorbed by a small volume of sulphuric acid, which takes up more than 5,000 times its volume of the oxide but no significant amount of carbon dioxide, which is then absorbed in concentrated potash solution. A type of apparatus in which the gases are measured dry is described.

Reduction of Silver Ions by Hydroquinone

ALTHOUGH the reduction of silver ions by hydroquinone is of considerable interest in connexion with photographic development and fogging action, no detailed investigation of its mechanism has been made until recently. T. H. James (*J. Amer. Chem. Soc.*, 61, 648; 1939) has now studied the reaction in gelatin and gum arabic solutions. The reaction in slightly acid solution is strongly catalysed by colloidal silver, gold, palladium and silver sulphide. The rate of reaction catalysed by silver varies as the first power of the hydroquinone concentration and as the two thirds power of the silver ion concentration. The dependence of the rate upon the hydroxyl ion concentration shows that both unionized hydroquinone and the univalent ion participate in the reaction in the pH range 5.15-6.27. The rate of the catalysed reaction varies proportionately with the surface of the catalyst and inversely with the concentration of gum arabic. The mechanism suggested by the results involves a primary adsorption of silver ions on the surface of the catalyst, as is indicated by the fractional power of the concentration. No adsorption of hydroquinone is disclosed by the experiments. The difference between the mechanism and that found for the reduction of silver ion by ferrous ion, which indicates that the homogeneous reaction between the ions is very rapid in comparison with the rate of deposition of silver on condensation nuclei, is pointed out.

Solid Adsorption

THE great influence which the addition of a very small proportion of a second metal may have on the resistance of a metal to corrosion has been known for some time; for example, small quantities of aluminium added to copper or brass retard oxidation. In two recent papers (*Bull. Polish Acad.*, March-May and October-December, 1938), the first by Dr. S. Dobinski, the second by Drs. Dobinski and Jagielski of Cracow, it is shown that these effects are due to adsorption of one of the constituents of the solid solution at the surface, in accordance with the Gibbs rule of the 'Equilibrium' paper of 1878, that if diffusion of the constituents can take place the one with the smallest surface tension will concentrate in the surface. Unfortunately the surface tensions of solids have not yet been measured, but Desch and others conjecture that they are proportional to those of the liquids. By surface electron diffraction photographs the authors show that for alloys of lead and antimony, zinc and tin, copper and calcium, silver and cadmium, copper, aluminium and nickel, and copper, aluminium, nickel and magnesium, the constituent which concentrates in the surface when polished or when the alloy is heated to about 200 °C. is in each case that the surface tension of which in the liquid state is the least.

The University Observatory, Glasgow

By Prof. W. M. Smart

THE new observatory buildings of the University of Glasgow were formally opened on April 17 by Sir Arthur Eddington in the presence of a representative assembly presided over by the Chancellor of the University, Sir Daniel Stevenson, who was supported by the Principal, Sir Hector Hetherington, and Prof. John Walton, dean of the Faculty of Science. During the proceedings, Sir Arthur Eddington gave an address on "The Expansion of the Universe", in which he described his recent work, involving relativity and quantum theory, of predicting the actual rate of expansion.

UNIVERSITY OBSERVATORY, GLASGOW. TOPS OF THE TRANSIT HOUSE AND THE 7-INCH DOME ARE SEEN ON THE RIGHT. [Glasgow Herald.]

Owing to the exacting demands of modern observational astronomy as regards instrumental equipment and favourable atmospheric conditions, the new observatory (which is within a stone's throw of the main University departments) has been designed mainly for instructional purposes. The principal room of the main building is a library which can also be used for lantern lectures: a fine collection of fifty astronomical transparencies is mounted in this room. The other accommodation consists of a large instrument room and rooms for the director and his assistant. A 7-inch refractor carrying a small spectroscopic equipment is mounted on the high ground behind, and close by is a transit house. The observatory is also well equipped with subsidiary instruments. For two centuries and perhaps more, particularly during the last thirty or forty years, comprising the directorship of Prof. Becker, astronomy has proved, academically, to be of interest to a fair number of students, and it is hoped that the new facilities will further encourage astronomical study and research in the University.

The present observatory is the third astronomical institution established by the University. The Old College of Glasgow was in possession of a telescope so far back as 1603, and although astronomy was one

of the subjects taught in these early days by the occupant of the chair of physics (or, from 1727, of natural philosophy), no proper accommodation for observational work was provided until 1756, when the University received the valuable bequest of the instruments belonging to Alex. Macfarlane, a wealthy Jamaican merchant and a graduate of the University. The erection of an observatory—known as the Macfarlane Observatory—was immediately undertaken and the regius chair of practical astronomy was established in 1760 under a warrant of King George III. It is noteworthy that it was the establishment of the

Macfarlane Observatory that led directly to James Watt's appointment as instrument maker to the University, and it was in this capacity that he effected the improvements in the steam engine that made his name world famous.

At the beginning of the nineteenth century the rapid extension of the city and the increasing industrialization of the neighbourhood made astronomical observations almost impossible, and matters were not improved when some fifteen or twenty degrees of the meridian were securely blocked by the high steeple of a new parish church. It would appear that by 1820 the Macfarlane Observatory was reduced to little more than a centre of instruction, and it was there that Kelvin was taught the use of astronomical instruments.

In 1836 Prof. John P. Nichol was appointed to the chair—one of the applicants, it is of interest to note, was Thomas Carlyle. Nichol's success as a lecturer led to the formation of the Astronomical Institution of Glasgow, and a new observatory, with Nichol as director, was established as a private concern in 1841 at Dowanhill. The enthusiasm of the Glasgow citizens, however, waned with almost as great a rapidity as it had been stimulated and in 1843 the University acquired the Observatory together with the liabilities of the dead society. Nichol's successor was Prof. Robert Grant, whose two great publications—"The Glasgow Catalogue of 641 stars" and the "Second Glasgow Catalogue of 215 stars"—form a remarkable output for an observatory with such limited resources. The last effective directorship at Dowanhill was that of Prof. Becker, from 1891 until 1935. On his retirement, the University was confronted with the same problem which the academic authorities had to face, a century or more before, in connexion with the Macfarlane Observatory. The new observatory at Gilmorehill represents the solution. If auguries have any significance, the brilliant address of Sir Arthur Eddington and the benediction of an unclouded sun on the opening day should speak the beginning of a career of usefulness to the new institution in a University and City where astronomy and science as a whole have such long traditions.

The Early Sealers in West Antarctica*

PROF. W. M. HOBBS has written a long and elaborately illustrated monograph on the history of the Graham Land area of Antarctica from Smith's discovery of the South Shetlands in 1819 to Ellsworth's flight in 1938. The earlier years of this history have been much discussed by Mill, Balch, Nordenakjöld, Bruce and others, but assiduous search from time to time reveals new material, chiefly in the form of forgotten log books. Prof. Hobbs's reproductions of early maps alone give his monograph great interest. Some of his conclusions, however, do not appear to be justified from the available facts. Thus he goes to great pains to prove that the Antarctic continent was first sighted in November 1820, when the American sealer, N. B. Palmer, saw land to the south and south-east of Deception Island of the South Shetlands. This land soon after appeared on maps as Palmer Land and is now regarded as a part of the Trinity Peninsula of Graham Land. Prof. Hobbs, however, is entirely unconvincing in his refutation of the accounts and charts which are available establishing Bransfield's sighting of Trinity Land in January and February 1820. W. S. Bruce, and later R. T. Gould, have shown convincingly that Trinity Land was the original discovery of Antarctic and antedated Palmer's discovery by at least ten months. The attempt to establish an American discovery of Antarctica fails.

The chief interest, however, in Prof. Hobbs's monograph lies in his strictures on Weddell. These strictures have a weak foundation, but since they impugn the veracity and reputation of a notable explorer, cannot be overlooked. Between 1819 and 1824, Weddell made three southern voyages in the course of which he surveyed in part the South Shetlands and the South Orkneys and gained a high southern latitude in lat. $74^{\circ} 15' S.$, long. $34^{\circ} 16' 45'' W.$ in the Sea of George the Fourth, which is now called the Weddell Sea. He published his account of these voyages, his discoveries and his route chart in his well-known volume "A Voyage Towards the South Pole", etc. (London, 1825). He sailed southwards into the Weddell Sea about long. $30^{\circ} W.$ and came

north again between long. 30° and $40^{\circ} W.$ from his southern record where he saw a sea free from field ice with only four icebergs in sight. He had, however, seen "many ice islands" in places on the way south. Ross, twenty years later, failed on account of ice to follow Weddell's route, and the *Scotia* in 1903 had to keep farther eastward to gain a high latitude, but in 1904 crossed the middle of an almost ice-free Weddell Sea and reached lat. $72^{\circ} S.$ before difficulty began. The *Deutschland* and the *Endurance* in later years were caught and drifted in Weddell's longitudes. But from these scanty records we are not entitled to assert, as Hobbs does, that the Weddell Sea is unnavigable. The pack of the Weddell Sea is partly due to local formation in that sea and partly due to the sweep of pack from the east which is caught in this great bight. The pack is carried towards the south-west coast which may be always blocked, and then flows north before wind and current until, in the latitudes of 65° to $60^{\circ} S.$, it is swept eastward again by the set of winds and the eastward drift of the waters. With the amount and distribution of the pack in the Weddell Sea dependent on many factors, local and general, it would be surprising if the distribution of ice remained constant, as indeed a limited knowledge of that sea shows not to be the case.

Wordie has commented on the low average wind velocity in the Weddell Sea as promoting ice congestion in the western side. A year of unusually strong southerly winds in this area might easily clear away the ice for several weeks or even for a whole season. Years or periods of open water are likely to occur, and Weddell was fortunate enough to sail in such a season. Hobbs's deductions on the state of ice, based on the scanty data available, are not a foundation for the destruction of Weddell's reputation and the slandering of his name. Similarly, Hobbs's charge that Weddell did not make surveys in the South Shetlands but merely copied Powell's earlier map (published in 1922) would seem to ignore Weddell's practice of surveying from boats and not direct from his ship, for which reason Weddell did not mark his route among island groups. It is a pity that such charges should disfigure a work that comprises much research, even if some of it lacks scholarship.

Absorption Spectra of Single Crystals of Hæmoglobin in Polarized Light

By M. F. Perutz, Cavendish Laboratory and Molteno Institute, Cambridge

SINGLE crystals of hæmoglobin generally show strong pleochroism¹. They are dark red and almost opaque in two extinction directions and become light red and transparent in the third. An investigation of the absorption spectra corresponding to the principal vibration directions was undertaken with the view of obtaining information on the molecular structure of hæmoglobin.

Horse methæmoglobin crystallizes in the monoclinic system, as described in a previous paper², and is usually obtained in the prismatic form terminated by domatic faces (Fig. 1). The orientation of the optic axes may be seen from the figure; the sign of the double refraction is probably negative. The crystals show strong absorption in vibration directions parallel to β and γ , and weak absorption parallel to α .

The absorption spectra of the crystals were studied while they were mounted on microscope slides and immersed in their mother liquor (3 parts sat. $(\text{NH}_4)_2\text{SO}_4$ + 1 part molar $(\text{NH}_4)_2\text{HPO}_4$; pH = 6.3) to which gum tragacanth had been added in order to keep the crystals stationary. Preparations were made with crystals lying on their a , b and c faces respectively, the last two having been cut with a razor blade. The absorption spectra were observed through a microspectroscope replacing the eyepiece of a polarizing microscope.

Fig. 1.

CRYSTAL OF HORSE METHAEMOGLOBIN.

The axial ratios are $a:b:c = 1.72:1:0.86$; $\beta' = 68^\circ$. α makes an angle of 12° with a ; β is parallel to b ; and γ makes an angle of 10° with c . The domatic faces are 210 faces.

In unpolarized light, the spectra of the crystals conformed with the spectrum of acid methemoglobin in solution, showing a strong absorption band at $637 \text{ m}\mu$, faint bands at $582 \text{ m}\mu$ and $548 \text{ m}\mu$ and a general absorption increasing from the green towards the violet end of the spectrum. (The band at $504 \text{ m}\mu$ was not visible owing to the low resolving power of the spectroscope.)

The results of the spectroscopic examination in polarized light are recorded in the accompanying table.

Vibration direction parallel to	Absorption band at $637 \text{ m}\mu$	Absorption bands at 582 and $548 \text{ m}\mu$	General absorption in the green and blue
α	weak and smeared	faintly visible	weak
β or γ	strong, broad and sharply defined at the boundaries	not visible, probably overshadowed by general absorption	very strong

As the α , β and γ directions are parallel or nearly parallel to the a , b and c axes, the crystals show strong pleochroism when the light is travelling perpendicular to the b or c planes, whereas pleochroism is completely absent when the light is travelling at right angles to the a plane.

Crystals of methemoglobin can be treated with acid without being immediately dissolved. If a drop of $n/10 \text{ HCl}$ was added to the mother liquor, the

acid could be seen to penetrate the crystal by the change in colour which travelled from the edge towards the centre. Simultaneously, the spectrum changed gradually from that of methemoglobin to that of ferrihematin chloride, the edge of the absorption band in the red ($637 \text{ m}\mu$) shifting from $640 \text{ m}\mu$ to about $675 \text{ m}\mu$, until finally a very broad band stretched from about $640 \text{ m}\mu$ to $680 \text{ m}\mu$. At the same time, an increase in the general absorption in the green and blue could be noticed. Strong pleochroism was visible for several minutes after the acid had penetrated the crystal, which was lying on its c face. When the vibration direction was parallel to β , the bands of the spectrum of acid hematin, especially the band in the red, were strong and sharp. If the nicol was turned, the band contracted from the red end until it was narrow and smeared, when the vibration direction was parallel to α . After five minutes the pleochroism disappeared and the crystal dissolved.

Crystals of *sheep methemoglobin* were obtained in large thin pseudohexagonal plates which X-ray analysis had shown to be triclinic. Their spectrum

Fig. 2.

ABSORPTION SPECTRA OF A SINGLE CRYSTAL OF SHEEP METHAEMOGLOBIN.

(a) taken in polarized light with the vibration direction parallel to α ; (b) it is parallel to β ; and (c) shows the spectrum in unpolarized light. The exposure times of (a) and (b) are equal; in (c) the time is reduced to one third to counterbalance the absence of the nicol. (a), (b) and (c) are taken on a panchromatic plate, (d), (e) and (f) are the same photographs taken on an isochromatic plate. The reproductions are positives. The arrow in (c) indicates the absorption band in the red.

was similar to that of horse methaemoglobin, except that the absorption in the green was more pronounced. The small thickness of the crystals rendered examination in any other than the *c* plane impracticable, but made it possible, on the other hand, to get spectra which were bright enough to photograph (Fig. 2). The photographs taken on the panchromatic plate show the change in width and strength of the band in the red, while those on the isochromatic plate illustrate the variation of the general absorption in the green and blue.

In needles of horse oxyhaemoglobin, both the characteristic absorption bands in the green and in the yellow were strong and sharp when the vibration direction was perpendicular to the needle axis, and faded out when the vibration direction was parallel to it.

In horse methaemoglobin the absence of pleochroism in the *a* plane and the sharpness of the band in the red in combination with the high general absorption in the green and blue in vibration directions parallel to β and γ , indicate that the four haeme groups contained in one molecule are approximately parallel to each other and lie in the *a* plane. This orientation also agrees with the positions of the high refractive indices. It was shown by the effect of acid on the crystals that the absorption must be due to dipoles induced in the haeme groups themselves, since the relation of the absorption bands to the vibration directions in the crystal remained unchanged even after the haeme groups had become detached from the globin component and the position of the absorption band had shifted to that corresponding to free haematin chloride.

In drawing these conclusions it has been assumed that the coefficient of absorption is high when the electrical vibration of the polarized light is parallel to the haeme groups and low in any other direction. This assumption appears justified, since the strong colouring power of the haematin complex is understood to be due to its large planar system of conjugated double bonds, and dipoles induced in this system

must reach their maximum value when the electrical vibration of the light is parallel to the plane containing the double bonds. This relation between pleochroism and molecular orientation has been established by Bernal and others, who applied it to the structure analysis of crystals possessing layers of flat molecules or chains*.

X-ray data showed that the four haeme groups in methaemoglobin must be arranged in pairs related by twofold axis¹. Their parallelism now indicates that they may lie at the corners of a square as suggested by Pauling². In horse oxyhaemoglobin their arrangement appears to be the same as in methaemoglobin, since its crystals belong to the same system, have similar axial ratios and exhibit the same type of pleochroism³. According to Haurowitz⁴, reduced horse haemoglobin crystallizes in the form of hexagonal plates, which on contact with oxygen change spontaneously into the monoclinic needles of oxyhaemoglobin. This change of symmetry indicates that a rearrangement of the haeme groups may take place on reduction.

I have to thank Dr. G. S. Adair for his collaboration in preparing the crystals, Prof. J. D. Bernal for suggesting this research, and Prof. D. Keilin and Dr. E. F. Hartree for much practical help and advice.

Summary. The absorption spectra of single crystals of haemoglobin in polarized light have been examined. In met- and oxyhaemoglobin of horse and in methaemoglobin of sheep, the width and strength of the absorption bands was dependent on the vibration direction of the polarized light. The results indicate an approximate parallelism of the four haeme groups in the met- and oxyhaemoglobin molecule.

Chemistry and its Applications in Modern Life

Meeting of the American Chemical Society

A MEETING of the American Chemical Society was held early in April at Baltimore, when many papers of topical interest were presented. Grouping the papers by subjects, it is possible to indicate some of the more striking advances which were recorded.

One group of papers dealt with vitamins and hormones. The close relation between vitamin A and vitamin A₂ (occurring in visual purple and in the livers of freshwater fish) has been established by distillation under very low pressure. Papers on the content of vitamin C in various vegetables and its changes on boiling and storage showed, among other things, that loss on boiling is reduced by putting a cover on the vessel so as to exclude air. A covered aluminium vessel was better than covered glass or enamel vessels unless sodium carbonate was added to the green vegetable, in which case the loss was greater with the aluminium vessel. Contrary to the general belief that citrus fruits and tomatoes are the

richest sources of the antiscorbutic vitamin C, it has been found that freshly picked parsley, broccoli, kale and cauliflower contain two to three times as much vitamin C as citrus fruits. Vitamin A concentrates were found not to lower the fat content of milk produced by cows fed on them, whilst fish oils tended to lower the fat content.

Whey has been shown to be a valuable source of vitamins and vitamin products, including all the known water-soluble vitamins, the fat-soluble provitamin D, vitamin K (pro-thrombin), vitamin E, oestrin and vitamin B₂ or G. The importance of whey as an adjunct to feeding animals was shown experimentally. The use of whey products in human foods, especially in bakery goods and confectionery, has also been the object of research.

Zinc insulin crystals have been widely used in the treatment of diabetes in the United States and Canada. The chemistry of the visual systems and of the adrenal cortical hormones has been actively

worked upon. Adrenal gland extract has been shown to contain at least twenty-four different substances allied to cholesterol, bile acids and the sex hormones, one of them being progesterone, the hormone produced by the corpus luteum of the ovary. The biological functions of the pituitary gland have been more closely investigated and the results correct many views formerly held in this field. For example, it is now known that certain physiological effects claimed to be due to different separate anterior pituitary principles can be attributed to one principle, exerting these effects in ways depending on its mode of administration. Doubt has been cast on the assumption that the thyroid stimulating effect of the pituitary is produced by a separate principle acting on the thyroid gland only.

Another group of papers dealt with cellulose and cellulose products. The purification and utilization of wood cellulose have been investigated, and the suitability of various kinds of woods studied. The main object in view was the production of a cellulose suitable for the production of viscose, since this accounts for 80 per cent of the wood-pulp cellulose used for chemical purposes. An interesting paper dealt with the use of the whole cotton plant with ripe bolls for the production of cellulose; the oil is first extracted from the seeds of the whole ground plant and the cellulose isolated from the residue.

Petroleum and its products received attention from several points of view. The dehydrogenation of petroleum by cracking has led to an increased supply of reactive olefines used in the synthesis of iso-octane, ketones, organic derivatives and plastics. The production of aviation fuels by high-pressure hydrogenation is increasing, one of the principal blending agents being iso-octane. New catalysts have been developed. The superior fuels now available have enabled engine manufacturers to build engines capable of greater power output per unit weight. The stabilization of petrols by small quantities of organic compounds known as deactivators, which prevent oxidation, is an important advance.

Casein products and the utilization of lactic acid provided topics of interest from the point of view of plastics, including polymethylacrylate from lactic acid. A wool-like fibre is made from casein by dissolving in alkali solution and forcing under pressure into a solution containing acid, formaldehyde and either salts or sugars. The fibre is then treated with oils and other substances to increase its flexibility and strength and to bleach it, and is cut into staple lengths, carded and spun into yarn. It may be dyed and laundered in the same way as wool. It shrinks less than wool but has poor tensile strength, especially when wet.

Resins, shellac varnishes, house paints, organic sulphur compounds, and other topics of technical interest also featured in the papers. Of more academic interest were papers on exchange reactions of heavy isotopes of oxygen and nitrogen. The use of aspartic acid as an anticoagulant for blood is of medical interest, as it prevents clotting in the circulation. Aspartic acid is a natural component of plant and animal tissues; it is used as the sodium salt injected intramuscularly, but further studies are to be made of the possible injurious effects on the kidney such as are noted with other anticoagulants. It is stated that, of the long list of amino-acids formed from proteins in digestion, only two have any appreciable effect in preventing clotting, namely, cysteine and aspartic acid, and aspartic acid is much more potent.

Science News a Century Ago

The Zoological Society

THE anniversary meeting of the Zoological Society was held on April 29, 1839, Lord Braybrooke being in the chair, when the reports for the year were submitted. That by the auditors stated that the receipts had been £14,094 2s. 9d. and the expenditure £12,588 12s. 1d. Among the assets of the Society was the farm at Kingston valued at £11,000. In the report of the Council it was stated that steps were being taken to reduce greatly the permanent expenditure. In 1837 salaries were £3,548, but for the coming year that would be reduced to £2,916. An increase had taken place in the cost of provisions due to an increase in the number of animals, "and amongst other circumstances to the growth of the larger elephant". There were 3,010 members of the Society, 38 candidates for election and 126 corresponding members. The Museum contained 760 mammalia, 5,230 birds, 1,000 reptiles, 1,170 fishes and 83 mounted skeletons.

Jupiter's Satellites

UNDER the above title, the *Athenaeum* of May 4, 1839, said, "An irregularity in the first satellite of Jupiter has for some time attracted the attention of M. Boguslawski, the director of the observatory at Breslau. He observed it on the 14th of April 1838, and on the 1st of May he made further observations, when he found that its lustre, which, generally speaking, is greater than that of the second, appears to be much weaker when it quits the disc of the planet after its passage across, especially when its shadow is seen upon Jupiter. By means of the heliometer he kept the second satellite always by the side of the first, and at the same distance from the disc, in order to ascertain if the light of the planet were the cause of the diminution. For several hours after leaving the disc at 12 h. 54' 26.2" sidereal time, the first satellite was evidently paler than the second; it then slowly began to resume its light, but which at 15 h. 18' had not yet attained that of the second. The next day it had quite resumed its lustre, and again surpassed that of the second".

Palon Heinrich Ludwig von Boguslawski was born at Magdeburg in 1789 and died in 1851. He was well known for his observations of comets and published an astronomical year-book, entitled "Uranos".

Further Discoveries by M. Lartet

IN its column of Miscellaneous, the *Athenaeum* of May 4, 1839, said: "The indefatigable M. Lartet, of whose labours we have so often spoken, announced the discovery of two fossil Carnivora, one of which appears to constitute a sub-genus, intermediate between the badger and the otter, and the second approaching to the dog, differing but little from that gigantic fossil which he has described under the name of *Amphicyon*. He is of the opinion that the latter is the same animal as that of which some remains were found at Epelsheim, and which constitute the *Agnotherium* of M. Kaup. There are a considerable number of fossil mammifera found on the border of the Rhine, which appear to be identical with those which are daily brought to light at the foot of the Pyrenees. These affinities are the more interesting, because the intermediate countries, Auvergne, for instance, possessed very different races of animals."

Societies and Academies

Paris*

Academy of Sciences (C.R., 208, 853-952,
March 20, 1939).

A. ROSE: Thermal dissociation of zinc carbonate.
A. DOGNON and C. PIFFAUT: Action of various radiations on superficial films of proteins.

MME. M.-E. RUMPF-NORDMANN: Contribution to the study of some permolybdates.

E. GRILLOT: Lead halogen-ethanoates.

H. SCAFFTA: A phenomenon of *expirgation altitque* of tropical soil in West Africa.

N. MENCHIKOFF: Carboniferous of Issaouane (Central Sahara).

C. FRANCOIS-BOTUF: Remarks on some measurements of salinity of the waters of the Orne, between Jaen and the mouth (Franceville).

L. CAGNIARD: Propagation of a signal in a rarefied ionized atmosphere. The speed is that of the group.

G. BOUVRAIN: Presence of woody bundles in the upper part of the root of *Helianthus annuus* (var. *viriflorus*).

J. MAGROU: New attempts at the cultivation of mycorrhizal fungi.

MME. L. LEVINA: Contribution to the study of the movement of water and of dissolved substances across plant tissues.

L. PLANTEFOL and R. GAUTHIER: Glucose and the respiration of plant tissue cultures.

A. DE PUYMAY: Modifications undergone by an alga taking part in the constitution of a lichen *Placynthium nigrum* S. Gray).

MME. L. PITTIER: Differentiation of reproductive organs in abnormal buds of *Solanum tuberosum* L. var *Estorlingen*.

MME. S. VILLENEUVE-BRACHON: Superficial structures of heterotrich ciliates and the genetic continuity of their *cinétozo*.

P. LEBES: Polymorphism of certain Bostrychid Coleoptera.

M. ROSE: Physiology of the parabasal of *Trypanophis Grobneri* Poche.

MME. L. RANDOIN and C.-P. LEBLOND: New biochemical method of estimating vitamin C.

MME. P. BERTHELE: Coefficient of specific magnetization of oxyhaemoglobin.

A. LEBES: Examination of some substances as precursors of ascorbic acid.

J.-H. VIVIEN: Role of the hypophysis in the determinism of the female genital cycle of a teleostean, *Gobius paganelus* L.

J.-O. VILIS: Physico-chemical properties of desoxycholic acid.

(*Continued from p. 695.)

Cracow

Polish Academy of Sciences and Letters (Feb 6, 1939).

S. BANACH: The 'supreme law' of Hoene-Wronski.

MME. L. STANKIEWICZ: Some formulae of the calculus of inverses.

M. WOJCIK: The degenerate states of helium. If the two states I and II are due to degeneration, they ought to exist also in solid and gaseous helium.

M. KAMINSKI: Origin of Wolf's comet (1).

S. PIOTROWSKI: Graphical method for finding pairs of stars of which the geographic latitude is determined by the method of corresponding heights.

J. CHOJNACKI: Modifications of biacene ($C_{24}H_{18}$). Two forms, α and β , are obtained by crystallization of solutions in benzene below and above $100^\circ C$. respectively. Crystallographic data are given.

M. CHENTERSZWER and A. WOLDENBERG: Presumed disaggregation of metals in liquids under the influence of ultra-violet light. Colloidal solutions in water of iron, lead, silver and mercury are formed, due to the production of ozone which acts as an oxidizing agent.

MME. R. LUDWICZAK and J. SUZKO: (1) Dibrom derivatives of quinidines and their transformation into natural bases. (2) Vinyl-phenol bases of quinidine: cupreine and cupreidine.

K. KONIOR: Geological structure of the neighbourhood of Strzyków.

A. BURSA, MME. H. WOJTUSIAK and R. J. WOJTUSIAK: Researches on the submarine fauna and flora of the Bay of Gdańsk, Baltic Sea, carried out with the aid of a diving apparatus.

J. BOBYNOWICZ: Comparative researches on the cyto-architecture of the corpus geniculatum externum.

E. BORTO LOTTI: Differential projective geometry of dualistic transformations.

R. CALAPSO: Deformation of the Voce lattices of a Euclidean S_4 .

C. MIRANDA: A problem of differential geometry set by Minkowski.

U. SALINI: Applications of Minding's method for the deformation of ruled surfaces.

A. TONOLO: Extension of a trigonometrical theorem of Legendre.

M. VILLA: Quasi-asymptotic curves (1).

G. COLONNETTI: Investigation of the experimental foundations of the theory of elasto-plastic equilibrium.

G. B. BONINO and R. MANZONI-ANSIDINI: Raman spectrum of ortho-deuteroxybenzaldehyde.

G. GOMDANICH: Influence of the stock on the receptivity of the graft towards parasitic infections.

V. ZAGAMI: Researches on the seminal fluid (8). pH value of the seminal fluid of the rabbit.

Forthcoming Events

[Meeting marked with an asterisk is open to the public.]

Monday, May 1

ROYAL GEOGRAPHICAL SOCIETY, at 5.30.—A. M. Champion: "By Motor Van from Cape Verde to Nairobi" (Film).

Tuesday, May 2

UNIVERSITY COLLEGE, LONDON, at 5.—Prof. E. J. Bigwood: "Chemical Reactions between Proteins and Electrolytes".*

ST. MARY'S HOSPITAL, LONDON, W.2, at 5.—Dr. Wilson Smith: "The Prevention and Control of Virus Diseases".

INSTITUTION OF CIVIL ENGINEERS.—Prof. Karl von Terzaghi: "Soil Mechanics: A New Chapter in Engineering Science" (James Forrest Lecture).

Thursday, May 4

UNIVERSITY OF CAMBRIDGE (CAYNENDISH LABORATORY at 4.30.—Prof. P. M. S. Blackett, F.R.S.: "Cosmic Rays: New Results and Further Problems" (Soc. Lectures. Succeeding lectures on May 5 and 8).

PHYSICAL, CHEMICAL AND ROYAL METEOROLOGICAL SOCIETIES (at the Royal Institution), at 5.30.—Discussion on "Chemical and Physical Investigations of the Upper Atmosphere" to be opened by Prof. F. A. Paneth.

Friday, May 5

ROYAL INSTITUTION, at 9.—Prof. W. L. Bragg, F.R.S. "Magnets".

IRON AND STEEL INSTITUTE, May 3-5. Annual meeting to be held at the Institution of Civil Engineers.

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

SCIENTIFIC OFFICERS, JUNIOR SCIENTIFIC OFFICERS AND ASSISTANTS (grade II) in the Chemical Defence Research Establishment, Sutto Oak, or the Chemical Defence Experimental Station, Porton—Chief Superintendent, O.D.R.D., 14 Grosvenor Gardens, London, S.W. (May 5).

ASSISTANT CHEMIST for the London Shellac Research Bureau—The High Commissioner for India, General Department, India House Aldwych, W.O.2 (May 6).

SENIOR RESEARCH OFFICER (grade II) to take charge of the Poultry Disease Laboratory, Edinburgh and RESEARCH OFFICERS for work in parasitology in the Veterinary Laboratory, Weybridge—The Secretary Ministry of Agriculture and Fisheries, 10 Whitehall Place, London S.W.1 (May 8).

PROFESSOR OF GEOGRAPHY in an Art College for Girls to be opened in Calcutta—The High Commissioner for India, General Department India House, Aldwych, London, W.O.2 (May 13. Quote 3/64A).

JUNIOR SCIENTIFIC OFFICERS in the Chemical Research Laboratory Teddington, Middlesex—The Establishment Officer, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster S.W.1 (ref. J 89/6, May 16).

SENIOR LECTURER in the ZOOLOGY OF VERTEBRATES and JUNIOR LECTURER in the ZOOLOGY OF INVERTEBRATES in the University of Edinburgh—The Secretary (May 23).

NIGHT CHEMISTS in Admiralty Cordite Factories—Secretary of the Admiralty (O.E. Branch II), London, S.W.1.

Industrial Development and Social Welfare

FEW major questions have emerged so rapidly from the theoretical to the practical stage in recent years as that of the location of industry. When the problems of the location of industry in Great Britain were first discussed by Political and Economic Planning (P.E.P.) in 1931, the idea of aiding the location of industry was generally dismissed as impracticable, and little improvement in public opinion was discernible when P.E.P. in 1935 first began the preparation of its report on this question, a summary of which appears elsewhere in this issue (p. 770). Since then, however, many authorities and considerations have stressed the importance and urgency of attention to the complex problems which this question presents.

This was one of the main points made by Lord Stamp in urging the establishment of a Royal Commission upon population changes and the agencies required to deal with questions arising from these problems as they develop. A programme of research proposed by a group of experts in the universities, quoted by Lord Stamp in his "The Science of Social Adjustment", includes a quantitative investigation of regional distribution of population with reference, among other matters, to the location of industry. The report of the Town Planning Institute last year, recommending the National Advisory Board, directed attention to the importance of recognizing trends in population changes due to the location of industry as well as to changes in age distribution and the declining birth-rate.

Already in 1934, in endowing the Commissioners for the Special Areas with financial and other powers to induce industries to locate themselves in areas of unemployment, Parliament has given limited shape to the public concern that industrial enterprise should be so prompted and directed

that it would meet effectually the requirements of the community, not only in the supply of goods and services at the point where they are wanted, but also in the supply of employment where it is wanted. The reality of that public concern finds further expression in the view asserted in Parliament and elsewhere that the Special Areas Act itself is an experiment to determine the value to these areas of providing special treatment, and to learn whether the results obtained warrant a wider application. The pressure of opinion which compelled the Government early in 1937 to over-rule a departmental decision to build an aircraft factory in the Maidenhead district sprang as much from growing awareness of the necessity of long-range statesmanship and resolute scientific investigation in the interlocked problems of town planning, location of industry, national health and defence and the provision of amenities, as from the threat to amenities and the vulnerability of a factory contiguous with the Greater London area.

The dangers of the excessive concentration in the Greater London area were emphasized in many ways at the time of the September crisis last year, and planned control of the growth of London has been advocated by Sir Raymond Unwin before the Garden Cities and Town Planning Associations. Since then, the question of planning the location of industry in regard to defence has assumed increasing importance as a factor in defence against air attack, and defence considerations have to be taken into account in any system of State guidance or location of industry.

The P.E.P. report leaves no room for doubt as to the complexity of the problem and its dynamic rather than static character. Essentially the location of industry involves the problem of the

use of the land. This is the affair of town and country planning and of land management. With this particular aspect, local authority planning committees, the Ministry of Health, individual landowners and agents in charge of public or semi-public estates are already dealing. The chief need here is to secure a better informed and more co-ordinated type of development, through a central planning body able to collect the necessary information and use it in guiding the local authorities concerned. Some pooling of ownership and management, in the public interest, of land in and around growing towns may also be required.

Secondly, there is involved the maintenance of a balance between different regions of Great Britain which will prevent some from exploiting and sapping the vitality of others, and in particular prevent London from dominating further and enfeebling the life of the rest of the country. The third problem is regional development and the guidance of the location of industry. This problem affects the industrialist, the utility services, the Board of Trade and the Ministries of Labour and Transport, just as the second concerns public administration, aided by the universities, the British Broadcasting Corporation and other cultural agencies.

The report frankly recognizes that a long-term policy is involved, and that many years may pass before the full effect of that policy is felt, even if a number of immediate steps could be taken to improve the present situation or minimize its dangers. The first need is, however, the elaboration of a definite and constructive national policy, and in this a clear statement of objectives is required. The State, it is true, cannot be expected to avert the consequences to industries of natural phenomena, technical progress or international forces. At the best it can only mitigate them. When, however, the odds are lengthening against the selection, by the most far-sighted industrialist, of a location which will remain economic for him for a long period, owing to the increasing rate of technological change and the multiplication of extraneous and unpredictable factors, it is essential that the State be prepared to establish services which will enable the industrialist to perform his function more efficiently.

To promote the efficient functioning of industry without detriment to existing standards of living or disruption of society is one of the first objects of national industrial policy. A second objective must be the co-ordination of the many State

activities which affect industry and economics, and as to eliminate overlapping and waste and to co-ordinate the provision of State services generally with industrial requirements over a long period. Powers will also be required to curb the activities of the minority of economic pirates whose influence may be out of proportion to their numbers, and it is now necessary for the State to possess power to direct the nature of industrial development with reference to the requirements of national security.

The primary need, accordingly, is a well-formulated but flexible policy which will guide the use of all national resources. In several spheres start has already been made in this direction: the unification of coal royalties in the hands of the Coal Commission, the establishment of the Electricity Commission and of the Central Electricity Board, as well as the unification of numerous local bodies into catchment boards, being examples. As yet, however, the control of the use of the land under the Town and Country Planning Act which must form the starting-point of any form of actual control over national resources, is scarcely effective, and it is evident that local authorities should be given more explicit guidance in the principles they should observe.

Industrial location is, of course, a wider problem involving a balance between the varied economic requirements of the community and the requirements of the manufacturer, and a fundamental conclusion of the report is that it requires treatment as a whole on a national as well as on a regional or local scale. Reconditioning of the present Special Areas and the prevention of the recurrence of the same troubles elsewhere can only be a gradual process. Permanent machinery is required for guiding and adjusting industrial growth.

Extension of national action in this respect would require a reassessment of priorities, and this in turn involves the collection of information and the evolution of a satisfactory method of measurement. Existing methods of measurement have scarcely been adequate for the complex problem of measuring the current prosperity and future prospects of localities, and accordingly one of the major tasks of the Industrial Development Commission proposed in the report would be the provision of a centralized information service to assist industrialists in the choice of sites and locations of new plant and in problems of industrial development generally.

This proposed Commission would accordingly be charged with the responsibility of keeping und

review factors affecting the efficient operation of industry, with particular reference to those factors arising from the choice of location. It should be empowered to publish information concerning the facilities available for the establishment of factories in all suitable areas. It should be provided that the services of the officers of the Commission would be available for prior consultation by persons desiring to apply for licences in respect of new factories or extensions.

This is regarded as one of the most important sections of the work of the proposed Commission, and the smooth working of the machinery as a whole would probably depend largely upon the success achieved by the Commission in collecting and disseminating information and advice calculated to assist manufacturers in this matter. An efficient central advisory service, in practice, might obviate all question of compulsion in the majority of individual cases, since the choice of a suitable site would be determined in amicable agreement, and confirmation of that choice through the licensing machinery would then be a formality. Moreover, such a service, on the basis of continued research, should relieve industrialists of the laborious and wasteful task of conducting their own preliminary investigations, and present the relevant facts for consideration much more rapidly and lucidly. It might also put before the industrialist factors he might otherwise overlook, such as the interest of the industrialist as well as of the community in creating and maintaining a reasonable balance of industries within broad economic regions.

The organization of an efficient information service is largely a matter of intensive economic research into the growth of industry and the factors affecting it, and of ensuring that the service is recognized by industry and used in practice as a matter of course. The task of undertaking the necessary research and keeping the information up to date should not, however, be underestimated. It involves, for example, the determination of the economic regions into which Great Britain would be divided by the Commission, and the needs of those regions in relation to industrial balance. A comprehensive knowledge of sites available and suitable for further industrial development is essential as well as a full knowledge of the existing distribution of industry and of national resources generally. It also involves the determination of a line of policy with regard to social and strategic considerations

in relation to the distribution of unemployment, vulnerability to attack and other factors.

We have here, in fact, a scientific approach and a programme of research which have long been advocated by those, within the ranks of scientific workers or without, who have sought to approach these complex problems in the spirit of science. This alone should commend the report and its recommendations to the interest and support of scientific workers, while the value and magnitude of this preparatory work are indicated in the opinion expressed in the report that a considerable interval would be justified between the establishment of the Commission and the coming into force of certain of its executive powers, such as the licensing provisions.

The second main purpose of the Industrial Development Commission recommended by the report is the co-ordination of policies and actions of central and local government authorities, public utilities and other institutions, and it is in pursuance of the task of guiding the future location of industry, to avoid the repetition and multiplication of mistakes of the past, that the report suggests that the Commission should be charged with the responsibility of licensing new factories or extensions to existing factories. Such powers of restraint are regarded as essential, although it is believed that only rarely would it be necessary for the Commission to exercise its veto. Not the least service of the report is the way in which, fairly but undisguisedly, it puts the case for such compulsion.

These proposals of the report in regard to the licensing of new factories and evacuation and resettlement schemes for derelict areas, radical as they seem, are only the logical extension of principles which have already been tentatively adopted. Moreover, the clear but far-sighted statement of the principles of evacuation or re-settlement which the report contains should dissipate controversy on general ideas and facilitate the elaboration and execution of detailed plans, even if the financial estimates of the report prove to be somewhat optimistic. The conception of spending to create a model town, instead of prolonging the life of one that is moribund, is essentially in keeping with a scientific policy, and the bold constructive proposals of this report have strong claims on the attention of all scientific workers who are in sympathy with its underlying conception of a new co-operation both in form and in purpose for the integration of industrial expansion and social welfare and stability.

Science and Trusteeship in Africa

Science in Africa

A Review of Scientific Research relating to Tropical and Southern Africa. By Dr. E. B. Worthington. (Issued by the Committee of the African Research Survey under the auspices of the Royal Institute of International Affairs.) Pp. xiv+746. (London, New York and Toronto: Oxford University Press, 1938.) 10s. 6d. net.

IN his Rhodes Memorial lecture in 1929, General Smuts directed attention to the paucity of information available regarding the policies, activities and plans of the different European colonial powers in Africa, and made the valuable suggestion that a comprehensive survey should be undertaken to collect such material. A committee was appointed to give practical effect to his proposal; funds were made available by the Carnegie Corporation of New York; Sir Malcolm (now Lord) Hailey was invited to direct the survey, and a number of preparatory studies of different aspects of the survey were commissioned. Among other studies, Dr. E. B. Worthington, whose biological studies of East African lakes are well known, was asked to prepare a report on the progress of scientific research and technical services having a bearing on African development. Dr. Worthington began this work in the autumn of 1933, and in the course of his studies accompanied Lord Hailey during 1935 and 1936 in his visits to Nigeria, Dahomey, Togoland, the Gold Coast, Sierra Leone, Gambia, Senegal and the French Sudan.

When Dr. Worthington's draft report was completed, the committee in charge of the Survey came to the conclusion that the material it contained should be published as a separate volume: for while much of it could be summarized and incorporated in Lord Hailey's comprehensive survey, to do full justice to Dr. Worthington's studies and to provide scientific workers and scientific and technical institutions, both in Africa and Europe, as well as the many interests associated with African finance and administration, with a detailed record of scientific endeavour and its bearing upon African development, demanded space which would have added too greatly to the bulk of the major volume and upset its balance. The committee is to be congratulated on its decision and Dr. Worthington on the result of his labours. With the assistance of specialists in many fields of research, he has presented us with a clear account of the nature and extent of the

problems confronting African administrations, the contributions which scientific workers have already made towards their solutions, an indication of the paths in which their future activities should be directed and the organization necessary in order that the results of research may be more effectively applied.

From one point of view this is an encouraging volume: from another, exasperating. It is encouraging because much has been done during the past fourteen years to improve and extend the scientific and technical services in British Colonial Africa, where any existed, and to provide them where there were none. At least some of the prejudice against central research stations has been broken down with recognition of their obvious utility. Also there is a growing tendency to utilize the services provided by the Imperial Research Bureaux. Other European Colonial powers are paying much more attention to the function of utilitarian scientific research in the development of Africa's resources. The Belgians—to a lesser extent the French—have developed a system of co-ordination between scientific workers in Africa and those in the universities and research institutions in Europe which presents features that might with advantage be incorporated in our own. Another important point is the realization by the several European Colonial powers that certain problems are common to all African territories, for the solution of which international co-operation and pooling of funds and effort is essential. Some of this co-operation is effected through the Health Section of the League of Nations, some by the interchange of information and literature between the different centres in Europe, and at least one major menace, the locust, has led to the formation of an International Locust Control Committee.

It is expecting too much, however, for international co-operation to advance rapidly while the co-ordination of research and technical services of British territories is still meeting with opposition. Many local executive and legislative councils still lack the vision to realize that well-staffed and well-equipped laboratories serving groups of territories and drawing financial support from each member territory of the group would result in economies as well as more effective work, at the same time giving urgently needed assistance to those territories which at present lack the money to provide any research services of their own. Again, even in some British territories there is

such avoidable waste of effort due to the non-existence of any machinery for the systematic collection and dissemination of data from the notebooks of field-workers: neither is there any effective agency for the interchange of results and information between the different scientific and technical departments. Further, there is still far too little co-operation between the universities of the British Empire and other centres of research, and those agencies directly responsible for the investigation of African problems.

There is yet another aspect of co-operation to which Dr. Worthington directs attention. It must be obvious that the fight against human, animal and plant diseases, the war against pests like the mosquito, tsetse-fly and locust, effective measures against erosion, soil desiccation and the destruction of forests, and the general improvement in methods of cultivation, stock-raising and the health of the people, depend upon the effective co-operation of Africans with the European personnel. In their present stage of development, the tropical and sub-tropical African territories cannot be expected to shoulder much more in the shape of additional financial burdens involved in the essential expansion of the specialist services, unless the expansion either takes the form of the employment of African personnel or the European powers are prepared to advance the necessary funds for considerably more European specialists. But even if money is forthcoming from outside Africa, it would better be spent on the training and recruitment of Africans than on the provision of many more

Europeans. Already the time of many highly trained Europeans is too much occupied in performing routine field duties which experience has shown could be quite efficiently done by Africans were they given the necessary preliminary education and training. This much is certain—not until there are thousands of trained Africans co-operating with Europeans will the results of the researches of the latter into African problems bear the fruit they deserve. Africa has an abundance of generals, but it lacks the disciplined forces to fight this epic battle with Nature. Mass education for Africans alone can provide the material from which these forces can be raised.

It is impossible to give, even in outline, an account of the work on African problems which Dr. Worthington surveys in seventeen chapters on the different specialist services, or even to summarize the gaps and deficiencies which must be made good. It must suffice to commend the volume to the attention of all scientific workers interested in tropical and sub-tropical research: to all individuals and companies interested in the economic development of the territories: to all missionaries and education officers: and to all members of African administrative services. It will be of the greatest service to them. Together with Lord Hailey's survey and Prof. Frankel's masterly account of "Capital Investment in Africa", it should help them to appreciate the magnitude and complexities of the tasks before them and, above all, the implications of European trusteeship.

Precautions against Air Raids

Commonsense and A.R.P.

A Practical Guide for Householders and Business Managers. By Major-General C. H. Foulkes. Pp. 92. (London: C. Arthur Pearson, Ltd., 1939.) 1s. net.

THERE has been so much nonsense talked and written about A.R.P. that it is refreshing to read this little book, even if one does not entirely agree with all it contains. It will not be popular to suggest that the reason for the better balance with which the subject is here presented is that the book is written by a soldier; but much misunderstanding would be avoided if the public could be made to realize that A.R.P. is a war problem. It is true that General Foulkes is an exceptional soldier, because besides being an engineer officer of great experience he was Director

of Gas Services during the war of 1914-18; so that anything he has to say, either on the subject of cover from high explosive or on defence against gas, is worthy of the closest attention. He has also been consulted by many important works and offices about their A.R.P. schemes, so that he has a wide knowledge of the problems that actually arise. The book lives up to its title, and is a simple and practical guide to those who wish to take reasonable precautions.

I must join issue with General Foulkes on one point. On p. 27 he says:

"Expert opinion is now almost unanimous in believing that gas is very unlikely to be used, not because of its supposed inhumanity, but because it would not be as effective, weight for weight, as high explosives when employed against an organised community sheltered in buildings. The

conditions were very different in the chaotic state of the battlefield: men had necessarily to occupy gas-contaminated ground for days at a time; and guns had to be served and ration and working parties were compelled to expose themselves in the open. Decontamination of scores of square miles of scarred surface was an obvious impossibility, and the air in a bombarded area remained dangerous for days, while contaminated mud was often carried unwittingly into sleeping quarters, with disastrous results."

Now consider an area containing important munition works surrounded, as many are, by workers' dwellings; after a bombardment with high explosive many of the houses would be blown down, and the area covered with dust and debris. If such an area were bombarded with mustard gas it would be extremely difficult to decontaminate—in fact, the present method of decontamination would not succeed in removing mustard gas from a pile of broken brick and plaster—so that, to quote General Foulkes, the air in the bombarded area would remain dangerous for days. The workers would therefore either have to evacuate the area, remain in their houses, or stay in the factories. Unless they stayed in the factories, work would be stopped, and even if they did stay, transport to and from the factories would have to pass through the area to bring food and materials and to remove manufactured articles. In any event, I think that there would be a large

number of slight casualties from carelessness, and a hundred thousand sick, on account of the care they would require, may be a great disadvantage in war.

I do not wish to exaggerate the power of gas, but it is dangerous to belittle it, and we should not forget that during the Great War mustard gas was distributed in shells and only came in pints, whereas in aeroplane bombs it would come in gallons.

The book makes no mention of the magnesium incendiary bomb, which in my opinion is likely to prove more effective than the thermit bomb. I am also sorry to find that there is no reference to the possible use of bacteria. But perhaps these matters are left out for the sake of simplicity which is the keynote of the whole book.

The author has a keen sense of humour but he has carefully suppressed it, so that it only breaks out, generally in the form of a footnote, when some irresistible absurdity has to be exposed. The book is cheap, clear, and concise, and should be read by everyone in a position of responsibility. Its value is largely due to the acceptance of three fundamental facts, namely: (1) that if we fight at all the paramount policy is to win the war; (2) that our resources, though large, are not unlimited, and must be disposed of in accordance with this policy; and (3) that in war time some casualties are inevitable.

H. A. Sisson.

To-day and To-morrow in Inorganic Chemistry

Modern Aspects of Inorganic Chemistry

By Dr. H. J. Emeléus and Dr. J. S. Anderson. (Twentieth-Century Chemistry.) Pp. xi+536. (London: George Routledge and Sons, Ltd., 1938.) 25s. net.

THE science of inorganic chemistry to-day is very different from what it was fifty years ago; it has been invaded, even pervaded, by physics to an extent that it is the physical and physico-chemical aspects which are taught to-day and are destined to provide the developments of to-morrow.

The modern student of honours standard has no difficulty in approaching the subject from this angle; the older generation find it less easy, especially as the rate of progress is so fast that what is regarded as fact to-day may be cast aside to-morrow. Perhaps only believers should study modern physics; critics as a class may have to

wait a decade before they are tolerated as of service.

The personal reputation of the authors of the work under notice ensures their competency to undertake the task, which they avow in the preface, of reviewing the developments of the last two decades and relating them to the science as a whole: the book is intended for teachers, honours students and research workers and has the further laudable object of helping to overcome the comparative neglect of inorganic chemistry in Great Britain as compared with its popularity in Germany. The authors believe that it should rank as an absorbing experimental science which offers unlimited opportunities for the development of new experimental methods.

The reviewer endorses this view the more because he clearly remembers practically the same thing being said by the greatest of organic

hemists, Emil Fischer, about 1900 to his two young assistants, O. Ruff and A. Stock, when first causing them to work on the subject of inorganic chemistry. The literature shows how much these two men and their students have now contributed to the subject, and one can admire the prescience of Fischer at a time when organic chemistry was so vigorous. It is to be hoped both that the British authors will imitate the men mentioned and that their book will inspire others to do likewise.

The time-worn method of discussing the elements in groups has been abandoned. First comes atomic, then molecular structure, followed by

chapters on co-ordination compounds and inorganic stereochemistry, which leads up to polyacids and silicates. Hydrogen and the hydrides receive a chapter, as do the peroxides and peracids, the carbonyls, etc. Another section deals with reactions in liquid ammonia and liquid sulphur dioxide, and a final one with radioactivity and atomic disintegration.

At bottom the book is essentially chemical, and though stiff reading to many of us, it is as clearly written as is possible in these days when scientific language contains so many coined words that it requires the aid of a glossary to interpret it.

Rock Carvings in the Far North

Monumental Art of Northern Europe from the Stone Age

by Gustaf Hallström. 1: The Norwegian Localities. Pp. 544 + 64 + 48 plates. (Stockholm: Bokförlags Aktiebolaget Thule, 1938.) n.p.

THE occurrence of rock carvings in Norway and Sweden has long been known. They are found on hard rock surfaces on the west coasts of Scandinavia from the county of Tromsø right up to the north to the extreme south of Sweden. They also occur inland in Jemtland and elsewhere. More than one technique can be observed and alimpeests also have been found. Clearly this art includes figures of very different ages. Actually two distinct groups can be distinguished. One is centred in Bohuslän, north of Göteborg, and is well known, being characterized by the large number of ships depicted; it dates for the main part to the Bronze Age and has been well studied and published; figures belonging to it are found so far north as the Trondhjem district.

The second group, with which the present work is concerned, is the older. This can be demonstrated at Bardal where a superposition occurs, figures belonging to the Bronze Age group being uppermost. For the most part these older rock carvings are of animals executed in a naturalistic or semi-naturalistic way, but signs and other figures do also occur. Very occasionally paintings both of human beings and of animals are found, but these are invariably extremely conventionalized. This earlier art group can be subdivided, a three-fold chronological sub-division having been determined by considering (a) palimpeests, (b) style, (c) position. As many of the decorated rocks occur on raised beaches which were once under

the sea, it is sometimes possible to be certain of a date *post quem*, at any rate. This art is usually connected with the Arctic Culture, the roots of which lie far back in mesolithic times. The motives underlying its production are completely unknown.

The present work is in the nature of a catalogue of this early art group in Norway. The second volume, dealing with the sites in Sweden, Finland and Russia, will be published in about a year's time. Actually, of course, the title is misleading. These glacier-worn surfaces of rock covered with engravings or peckings should not be described as monuments, but this does not detract from the very great importance of the work as a whole, and archaeologists will be particularly grateful to Dr. G. Hallström for having at last put on record a corpus of the finds. The system he has adopted is geographical, and a numbered sketch map gives the position of the various sites, which are then described in order. There is a number of illustrations at the end of the volume and a separate portfolio of reproductions of the drawings.

In no sense is the work meant for armchair reading. It is a catalogue, but none the less important for that. The English, though sometimes a trifle quaint, is not obscure. May I recommend that anyone wishing to spend an interesting vacation abroad should acquire this book and visit some of the sites therein described. Doubtless the explorer will find it wise to bind up the work in three or four smaller fascicules for convenience of handling, but I know I can promise him a very interesting expedition, made possible for the first time by the publication of this work. We all eagerly await the second volume.

M. C. BURKITT.

The Ojibwa Woman

By Ruth Landes. Pp. viii+247. (New York: Columbia University Press; London: Oxford University Press, 1938.) 15s. net.

THE psychological study, of which Miss Landes gives the results in "The Ojibwa Woman", was undertaken with the express purpose of pursuing the inquiry in conditions other than those, that is, of Western civilization, in which similar psychological investigations have usually been carried out. Her choice of the Ojibwa of western Ontario, among whom she spent seven months collecting material, was well judged. The conditions, which here form the background, were certainly both unusual and peculiar. In the Ojibwa society, which came under Miss Landes's observation, it is only the male half of the population and its activities which fall under traditional regulation. The female half is left to a spontaneous and confused behaviour. In consequence there is a wide range of development in the personalities and careers of the women. As the author says, "Some rival the most successful men in ambitions and honours received, but do not pursue them in systematic male fashion; others engage in both male and female pursuits; still others are reduced to an incompetence that continues until death". This dictum is demonstrated in detail, and the resulting conduct and mentality of men and women are contrasted in youth, in marriage, in occupations and in abnormal manifestation. The force of the study is much enhanced by a free use of the actual words of the subjects under observation, and further illuminated by a number of life-histories.

Étude pratique des rayonnements

Solaire, atmosphérique et terrestre (méthodes et résultats). Par Ch. Maurain. Pp. iv+189. (Paris: Gauthier-Villars, 1937.) 80 francs.

IN this monograph, Dr. Ch. Maurain, the director of l'Institut de Physique du Globe, covers chiefly from an observational point of view the important study of radiation, solar, atmospheric and terrestrial. Certain phenomena associated with the ionosphere indicate that the sun's ultra-violet radiation varies in sympathy with the eleven-year sunspot cycle; yet the reality of a related periodic variation of the integrated radiation (the 'solar constant') as received at the earth's surface is extremely difficult to demonstrate in spite of years of observation linked with the name of O. G. Abbot (see NATURE of April 29, p. 705). Passing from the determination of the solar constant, there is the allied study of the incoming solar radiation as it passes earthwards through the atmosphere; the long-wave radiation from atmosphere and earth, and the distribution of these various factors in the energy balance sheet, which Dines first showed meteorologists how to prepare.

The present work usefully brings together the methods of measuring the various quantities involved, the instruments used, their principles and the practical difficulties encountered. A number of numerical examples and other tabular matter include observations made at the Observatory of Saint-Maur near Paris.

La Vie morale et l'au delà

Par Jacques Chevalier. (Bibliothèque de Philosophie scientifique.) Pp. 211. (Paris: Ernest Flammarion 1938.) 17 francs.

THIS timely work gives an analysis of the ultimate causes of the darkened intellectual outlook of our time, and proposes the necessary remedies. The excess of liberty and the restriction of liberty which characterize our age are to be accounted for by the absence of strict moral discipline. But an ethical doctrine is not to be constituted at random to suit some particular ends: it must be founded upon a rigorous metaphysics embodying a clear vision of reality and the spiritual values attached to it. This reality does not stop short at the world of appearance; but it goes beyond it and causes our belief in another life the nature of which is the real foundation of our moral discipline in this world.

Written in beautiful language and displaying with restraint a valuable metaphysical experience, this recent work of the learned dean of the Faculty of Letters of the University of Grenoble is well worth of an English translation. T. G.

An Introduction to Chemistry

By Prof. John Arrend Timm. (International Chemistry Series.) Third edition. Pp. xx+568. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 21s.

IT is not surprising that Prof. Timm's book has reached a third edition since its first publication in 1930, for it has many features which will recommend it to students and teachers. It is not so much a regular text-book of physical or inorganic chemistry as a general survey of many parts of chemistry which are of particular interest. It does not deal systematically with the elements, and in fact it requires much supplementing by other books; but it takes up such topics as the atomic and molecular theories, atomic structure, valency, combustion, radioactivity, solutions and electrochemistry, colloids, and some part of organic chemistry, and develops these subjects in a very interesting manner. There are many historical allusions.

Les Méthodes actuelles de la chimie

Par Prof. Pierre Jolibois. (Collection Armand Colin. Section de Chimie, No. 37.) Troisième édition entièrement refondue. Pp. 224. (Paris: Armand Colin, 1938.) 15 francs.

THIS unpretentious little book gives a very accurate and readable survey of the fundamentals of physical chemistry and their application which all students could digest with profit. The mathematical equations are not deduced; but they are clearly stated and their applications are illustrated by well-chosen examples. Recent advances, such as Raman spectra, strong electrolytes and the structure of crystals, are included, and the sections on the phase rule are particularly good. Students who wish to improve their knowledge of scientific French and at the same time to clarify their ideas on many branches of physical chemistry will find this an excellent book for their needs.

The National Nutrition Conference

THE modern State accepts without serious question the duty of applying, without stint, all the resources of science and finance to the effective defence of its citizens from enemy attack. It would appear at least equally important that the democratic State should utilize all the help of modern science to make its citizens worth protecting.

The cost in money of providing proper and adequate food for every citizen in Great Britain who at present is unable to provide it for himself is at the worst only a fraction of the cost of defensive armaments, whilst the cost in disease, in social and industrial, or even military inefficiency and in sheer human distress of allowing malnourishment to continue is one that no civilized people can afford.

An adequate scientific basis has existed for several years for a positive national nutrition policy linking health and agriculture; there has been wide discussion of the bases of such a policy, and an increasing demand from several quarters that it be put into practice. This policy would on the one hand provide the benefits of a sufficient supply of total nutrients, and in particular of protective foods—milk and dairy produce, fresh fruit and vegetables, eggs, fish, and, to a lesser extent, fresh meat, most of which are produced at home or in the Dominions—to citizens of all ages; and on the other hand it would assist the home farmer by giving him a much larger and guaranteed market for that type of human food which the climate and soil of Great Britain are particularly fitted to provide.

All interested in the development of a healthy, physically fit citizen must therefore have welcomed the decision of the British Medical Association to call a national conference to deal with the wider aspects of nutrition.

The conference was duly held during April 27–29 at British Medical Association House. In view of the quality of the discussions and the character of the participants—there were many senior representatives of medicine, physiology and nutritional science, agriculture at home and abroad, industry, social services, and education present—their pronouncements can only be ignored by a Whitehall completely insensitive to informed public opinion. With our present Government, these discussions can scarcely fail to encourage those who frame our policy to act, and to act quickly. The gap between the extent of our nutritional knowledge and the social utilization

of such knowledge on a national scale has been widening steadily, and further delay can only mean, in terms of readily understood coinage, inferior recruits, persistent industrial inefficiency, continued high expenditure on hospitals and sanatoria, and more subsidies of the wrong kind to farmers, and, in terms of a different coinage, an unconscionable waste of human life, happiness and potentialities.

The conference covered a wide field. The inaugural address was delivered by Sir Arthur Salter, M.P., who summarized the general findings of recent nutritional surveys in Great Britain and recalled the inevitable conclusions drawn as to the inverse relationship, on the whole, between income on one hand, and disease and death-rates on the other. He pointed out the great part played by milk in the prevention of malnutrition, the severe economic penalty now attached to large, or even moderate families, and the necessity that the cost of the major items in the cost of living figure should be kept to an absolute minimum. One of the policies he advised is a standard guaranteed price to home producers of the more important foodstuffs. He criticized severely some of the recent measures adopted by the State to help farmers as ill-conceived and wasteful, and in particular the weaknesses inherent in the Agricultural Marketing Acts. By this legislation, for example, the consumer price of milk is controlled by the statutory power of the Milk Marketing Board, a body composed solely of producers, which must inevitably consider milk primarily as the channel of an important part of the farmer's income, and only secondarily as the most essential of foods. The whole system of control should be reformed so as to make the public interest prevail.

Sir Arthur gave an account of the present position of Great Britain as regards food storage requirements, and urged the need for provision of food reserves on a much more adequate scale than anything that has yet been done. One per cent of our annual defence expenditure would provide the total sum required to handle the necessary quantities.

Following the inaugural address came a discussion on the physiological aspects (misnamed in the programme the 'medical' aspects) of nutrition. Prof. E. P. Cathcart pointed out that proper nutrition depends not only on an adequate and balanced food intake, but also on exercise, sleep, housing and working conditions, and adequate relaxation of body and mind. He made a cautious

survey of some of the requirements of an adequate diet, emphasized the need for education on how best to spend a relatively low income and how to make the best use of available foodstuffs. Dietary habits, despite man's natural conservatism as regards food, are changing for the better. It is most desirable to study the means by which this slow change in dietary habits could be accelerated. Dr. G. P. Crowden mentioned, *inter alia*, one of the ways in which this is being done, namely, by wide circulation of small, inexpensive household guides on sound dietetic lines, containing shopping lists, menus and recipes.

Major-General Sir Robert McCarrison, in a cogent contribution, emphasized that there is now no controversy about the main principles of nutrition. Food, as fresh and natural as possible, produced from unimpovertished soil, is the main factor for health. He regards malnutrition as essentially a functional disturbance, and only in its later stages does malnutrition lead to gross bodily changes. His plea for more precise methods of assessing malnutrition, especially in the young, was repeated time and again throughout the conference. Another factor requiring further research and elucidation is 'freshness' in food. What exactly does freshness mean, and how important is it, nutritionally? This was mentioned by several speakers. Later speakers also stressed the real need for keeping clearly distinct the *minimal* diet, on which health might be barely maintained, and the *optimal* diet which, without excess, provides a factor of safety.

The second session, on the "Means of Stimulating Production (a) Home Agriculture" was under the chairmanship of Sir John Russell. The thesis of Lord Astor's paper, which immediately followed the chairman's pertinent remarks as to possible ways of reorganizing agriculture, was that the abolition of malnutrition should be the next major social reform. He, in common with other speakers, expressed deep dissatisfaction with recent agricultural-cum-nutritional policy. It is high time that a home agriculture should be developed which is more suited to our times and needs—among which adequate nutrition of the whole population is the foremost—and which avails itself more freely of recent scientific and mechanical progress. Although home agriculture is still very much alive, the gross output of British farming being greater than it has ever been, he considers that, with the further spread of progressive methods of production, the protective foods could be provided for all consumers at cheaper rates than those now in force. Properly planned distribution, from which redundant services have been eliminated, can still further cheapen the consumer cost of milk, for example. These benefits should not be withheld

any longer by marketing boards, whose presence freedom from Parliamentary control should be withdrawn. He enlarged on the changes which might easily be brought about in milk production and would benefit producers and consumers alike and regretted the hasty withdrawal last December of the Milk Industry Bill before it received proper consideration by Parliament. Public money being spent on agriculture now in a wasteful way which helps only a few farmers. This money should be available to finance a properly conceived national nutritional-cum-agricultural policy, which would bring health and welfare to millions, not least to the farmers themselves. Dr. Keit Murray, in a thoughtful paper, also gave reasons for believing that some form of subsidy from the Exchequer would be required, at least until such time as increased productive efficiency, a factor normally of slow operation, should have caught up.

Mr. Anthony Hurd agreed that farmers could make a much bigger contribution than they are making at present towards the better feeding of the human community, and also stressed the need for wider education in food values. Both he and Mr. Cleveland Fyfe regard it as essential to consider also the balance of farming and the need for the preservation of the fertility of the soil so that the generations of farmers who come after can continue to play their part without hindrance in the future feeding of the nation. Prof. W. C. Miller emphasized that the health and adequate nutrition of farm stock are prerequisites to the production of satisfactory dairy produce, poultry and eggs, and that any increasing demand for home-produced protective foods could not be met without a sound foundation, on the farm, of knowledge and practice of disease prevention. Proper housing, satisfactory methods of rearing, adequate exercise, as well as feeding, are as necessary to the farm animal as to the citizen if health is to be maintained.

The direct interest of the Dominions and the role of the Dominion producer in Great Britain's nutritional policy were ably dealt with by Mr. F. I. McDougall (Australia) and by other Dominion representatives. A nutrition policy for the whole Empire is needed. Malnutrition exists in acute forms in various parts of the Empire, and, in fact, in the world at large. An effective endeavour to meet it would solve not only many of the problems of Dominion food producers, but probably also some of the international problems which underlie the present tension. Recent international agreements, far from remedying the acknowledged under-nourishment of half the world, have been agreements to restrict food production, to which Dominion Governments have been hesitant and unwilling partners.

Mr. G. V. Jacks regards the high food output of some of the Dominions as the result of ruthless over-exploitation of stored soil fertility which will have to be paid for in the near future by diminished productivity due to soil exhaustion and soil erosion. In Great Britain and some of the older countries soil conservation, including manuring, draining, proper crop rotation, etc., has been carried out for centuries as a matter of course. The costs of this good farming represent the major part of the difference in costs of production between home produce and similar produce from the Dominions. Prof. S. M. Wadham would not accept this view as applying to Australia, where farmers over the really productive areas are fully alive to the danger of soil exhaustion and have already dealt with it.

There was nearly complete unanimity that lack of purchasing power among the lower income classes of the population is at present the main factor in faulty nutrition. Mr. L. S. Amery, M.P., in introducing the discussion on family allowances, pointed out that a wage system which takes no account of family needs and responsibilities is to-day inflicting grave hardships on millions of malnourished children. He made a convincing case, both on the grounds of simple social desirability and of the future industrial and defence needs of the country, for additional purchasing power for families in which there are growing children. Parents are now finding their own solution to the problem by refusing to have children, and as a consequence we are heading for national catastrophe at a speed measurable by the decline in the birth-rate. Family allowances should effect an appreciable saving on the £300 millions annually which the nation pays for ill-health, not to speak of the new wealth they would add through the positive increase of national efficiency. Mr. Amery's views were supported by Mr. Laurence Cadbury and Sir Kenneth Lee, who emphasized that no time should be lost in getting a national scheme into working order. Where private industrial schemes of family allowances are already in being, increased expenditure on food, that is, improved nutrition of the family, has been shown to be the major result. Extensions of the facilities for provision of free milk and meals direct to school children and to expectant and nursing mothers were advocated by Dr. Stella Churchill, not as a substitute for family allowances but as an efficient supplement to them. She emphasized that money spent on school meals and milk meant less spent on hospital beds, sanatoria, and unemployment in later life due to ill-health resulting from early malnutrition.

The final session of the conference, presided over by Sir Cyril Norwood, linked up the scheme

for improved nutrition with education both in the schools and amongst adults. Mr. Lester Smith stated that the colleges at which housecraft teachers are trained are very much alive to their opportunity of improving national nutrition by training their students in what to eat, as well as how to cook it. He made the useful suggestion that school journeys ought to embrace visits to farms, market gardens and orchards, as well as to industrial and manufacturing concerns. The greater use of the radio for the education of the public in matters of health and nutrition was recommended by Prof. V. H. Mottram, and the part played by the women's institutes, whose membership is largely made up of those actually responsible for the purchase and cooking of the family food, was emphasized by Mrs. Henry Haldane. This discussion made it clear that one of the main requirements in our educational system, having in view the objective of an improved national nutritional status, is a greatly increased emphasis on the elements of science and their bearing on health, throughout school life. Through this educational channel every future consumer, housewife, farmer, administrator and statesman has to pass.

The text of the resolution passed at the end of the Conference may be given in full, as it marks a clear but conservative appeal which ought soon to be reflected in Government policy.

"This conference called by the British Medical Association and composed of representatives of Medicine, Agriculture at home and overseas, Industry and Education, is deeply impressed with the importance of nutrition to the national welfare. It urges upon the Government the formulation of a long-term food policy in which the requirements of Health, Agriculture and Industry shall be considered in mutual relation. It is convinced that measures to secure the more ready availability to all sections of the community of food-stuffs which are held to be desirable on nutritional grounds should be accompanied by an educational campaign to encourage their increased consumption."

It is reasonable to expect, in a democracy, that Government policy, particularly when dealing with home needs, will be largely under informed democratic control. If, with proper knowledge of the circumstances, public opinion asks for, and is ready to pay for, improved social conditions, then if democracy means anything at all an honest and pertinacious attempt must be made by executive authority to plan and provide the necessary services. The present international tension, far from excusing any delay in making such provision for an adequate long-term food policy, sharpens the need for it.

The Living Coelacanthid Fish from South Africa

By Dr. J. L. B. Smith, Rhodes University College, Grahamstown

THE recent discovery of the Coelacanthid fish (*Latimeria chalumnae* J. L. B. Smith) near East London, as described in NATURE of March 18, p. 455, has aroused great interest. This has partly found expression in numerous requests from all parts of the world for the earliest possible publication of a detailed description. I am able to pursue my investigations only in very limited spare time. The preparation of an adequately illustrated detailed description, under present conditions, will occupy several months. I have therefore decided upon the somewhat unusual procedure of issuing a synopsis of the more important results of my investigations to date. This is in the form of brief outlines without discussion.

Few scientific workers are as fortunate as those who have concentrated upon Coelacanthid remains. The present specimen is a living tribute to the accuracy of their interpretations and reconstructions.

The specimen was somewhat damaged in the trawl, the skin having been broken in several places. Repairs were skilfully executed by the taxidermist.

Skull and head. The skull is unfortunately not quite intact. The basisphenoid and part of the structures around the foramen magnum were removed (and discarded) in mounting. The soft parts of the head appear to have been removed rather roughly. The remaining tissues are in poor condition. Only the structures left intact will be described as fact.

Air-bladder. According to the fairly definite evidence of the taxidermist, this organ was at the very most but feebly ossified.

The scales are cycloid and but little ossified. The proportion of residue after ignition of the unornamented portion of a mid-body scale is very much less than, but qualitatively identical with, that obtained by similar treatment of a teleostean scale. The exposed surface of a scale varies from one fourth to one sixth of the total area. The ornamentation on the caudal scales is in the form of spines, on the rest of the body as tubercles. The tubercles are superficial only; each is set in a thin oval basal plate with corrugated surface. The plates are attached to the scales by tissue which is softened by alkali. The tubercles are of simple structure with a central cavity (see Fig. 1). The lateral line tubes are posteriorly widely bifurcate.

Fins. All the rays of the first dorsal, of the principal and of the supplementary caudal are spinate. A few of the rays of the second dorsal and of the anal are basally feebly spinate. The outer face of the pectoral is spinate. The pelvic only are quite smooth. The bony rays of the dorsal and caudal are articulated. The soft ray are finely articulated to their bases. All rays are composed of two fused lateral segments.

Dermal bones. The cheek-bones are a post orbital, a squamosal, a preopercular and a sub orbital (lacrimojugal). On the middle of the lower surface of each cheek is a small bony stud which may be an obsolescent quadratojugal. The opercular is moderate in size. There are two dermal structures in a stage of arrested metamorphosis from scale to dermal bone, which are regarded as subopercular and interopercular respectively.

The intertemporals and the supratemporal appear to be fused. The exposed portion of each frontal is small, oval and flat. These bones are at feebly ornamented. The splenial and angular alone show externally on the lower jaw. The gular are large and heavy.

Fronto-rostrals. Just beneath the skin there are nineteen bones in this series on each side. On large frontal and a smaller 'pre-frontal'; nine 'rostronasals', including a canal-bearing bone (No. 18) often named 'premaxilla' in fossils.

There are eight bones in the 'parafrontal' series the anterior expanded bones having been named 'antorbital' in fossils. Besides these nineteen there are the small dentigerous rostral plates. Most of these bones are small and laminate.

Sensory canals. The main canals run much as have been shown in reconstructions. From the lateral line the canal passes through the supratemporal and intertemporal, thence 'parafrontal' to the snout. There it has a small superior median branch. Just below that it gives off an inferior branch which is the infraorbital canal (running through the lateral limb of bone No. 18, which anastomoses with the suborbital). Below this junction is a commissure across the snout. The canal then runs downwards and curves outwards to end on the outer edge of the rostrum around the inner face of bone No. 18. Just behind the frontal is the junction of the infraorbital canal running downwards through the postorbital, which continues through the suborbital to the snout. The anterior limb of the squamosal anastomoses with the

Fig. 1.

SECTION OF A SCALE ($\times 50$) OF *Latimeria chalumnae* J. L. B. SMITH.

postorbital-suborbital anastomosis and carries the uveal canal which continues through the preopercular, thence as a tube in the skin obliquely over the lower outer face of the quadrate. It enters the angular very obliquely and thence runs forward on the lower margin just below the surface of the symphysis. There is a posterior branch on the lower surface of the angular.

Olfactory organs. There are on each side three 'narial' apertures, two conventionally on the side of the snout before the eye, the third on the front of the rostrum. Each opening is the end of a simple tube which leads from a median capsule situated beneath a thin layer of mesethmoidal cartilage. The tubes and the capsule were apparently lined with fine rugose tissue. The capsule is depressed conical in shape. There is also on each side of the rostrum an infero-lateral nasal tentacle, apparently imperforate. On each side of the snout, anterior and anterior to the median nasal cavity, lies a sac, typically covered below, laterally, and partly behind, by the prevomer, in front by bone No. 18. That bone lies against the outer surface of the hind column of the prevomer. These sacs correspond with the usual 'olfactory capsules', but do not appear to have any external narial opening. The nerve supply to these paired capsules appears to be from the olfactory lobe, and to enter at the upper inner portion of the surface. The nerve supply of the mesethmoidal (pineal?) cavity appears to come from farther back.

Respiratory organs. The branchial arches and appendages were lost. The arches are stated to have been strongly spinate. Remaining is a spinate epihyal and ceratohyal. Also a superficially ossified tuberculate copula ('tongue'), to which appear to have been attached four branchial arches. There is apparently a hyoidean gill-slit behind the free margin of the 'preoperculum'. The spiracles are small and probably functionless.

The palato-pterygo-quadrate apparatus is massive

and typically oelacanthid. There is no hyomandibular. The prevomer is an unexpectedly solid structure, with the anterior edge of the autopalatine bearing against the hind surface of its outer columnar vertical process. The ectopterygoid overlaps the autopalatine and the pterygoid above.

Upper jaw. Maxillæ are absent, probably also premaxillæ. The upper jaw bears paired dermal plates attached to rostrals, prevomers, palatines and ectopterygoids. These plates are of fused

small teeth, and each bears one or two large conical tusks. On the pterygoids and parasphenoid are conical granular teeth. There are two feeble granulate 'epi'-pterygoid areas.

Lower jaw. There is a series of small 'labial' dentate plates on the outer surface of the dentary. Superiorly are four dentate plates on each dentary. The anterior coronoid is small and bears granular teeth as well as several large tusks. The posterior coronoid is large and feebly granulate at the base. The articular-prearticular plate is very long and is granulate anteriorly only.

Several letters from overseas have contained very harsh criticism about the loss of the carcass of this fish. Few persons outside South Africa have any knowledge of our conditions. In the coastal belt only the South African Museum at Cape Town has a staff of scientific workers among whom is an ichthyologist. The other six small

Fig. 2.

ROSTRO-NASAL, No. 18. NAT. SIZE. INNER MARGIN TO THE LEFT. A PIECE OF WHITE PAPER HAS BEEN INSERTED INTO THE CANAL. THE DOTTED LINES SHOW THE COURSE OF SENSORY CANALS. THE RIGHT-HAND LIMB ANASTOMOSES WITH THE SUBORBITAL.

museums serving the coastal area are in extremely poor circumstances, and generally have only a director or curator, who cannot possibly be an expert in all branches of natural history. There are not uncommon fishes in the sea which to any of the

latter would appear as strange as, if not stranger than, a coelacanthid. It was the energy and determination of Miss Latimer which saved so much, and scientific workers have good cause to be grateful. The genus *Latimeria* stands as my tribute.

Science at the Royal Academy, 1939

THE one hundred and seventy-first exhibition of the Royal Academy of Arts, which opened on May 1, may be described as conservative artistically, although many will regard it as dull. Whatever trends in art it may reveal, it is remarkable in that it reflects nothing of the alarms and excursions, of political events almost unparalleled, of the clash of arms and the clatter of armoured vehicles that dominated the period in which the painting was done. In the exhibition there are more Elizabethan men-at-arms on one picture than there are modern soldiers in the thousand other works. There is one interior that contains a gas-mask, and, surprisingly, only two or three pictures of refugees.

Few will grieve at this eclipse of war even if only on canvas; but the neglect of belligerent science extends also to the other branches almost as much, and, of the thirteen hundred pictures on show, only about one hundred can be said to include any features of scientific interest and that even in the widest possible sense. Of the nine or ten branches of science which one may allege to be represented, botany and geology appear to be the most favoured.

Agriculture is fortunate in being depicted in two of the finest works in the Academy. "Harvest", by Dame Laura Knight, R.A., with its sun-chequered scene, and James Bateman's "Haytime in the Cotswolds", one of the pleasantest landscapes of the year.

Antiquaries have not far to seek for interest, because the second picture in the first room is "Antiquity", by Alan Beeton, A.R.A. This shows a human skull surrounded by palaeoliths and resting upon a copy of *Antiquity*. The work is rather small, but this is compensated by the very large panel, destined for Brighton Grammar School, entitled "Hollingbury Camp, 1929", by Louis Ginnett, in which a party of archaeologists is seen at work in the field. The anthropologists are better served, numerically, with a dozen pictures of much interest and considerable artistic distinction. Dame Laura Knight again heads the list with "Gipsy Family", a typically brilliant study

which is certain to be acclaimed as one of the pictures of the year. Negro studies are unusually prominent, of which "The Dance, Zululand" (218), "Zulu Woman" (271) and "Zulu Exodus" (278), should be mentioned. A. R. Thomson's "Prince Kessie of Ashanti" and Neville Lewis's "Pond Youth" are interesting portraits. A more comprehensive work is "The Village in the Jungle", by David Paynter, with a man, a woman and a child in the foreground. In addition there are a study of a Jamaican, Japanese and Chinese portraits and the delightful Burmese "Ma Seyn Nu", by Gerald Kelly, R.A.

For the botanists, there are a profusion of titles and a riot of colour. Apple blossom, carnations, celery, cinerarias, chrysanthemums, gladioli, lilies, marguerites, roses, tulips and even tobacco flower (these last by Dod Procter) are only a selection of the delights available. There are also surprises such as the unexpected "Flex Tree", a Montallegre landscape by Gerald Kelly. Gilbert Spencer's "Cherry Tree in Winter" and Sallis Benney's "Beech Trees" are other arboreal attractions. There are flowers under their own names, flower as "Still Life", "Rainbow Colours", "Purity", or just "Flowers". Mr. C. R. W. Nevinson's "Autumn bouquet", and Sir George Clausen's "Roses" are noteworthy, while Miss Grace English contributes a charming variety of colour contrasts in her "Summer Flowers".

Perhaps the most attractive of what may be termed the botanical works is Charles Oppenheimer's "Galloway Woodlands in February". This is a large picture with a background of typical rolling Galloway scenery. The woodland, the picture's main feature, is carpeted with snowdrops and the whole effect makes a charming picture one would like to possess.

Botanical and geological interests are combined in Malcolm Milne's "Val Fleuri", where the alpine flowers decorate the high valley. The other pictures which may interest the geologist cover various aspects of the science. Antony Ayrton's "Alpine Landscape" and Hilda Carlisle's "A Welsh Farm" illustrate a variety of mountain scenery.

which is supplemented by the stark but ominous grandeur of "Tulloch, Inverness-shire", by Oliver Lall, R.A. Less rugged aspects of the British countryside are portrayed by Charles Oppenheimer in "The Red Roofs of Whitby", by Miss Amy Brown in "East Anglia" with its very characteristic landscape, and particularly in J. McIlpatrick's quiet "Glamis Village". More informative geologically are Gerald Kelly's "River Lugno from Montallegro" with its clearly-shown valley forms, and Stephen Denison's "Lime Works at Tharfedale" with a quarry section. Sidney Lee, R.A., portrays varieties of bedding, an anticline and other folds, faulting and weathering in "The Road by the Cliff". The meander of a stream is well illustrated in "Pastoral" by George Henry, R.A.

Typical and pleasant coastal, cliff and rock scenery is shown by William Matthews in "Tantallon", by Julius Olsson, R.A., in "Rocks, Antibes", and by A. Raine Barker's "Bridport".

Applied geology is not forgotten, for there are quarry in Kent (588), the sandpit, Coldharbour (233), and "Cement Works in Surrey", by G. W. Leach. The last picture reveals that the industrial activity is less disturbing aesthetically than might be imagined.

Geologists, geographers and all Americans will be interested by Norman Wilkinson's "San Salvador". In this bay, Columbus landed on October 21, 1492.

If the mineralogists have but two pictures assigned to them, they may be reminded that quality is sometimes better than quantity. In any event, Gerald Brookhurst, R.A., is responsible for the two pictures, both of which are characteristically exquisite portraits. In the first, "Mrs. Hubert Raphael" is portrayed wearing scintillating emeralds and diamonds, while in the second, a portrait entitled "Mrs. Harrison", the amethystine brilliance of necklet, brooch, bracelet and ring is striking and attractive and reveals the masterly skill of the artist in his medium.

The zoologists have been served not quite so lavishly as might have been expected. Mr. Funnings has, however, made his usual and appealing testimonies to equine grace. Miss Winifred Austen, in one of the very few dry points, portrays equine leisure. There are dogs and cats in oils, greyhounds in wash and in bronze, and an antelope in wood. Mrs. Lilian Andrews contributes a swan and family in pastel, and Philip Bonnard, R.A., shows "Flying Swans", a piece of such distinction. Mrs. Daisy Smith has a delicate water-colour study of kookaburras.

The zoo aspect is supplied by "The Birdhouse" by Percy Shakespeare, with its toucans and para-

keets; and "Elephant in Regent's Park" by Henry Carr. "An August Evening in Suffolk", by Bertram Priestman, R.A., with its black-and-white cows, is peaceful; Mr. John Platt's "Bull across the Path", a colour woodcut, is more aggressive.

The march of time in applied science is amply demonstrated by Sir Muirhead Bone's impression in chalk "Building the *Queen Elizabeth*" and Charles Cundall's detailed picture of the launch of the same vessel. The launch of the *Mauritania* is the subject of a wood-engraving by Marjorie Biscomb. The less spectacular sides of industry are represented by "Tin Miners" (383) and "Coke Ovens" (437). The march of science is depicted in "Television Rehearsal" by Harry Rutherford; "Chelsea Power Station" by Gerald Ackermann, and, in a different sense, in "Pylons", where Miss Evelyn Sauer shows the feet of the pylons embedded in beautiful highland scenery.

The architecture section contains plans of much interest to many men of science. The new science buildings of the University of Oxford (1046), new or recent buildings of the University of London (1047), the Imperial College of Science (1082) and research laboratories at Berkhamsted (1079) are a few on exhibition.

Portraits of scientific men are not numerous, but the few are well worthy of note. There are Charles Wheeler's bronze bust of Col. W. A. Bristow and the marble bust of the late Sir Robert Mond by William King. Lord McGowan and Lord Weir are the subjects of splendid portraits by Harold Knight, R.A., and T. C. Dugdale, A.R.A., respectively. Malcolm Osborne, R.A., provides a dry point of Prof. Alexander Low, of Aberdeen, while an attractively academic portrait is Edward Halliday's painting of Prof. W. E. S. Turner. Others known in scientific and university circles who are portrayed include John Murray, principal of the University College of the South-West, Exeter (oil painting by R. G. Eves); Dr. A. W. Pickard-Cambridge, vice-chancellor in 1930-38 of the University of Sheffield (oil painting by George Harcourt); Sir William Elderton (oil painting by Harold Knight); the late Dr. A. C. Woolner, vice-chancellor of the University of the Punjab, Lahore (statue by Gilbert Ledward); and the late Lord Moynihan (bust by Sir W. Reid Dick).

If for any reason these aspects of science should prove of little attraction, or should they pall, it may be comforting to know that the Academy also bears testimony to another science, an applied science which is, one believes, still also a pure science, that the month of May particularly welcomes. It is brilliantly dealt with in No. 264, Mr. Charles Cundall's "Test Match at Lord's".

W. E. SWINTON.

Obituary Notices

Sir William Ramsay

BORN at Glasgow on March 15, 1851, and educated at Aberdeen Gymnasium, the University of Aberdeen, St. John's College, Oxford, and the University of Göttingen, William Mitchell Ramsay married early and spent the years 1878-85 in persistent and fruitful travel, first in Greece, then in Asia Minor, with the wise encouragement from 1880 onwards of Sir Charles Wilson, who came from the Survey of Western Palestine to be British consular-general for Anatolia, and with a travelling scholarship and later a research fellowship from Exeter College, Oxford. To the methods of historical geography followed by Hamilton and by Leake, Ramsay added the critical study of local coinage in its topographical distribution, and of the Byzantine and ecclesiastical administrations of Asia Minor, many of the centres and regions of which were inherited from Hellenistic and even much earlier times. Though he travelled in most parts of Anatolia, Ramsay's special region was Phrygia, and his largest coherent publication dealt with its "Cities and Bishoprics" (1895, 1897). For the methods of pioneer research, however, his "Historical Geography of Asia Minor" (1890) is a turning-point, and the patronage of the Royal Geographical Society, which published it, and later awarded Ramsay its Victoria Medal, was never better bestowed.

On the establishment of the Lincoln and Merton professorship of classical archaeology and art in Oxford, in 1885, Ramsay was an obvious first choice, and though he passed on in the following year to his old University of Aberdeen, where the facilities for summer travel were greater, he left his mark in Oxford in a succession of classical archaeologists and historical geographers, of whom the best known was David Hogarth of Magdalen, his constant travelling-companion. From Aberdeen he continued to direct and advise even after his retirement from the chair of humanity in 1911, when frequent ill-health had been aggravated by reckless exposure to austere conditions of travel. But Ramsay never stopped working: only last summer, on one of his busy visits to Oxford, he was as keen and clear-headed as ever, and full of problems and projects.

Ramsay's output of published work was larger than the titles already noted indicate; the only difficulty was to keep track of it, for his articles, large and small, are scattered among a score of periodicals in both hemispheres. It might have been larger on the geographical side, had he not devoted much of his middle life to more popular expositions of the early history of Christianity, in its relations with the Roman administration: "The Church in the Roman Empire" appeared in 1893, "St. Paul, the Traveller and the Roman Citizen" in 1895; and so on at frequent intervals until 1914.

Other interests arose from Ramsay's intimate experience of Turkish administration, before and after the revolution of 1909, and from his academic activities at Aberdeen. His essay on "The Imperial Peace, an Ideal in European History" (1913) has a fresh significance to-day. On the four hundredth anniversary of his University in 1908, Ramsay was knighted; he was an honorary fellow of Exeter, Lincoln and St. John's Colleges, an original member of the British Academy, and one of the founders of the Hellenic Society. From Pope Leo XIII he received a gold medal in 1893 in recognition of his contributions to the history of Christianity, and other marks of recognition were conferred on him by many universities and academies. J. L. M.

Mr. H. J. George

HERBERT JOHN GEORGE, whose sudden death occurred on April 19 at the comparatively early age of forty-six years, was fellow, tutor in chemistry, and senior bursar of Jesus College, Oxford, and University lecturer in chemistry.

George was educated at Cardiff High School and entered Jesus College as scholar in natural science in 1911 after a short period at University College Cardiff. He gained a first class in chemistry in the June before the Great War broke out. In the War he served in the Royal Welch Fusiliers in Gallipoli where he was wounded, and then in Mesopotamia and India. Later he was transferred to a department of the Ministry of Munitions.

In 1919 George returned to Oxford as research fellow and lecturer of his old college and became an official fellow and tutor a few years later. Since then Dr D. L. Chapman and he have been in charge of the teaching of chemistry to the large number of men whose centre was the Leoline Jenkins Laboratories of Jesus College. He was an excellent college tutor; he took great pains with his pupils. As University lecturer he took charge of colloid chemistry and lectured effectively to large classes on this for many years.

George's absorption in his tutorial work and latterly in administrative duties (he was successively librarian, junior bursar and senior bursar of his College and also an Oxford City councillor) did not leave him the time for research work that his abilities warranted. He published work on the adsorption of gases on glass surfaces, on the theory of strong electrolytes, on organic derivatives of thiophosgene and on other subjects. At the time of his death he was working on the constitution of thiophosgene derivatives and on the accommodation coefficients of metals. The results of these researches will be printed in due course. A. S. R.

News and Views

Prof. A. H. Gibson

At a meeting of the Institution of Civil Engineers on May 2, the James Alfred Ewing Medal was presented to Prof. Arnold Hartley Gibson, professor of engineering in the University of Manchester. This is the second award of the medal, which is presented for specially meritorious contributions to the science of engineering. Awards are made by the council of the Institution of Civil Engineers on the recommendation of the presidents of the Institution of Civil Engineers and of the Royal Society. Prof. Gibson was educated at Rishworth Grammar School and at the University of Manchester. In 1909 he was appointed professor of engineering of the University of St. Andrews, where he stayed until 1920, except that during the Great War he served in the Royal Field Artillery and was seconded in 1916 to the Royal Aircraft Factory, where he afterwards had charge of the investigation and research work on aero engines. He was president of Section G (Engineering) of the British Association in 1921, and was a member of the Board of Trade Committee on water-power of the British Isles; of the Air Ministry Engine Research Committee; and of the Severn Barrage Committee. He has written a number of papers on hydraulic engineering, including such subjects as experiments with tidal models, the resistance to rotation of disks in water at high speeds, formation of standing waves in an open stream, wave impact on engineering structures, etc., and, among other awards, has received a Wroughton Prize and a Telford Premium for papers published by the Institution of Civil Engineers.

Sir Frederic Kenyon, G.B.E., K.C.B.

THE anniversary meeting of the Society of Antiquaries of London on April 27 marked the retirement of Sir Frederic G. Kenyon from the office of president, which he had held since 1934, the statutory period of five years. His term of office has covered a period in the history of the Society of enhanced activity in the field—the excavation of Maiden Castle is a permanent landmark in the study of British prehistory—in the promotion of archaeological studies, and in efforts to preserve the antiquarian remains of Great Britain. Sir Frederic's wise leadership and tactful conduct of the Society's affairs have been more than worthy of the great tradition of the long line of his predecessors. His own special interests as an eminent authority on early classical and Biblical texts from papyrological and other sources have in no way been allowed, in the performance of his official duties, to colour, though they may have added inspiration to, his judgment in the broader fields of archaeological research. Sir Frederic Kenyon was director and principal librarian of the British Museum (Bloomsbury) from 1909 until 1930. Since his retirement, he has devoted himself strenuously to the advancement of learning and research by taking part in the ad-

ministration of several learned societies and other bodies, including the British Academy, the Society for the Promotion of Hellenic Studies, and the Society for the Protection of Science and Learning. Sir Frederic is succeeded as president of the Society of Antiquaries by Mr. Alfred William Clapham, secretary since 1929, and secretary of the Royal Commission on Historical Monuments, England, since 1933. Dr. R. E. Mortimer Wheeler will succeed Mr. Clapham as secretary of the Society.

Prof. Karl von Terzaghi

THE forty-fifth James Forrest Lecture of the Institution of Civil Engineers was delivered on May 2 by Prof. K. von Terzaghi, who took as his subject "Soil Mechanics: A New Chapter in Engineering Science". Prof. von Terzaghi was born at Prague in 1883 and, after attending the Technical University of Graz, was engaged on projects for hydro-electric developments and other construction-projects in Austria, Hungary and Russia until 1912, when he proceeded to the United States and was chiefly engaged in the study of modern dam construction and problems of engineering geology in connexion with the projects of the United States Reclamation Service. During the Great War he served in the Austrian Army until in 1916 he was transferred to the Technical University of Constantinople to take over the chair of foundation and highway engineering. From 1918 until 1925 he was professor and head of the Department of Civil Engineering of the American Robert College in Turkey. During this period, he was engaged on research in connexion with the physical properties of the most important types of soils and published in 1925 his book "Erdbeckenmechanik", which is acknowledged as the basis of modern soil mechanics. Between 1925 and 1936, Prof. von Terzaghi was lecturing at the Massachusetts Institute of Technology, the Technical University in Vienna, the Technical University in Berlin-Charlottenburg and at Harvard University. He was president of the first International Conference on Soil Mechanics and Foundation Engineering, which was held at Harvard University in 1936. In addition to his contributions to civil engineering, Prof. von Terzaghi has advanced knowledge in the field of physical chemistry and geology, his best-known work perhaps being his mechanical theory of swelling of gels.

George Miller Beard (1839-1883)

DR. GEORGE BEARD, an eminent American neurologist and psychiatrist, was born at Montville, Connecticut, on May 8, 1839, the son of a Congregationalist minister. He studied medicine at Yale, where he qualified in 1862, and four years later joined the staff of the College of Physicians and Surgeons of New York. In the course of his comparatively

short life he engaged in numerous activities, but the subjects in which he was chiefly interested were electrotherapy, hypnotism, functional nervous diseases, longevity and the reform of medical education. As a mental expert he took part in several famous trials and notably that of President Garfield's assassin Guiteau, whose case he reported in the *Journal of Nervous and Mental Disease* of January 1882. Of his numerous other writings the most important are "Medical and Surgical Electricity" written in conjunction with A. D. Rockwell (1875), "Neurasthenia (Nervous Exhaustion) with Remarks on Treatment" (1879) and "American Nervousness: Its Causes and Consequences", which was translated into German. He also contributed many articles to the *North American Review* in which he popularized scientific knowledge, and was the founder of the *Archives of Electricity and Neurology*, which had only a short existence (1874-76). He was one of the originators of the National Association for the Protection of the Insane and of the American Neurological Society. He died on January 23, 1883.

Preservation of Wild Geese and Wild Duck

THE Wild Birds (Ducks and Geese) Protection Bill, which passed its final stages in the House of Lords on May 2, and will come into force as an Act on August 1, marks a decided step forward in the efforts being made to conserve the world's stock of Anatidae. During its passage through Parliament, the Bill has been strengthened by amendments put forward by the promoters, the International Committee for Bird Preservation (British Section). The Bill, when first introduced in November 1938, was framed with the view of securing its rapid passage as an unopposed measure; but as opposition was encountered the promoters, while compromising on certain points, were able to gain considerably on others. The main terms of the Bill in its final form are: the extension of the 'close season' for wild geese and wild duck (of any species whatsoever, the merganser and goosander only being excepted) from February 1 to August 11; the addition of wild geese of all species to the schedule; and the prohibition of import of wild geese and wild duck from February 1 to August 11. Heretofore wild duck have enjoyed the benefit of being scheduled birds (by the Act of 1880), that is, protected from owners and occupiers of land on their own land—during the close season—but wild geese have not. The new measure, therefore, greatly increases the protection afforded to wild geese. However, in order to safeguard the interests of farmers, for, in certain cases, wild geese are considered to damage crops, a clause gives power to county councils to apply to the Secretary of State for Home Affairs to remove wild geese from the schedule in any area in the county concerned.

COUNTY councils also have the right to make similar application to extend the shooting season for wild duck and wild geese on the shore and land contiguous to it to a date not later than February 21. This clause is admittedly a concession, but the duck

it will affect are mainly widgeon. Though quite a number of widgeon nest in Scotland, their breeding season is during the second half of May, and a majority of birds are those passing through on their way north to breed, where the season is later and usually not until June. Allowing these birds to be shot until a later date would not have so much deleterious effect as would the shooting of early nesting species. Further, county councils retain the right to make application to extend the statutory close season, but not, as heretofore, to diminish it. The prohibition of import of wildfowl during the breeding season is an extremely important point, as it cuts off the demand from the London market of ducks caught in decoys in certain European countries at this time. Thousands of ducks have been caught annually in decoys on the Continent during the breeding season, and this has been a serious drain on the stock of European wildfowl; by means of the new Act this drain will now be effectively curtailed.

Sir Ambrose Fleming and the Thermionic Valve

WELCOMED by the Provost (Sir Allen Mawer), Professor R. O. Kapp and an appreciative audience, Sir Ambrose Fleming once again visited, on April 5, University College, London, where for more than forty years he occupied the chair of electrical engineering. The occasion was the formal presentation to the College by Mr. R. McV. Weston of a convenient exhibition case to hold early Fleming and other valves in the possession of the Electrical Engineering Department, including those presented recently to the Department by Mr. Weston and Sir Ambrose himself. After the case had been unveiled, with the appropriate aid of a torch, photocell, valve amplifier and relay, Sir Ambrose gave a remarkably clear and vigorous address on the history of the valves displayed. The story began when he investigated the reason for a white line on the clearer glass in the deposit of evaporated carbon from the filaments of early Edison-Swan lamps after many hours of use. He concluded that some of the carbon particles became charged and were driven off with high velocity from one end of the filament, throwing a 'shadow' of the other side of the hairpin loop on to the glass. Edison, in America, hung a metal plate within the loop, and found that when connected through a galvanometer to the positive end of the filament, a current flowed to the plate but not when connected to the other end.

EDISON left the subject with the discovery of the effect; but Fleming continued his experiments, which led to the construction of a bulb containing a filament at each end. With one filament hot, negatively charged particles would flow through the bulb to the other filament, if the latter was a few volts positive but not if negative. This was the first 'rectifying valve', and here Sir Ambrose left the work to concentrate on his teaching duties. It should be emphasized that this work was before the discovery of the electron by Sir J. J. Thomson. During the next decade, Sir Oliver Lodge, Marconi and others were

experimenting with wireless telegraphy, using coherers and magnetic detectors. In 1899, Sir Ambrose was appointed scientific advisor to the Marconi Company, and soon came up against the problem of finding a more stable detector, suitable for operating a morse rinter. In November 1904, he removed from the cupboard the rectifying valve, set up a high-frequency generator on the lecture bench, and was successful in using for the first time a thermionic valve detector of electromagnetic radiation. Very soon, special valves were being designed for this purpose. The cabinet of valves, occupying a prominent position in the College Engineering Department, will be a constant reminder of Sir Ambrose Fleming and of the rapid developments during the last thirty-five years.

Million-Volt X-Ray Tube

A PAPER on a million-volt X-ray tube which has been installed and is in operation for treatment at St. Bartholomew's Hospital was read before the Institution of Electrical Engineers by Allibone, Bancroft and Innes at a meeting held on April 13. A description was given of the design, equipment, lay-out and operation of the unit. Briefly, it may be said that the tube embodies the principles of the all-metal X-ray tube designed by Dr. Allibone for lower voltages, and the elaboration set out in the recent paper arises from the scale of voltages used. The X-ray tube consists of a steel tube 14 in. in diameter and 17 ft. long; the central portion of it, from which the X-ray beam emerges, traverses the treatment room and projects into each generator room. The generator rooms each house 500 kv. d.c. generators. The X-ray tube and thermionic rectifiers used in the d.c. generators are evacuated continuously by oil diffusion pumps, and the whole apparatus is readily demountable. Removable filament assemblies are fitted to the rectifiers and facilitate rapid replacement of filaments; a special cathode with six interchangeable filaments has been developed for the X-ray tube to avoid frequent admission of air into the tube during filament replacements. The tube is now used continuously at 1000 kv. and has been operated experimentally at 1100 kv. Curves relating X-ray output with voltage and filtration by metallic filters are given, and a radiograph is included to illustrate the capabilities of the tube if applied to industrial radiography.

Revised Broadcasting Wave-Lengths

AFTER sitting for some six and a half weeks during March and April at Montreux, the international broadcasting conference has terminated with the issue of a plan for the revision of the wave-lengths and power of broadcasting stations in the European zone, which includes Iceland and the Mediterranean basin. The 'Montreux Convention', as it is known in broadcasting circles, was signed by the representatives of thirty-one States, and provides for certain changes in wave-length and power of European broadcasting stations to come into effect on March 4,

1940. The changes to be made affect all the British stations, including those at Start Point, Clevedon and Norwich, which are not yet in regular operation. Details of the changes indicating the manner in which they may affect British listeners to broadcasting were outlined in recent issues of *The Times* and the *Wireless World*. Power limitations have been imposed by the Convention, varying from 500 kw. for long-wave stations by day only to 10 kw. for stations operating on the shortest wave-lengths of the medium wave-band. Although Great Britain has been allocated the exclusive use of only three wave-lengths, it is pointed out that our geographical position on the outer fringes of Europe is such that we can share wave-lengths with other countries in a way that would be impracticable in central Europe. Generally speaking, it may be said that the plan provides an improved state of affairs in the long-wave band, and also in the middle-wave band so far as home reception is concerned. In view of the developments of broadcasting, and the increase in number and power of stations during recent years, the Montreux Conference would appear to have achieved a satisfactory result if it has succeeded in avoiding any deterioration in the service now provided in all countries.

Further Extension of the Ashmolean Museum, Oxford

A FURTHER extension of the Ashmolean Museum in the University of Oxford was opened by Lord Crawford and Balcarres on April 25, towards the cost of which the Worshipful Company of Drapers has contributed the sum of £10,000. The Master of the Company, Sir Auston Harris, in the course of his remarks at the opening ceremony, said that while the City Companies can no longer vie with the munificent gifts of wealthy Englishmen, or with great American corporations, this gift would serve as another mark of the respect and esteem which an ancient City Company bears towards an ancient University. The extension is on the north-east corner of the building, and provides for the Museum's Egyptian collections, which it has now been possible to arrange in chronological order, a lecture room, and a storage basement. A set of smaller rooms on six floors has been built between the new wing and the Tylorian Institution. Here are students' work-rooms, a room for the keeper, Mr. E. T. Leeds, and rooms for the preparation of exhibits. This is the third extension added to the buildings in five years, and marks the final stage in the plans for the enlargement of the accommodation to relieve pressure on the Museum's space. The first extension was the provision of the Weldon Gallery in 1934, and the second was the addition of the Griffith Institute, which was opened in January last. The gallery in which the Egyptian collections were formerly housed has now been divided by screens into three rooms, to be devoted respectively to the European pre-historic period, covering the stone and bronze ages, the Minoan collection, by the gifts of Sir Arthur Evans now the finest in existence, and the Near Eastern Collections.

A Cornish Headland Fortified Site

SOME interesting results, it may be expected, will emerge from an archaeological exploration of a Cornish headland fortified site, which has been in progress under the direction of Dr. R. E. Mortimer Wheeler during the fortnight ending on April 24, when digging ceased. The site comprises a series of hut-circles within an enclosed area on Gurnard's Head, near Falmouth. The purpose of the investigation is to endeavour to trace evidence of connexion in the first century B.C. between these Cornish headland forts and the contemporary or earlier inhabitants of the sites on the south-west coast of Brittany examined by Dr. Wheeler's expedition last year. The fortified enclosure here is formed by three ditches running across the neck of the peninsula, protecting it from attack on the landward side. The hut-circles, according to a report in the *Western Independent* of April 23, begin close to the inner rampart, of which the wall was in three steps, recalling the structure of the hill-fort of Kerouradeo, near Quimper in Brittany, which has been described by Dr. Wheeler as fortified by three lines, with an inner rampart faced by dry stone walling, of which the innermost facing was stepped in three stages and surmounted by a timber palisade. A feature of the construction of the hut-circles, which is said particularly to have impressed the excavators, is the large size of the placed wall-stones. The discovery of a spindle whorl of pottery attests the presence of women, even though the hut-circles do not appear to have been places of permanent occupation. A number of sea-rolled stones include sling-stones; and two sherds of pottery show fragments of the spiral decoration of the first century B.C. A sherd with 'duck' pattern recalls a find at Ohm Castle, four miles away, made by Mr. Leeds in a fort resembling the forts of northern Spain, and interpreted by him as a relic of connexion due to ancient metal working.

Dermatology and Folk-lore

At a meeting of the St. John's Hospital Dermatological Society on April 28, Dr. J. D. Rolleston read a paper on this subject. After a few remarks on folk-lore in relation to skin diseases generally, in which he alluded to their supposed causation, prophylaxis and treatment, he dealt with the individual skin diseases with which folk-lore was most concerned. No skin disease, he said, or indeed disease of any kind, had received so much attention in folk medicine as warts, the literature on the subject even exceeding that on whooping cough or 'ague'. Next in importance in popular estimation came shingles, and then baldness, boils, burns, cosmetic defects such as freckles and wrinkles, congenital abnormalities, ringworm, urticaria, cancer of the skin and chilblains, in the order named. As in his previous paper on "Folk-lore and Medicine" (see *NATURE*, January 21, p. 111) Dr. Rolleston discussed the various preventive and therapeutic measures used in folk-lore under the following headings: (1) transfer of the disease to other persons, animals or inanimate objects; (2)

animal and plant remedies; (3) religious influence including invocations to patron saints; (4) the healing power of water in the form of wells, spring-fountains and streams; (5) the mystical power of odd numbers; (6) repellent and disgusting remedies including coprotherapy, for the object of driving on the evil spirit supposed to be the cause of the disease; (7) miscellaneous cures, such as the doctrine of signatures, the influence of the moon and fastin saliva.

Archæology and the Bible.

THE striking manner in which post-War archaeological investigation in the Near and Middle East has contributed to Biblical studies is concisely reviewed by Prof. S. H. Hooke in "Archæology and the Old Testament" (London, Thomas Murby and Co., 1938. Pp. 32. 6d. net), one of an excellent little series entitled "After 400 Years", which deal with various aspects of the Bible in the light of modern scholarship. Whereas at one time the efforts of the archaeologist in the interests of Biblical studies were directed mainly to the search for texts which might confirm the Hebrew record, modern excavations in Mesopotamia, in Syria and in Palestine and Egypt have not merely provided a measure of corroboration for the Biblical narrative of the course of events, but also—and to many this may seem of major importance—they have given the Scripture records a historical setting and cultural background both within the boundaries of Palestine and in relation to neighbouring peoples and empires, which has elucidated a multitude of obscurities in the Biblical historical narrative as well as in tradition in ritual and in belief. Thus Prof. Hooke, speaking of the recent investigations of Sir Leonard Woolley at Ur, of Dr. Dorothy Garrod in Palestine, and of others elsewhere, is able to say that "during the last thirty years archaeology has reconstructed the stage . . . on which the drama of the history of the Hebrew people was played . . . those great ancient civilizations, which surrounded and profoundly influenced that small country of Canaan". Making this his starting point, he passes on to show the manner in which the attitude of instructed opinion on Biblical questions has been profoundly modified by recent discovery in regard to the history of writing and its beginnings, early law and legal codes, the conquest of Palestine, the religion, ritual, and mythology of Canaan, the condition of Palestine at the time of the Lachish letters, the Hittites and the empire, and like matters.

New Air Speed Record

THE absolute air speed record of more than 46 miles an hour, set up by Herr Dieterle in Germany recently (reported in *NATURE* of April 15, p. 633) has now been broken. Herr Wendel, flying a Messerschmitt Me.109 R. fighter fitted with a Mercedes-Benz engine and a V.I.M. metal airscrew, claims to have attained a speed of 755 kilometres (469.11 miles) an hour. Reports claim that this aircraft is a new type of fighter, and the published rating of the engine

1,175 horse-power. A previous edition of this machine, the Messerschmitt Bf 109, with an engine of 950 horse-power, is credited with a maximum speed of 15 miles an hour, and this performance is about what might be expected for this class of fighter aeroplane with its necessary equipment. The great increase in speed of the new machine with so small an increase in rated power suggests that the term 'fighter' is a misnomer, and that the machine, while its design may be based on such a class, is almost certainly a specially fitted one which would be impracticable for the carrying of standard military equipment. Also the engine must have been giving considerably more than its rated power, which suggests that it was running under conditions that could not have been maintained in practical service work. Although this does not mean that the German Air Force now possesses a single-seater fighter of such performance, the setting up of the record is an achievement upon which the German aircraft industry is to be deservedly congratulated.

Engineering Research at the City and Guilds College

A SHORT general account has been issued by the City and Guilds College, Imperial College of Science and Technology, of researches in progress at the College which are mainly financed by an annual grant of the Clothworkers Company given to further engineering research. This research report for 1937-38 contains a brief account of the fluid motion research in the Department of Aeronautics. In the Department of Civil Engineering experimental work on the static loading of a 10-ft. span voussoir arch has been completed which has shown that the generally accepted method of design is unduly pessimistic since even lime mortar joints can resist some tensile stress, and with cement mortar the first sign of failure is at a considerably higher load than that given by the classical theory. An investigation of stresses in suspension bridges is in progress, and in addition to various structural researches the problems of river meander, tidal phenomena, wave research and tests of bituminous jointing compounds for liquid-retaining concrete structures have received attention in the Department. The Department of Electrical Engineering has constructed a high-frequency Wheatstone bridge and also a high-frequency Schering bridge. Besides its work on heat transmission, the Department of Mechanical Engineering has been responsible for work on heat dissipation from surfaces by natural convection in gases and liquids, including mercury, on heat transfer from gases flowing through packed solids, radiation from non-luminous gases, convection in pipes at low velocities, evaporation and convection, gumming tests on lubricating oils with the Helmore-Griffiths oil-testing machine, the mechanical properties of metals near their melting-point and on internal combustion engines.

Post-graduate Studies in the University of Bombay

THE Deccan College, which was abolished some years ago, is apparently to be revived by the Government of Bombay as an institution for post-graduate

work in arts. The scheme has given occasion to a candid friend of higher education in India in general and the University of Bombay in particular to direct attention in an article recently published in the *Mahratta* to some of its shortcomings, and to make suggestions for ensuring that they do not vitiate the work of the proposed Deccan College Institute. The existent provision for post-graduate instruction in the University is described as farcical and the standards of undergraduate work in India generally, and particularly in Bombay, as so low that the attainments of a B.A. or B.Sc. are, more often than not, at or below the level of a good freshman in a British university. "Research" or "direction of research" is too often a pretext for shirking genuine work, and much nonsense is talked about the evils of "over-lecturing" and "spoon-feeding". What is wrong with higher studies is a deficiency of strenuous, orderly, conscientious, healthily motivated work under competent direction and close supervision. It is suggested that the new Institute should make good the deficiency so far as possible by putting graduates through a discipline which they ought to have already experienced, including the regular and frequent submission of written work and its patient examination by instructors intent on eliminating the indolent and incapable. The proposed fields of study are mathematics, philosophy, English, philology, Indian languages, history and economics. In view of the growth of unemployment among the educated classes and the evils attendant on the existence of an unemployed and unemployable university proletariat the comment suggests itself: higher education for—what?

The Geographical Laboratory

A USEFUL pamphlet by Prof. Griffith Taylor, entitled "The Geographical Laboratory" (University of Toronto Press, 1938), sketches with a varying amount of detail a three years course in geography for North American universities. Much of it, however, would be equally applicable to students in Europe, and there should be no difficulty in adapting the more special American section to other requirements. The course is carefully graded, leading from map reading, simple surveying and standard projections to the treatment of statistics, the study of graphs and correlation coefficients and problems of navigation. The matter for the allied lecture courses is also indicated. The courses express an ideal which in their comprehensiveness might be difficult of fulfilment, but the pamphlet should certainly prove a useful guide to both teachers and students.

Conference on Photography

THE Manchester and District Branch of the Institute of Physics is arranging to hold a conference on "Photography" on July 3-4 in the Physics Department, the University, Manchester. The meetings will begin at 2.30 p.m. on the first day and will terminate at 4.0 p.m. on the second day; they are open without formality of any kind to non-members as well as to members of the Institute of Physics. The events

already arranged include lectures and discussions on theories of the photographic latent image, experimental work bearing on these theories, important properties of photographic materials, applications of photography to scientific research, and colour photography. Lectures will be given by Prof. N. F. Mott, Dr. W. F. Berg, Dr. J. O. M. Brentano, Dr. D. A. Spencer, Dr. E. R. Davies and Dr. S. O. Rawling. Full particulars will be announced at a later date.

The Royal Institution

THE anniversary meeting of the members of the Royal Institution was held on May 1, during which the annual report of the visitors was received and adopted. Matters mentioned in the report included the appointment of Prof. W. L. Bragg, Cavendish professor of experimental physics at Cambridge, to succeed the late Lord Rutherford as professor of natural philosophy in the Institution, and of Prof. E. N. da C. Andrade to succeed Sir Henry Miers as chairman of the Library Committee. A legacy of £1,000, free of duty, has been received from the late Mr. P. A. Molteno, and the first payment has been made by the Asiatic Petroleum Co. Ltd. of an annual grant of £100 in aid of the researches at the Institution. The following officers were elected at the meeting: *President*, Lord Eustace Percy; *Treasurer*, Sir Robert Robertson; *Secretary*, Major Charles E. S. Phillips.

Recent Earthquakes

Two earthquakes of considerable severity have been recorded by observatories in England recently. The first was recorded at Kew on April 21 at 4 h. 39 m. 56 s. (dilatation) and the second on April 23 at 16 h. 32 m. 24 s. G.C.T. The former is thought provisionally to have had an epicentre in north-eastern Asia, and to have had a depth of focus of some 500 km.; its occurrence is confirmed by a message from Dr. O. Somville of the Royal Observatory at Uccle, Belgium.

Comet Jurlof-Achmarof-Hassel (1939 d)

MUCH interest was shown in this comet, which was easily visible in field glasses, and it has been under observation since April 15, when it was discovered, until the present time. It had a tail about 4° in length, but on April 22 this suddenly disappeared. Observers are certain that the tail was not diminishing in brightness an hour before its disappearance, and it is remarkable that it should have vanished so suddenly. It is receding from both earth and sun and so is diminishing in brightness; but it may be possible to find it with a small telescope until the middle of May. An ephemeris for a few dates is given below:

	R.A.	N. Dec.
May 7	5h 46.3m	33° 01'
9	5 54.8	30 28
11	6 03.1	29 31
13	6 08.3	28 08

Its distances from the earth and sun on May 9 are 116 and 78 million miles respectively.

Announcements

PROF. EMILE DE WILDEMAN, professor of botan and agriculture in relation to the Belgian Congo i the Colonial University of Belgium, Anvers, has bee elected *correspondant* for the Section of Botany of th Paris Academy of Sciences, in succession to the lat Prof. V. Grégoire.

THE following officers of the North East Coast Institution of Engineers and Shipbuilders have recently been elected: *President*, Major T. Russel Cairns; *Vice-Presidents*, Mr. Robert Haswell, Comdr E. R. Micklethorn, Mr. H. B. Robin Rowell; *Honorary Treasurer*, Mr. W. H. Pilmour; *Secretary*, Mr. T. S Nicol.

THE Challenger Society for the Promotion of th Study of Oceanography will be making furthe grants in aid of research during the current year. The general committee is prepared to consid applications for small grants in aid of research i marine biology, the work preferably to be carri out at one of the recognized laboratories. Applica tions, accompanied by details of the proposed re search, should reach the Honorary Secretary, Mr J. R. Norman, British Museum (Natural History) S.W.7, before May 22.

IN compliance with the requirements of a gif under the will of the late Francis Amory, of Beverly Massachusetts, the American Academy of Arts and Sciences announces the offer of a septennial prize to be known as the Francis Amory Septennial Prize for outstanding work with reference to the alleviation or cure of diseases affecting the human genital organs. If there is work of a quality to warrant it, the first award will be made in 1940. The total amount o the award will exceed ten thousand dollars, and may be given in one or more awards. Further informati can be obtained from the Amory Fund Committee c/o the American Academy of Arts and Sciences 28 Newbury Street, Boston, Mass.

CATALOGUE 51, published by E. P. Goldschmid and Co. of 45 Old Bond Street, London, W.1, include a number of works illustrating the history of scienc and a few rare and important old medical books. The scientific works consist of first editions of book by Brahe, Copernicus, Galileo, Hutton, Huyghens, Kepler, Malpighi, Mendel, Newton and Pasteur while the medical works are represented by first editions of Auenbrugger, Claude Bernard, Liston Purkinje, Semmelweis and Steno. John Raphael Smith's oil portrait of Edward Jenner (1800) is als included, and modern but rare works such as th first edition of Freud's "Traumdeutung" (1900), Einstein's inaugural thesis (1905), Sir Charles Sherrington's "Integrative Action of the Nervous System" (1906), and Johannes Schmidt's "Contributions to the Life-History of the Eel" (1906). The catalogue is well illustrated and annotated.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 766.

Emission of γ -Rays from Fluorine Under Proton Bombardment

THE work of many experimenters¹ has proved that the excitation curve of the γ -ray emission from fluorine under proton bombardment exhibits a series of sharp resonances. Such resonant effects in the emission of γ -radiation are usually ascribed to the process of proton capture, and on this basis the γ -radiation from fluorine would be ascribed to the reaction:

Measurements of the energy spectrum of the radiation reveal the presence of a single line² of quantum energy 6.0×10^6 ev., whereas the total energy available according to reaction (1) is 13.1×10^6 ev. for the lowest resonance at 330 kv. This discrepancy could be explained if the de-excitation of the excited ${}^{10}\text{Ne}^*$ nuclei occurred by successive emission of two quanta of about 6×10^6 ev. energy, the full transition being forbidden, and we have therefore sought for evidence of the simultaneous emission of γ -ray quanta. Using a pair of γ -ray counters exposed to the radiation, the rate of occurrence of coincident impulses was found to be 0.2/min., whereas the minimum rate to be expected on the above view was 35/min. It seems therefore improbable that equation (1) provides the correct explanation of the γ -ray emission, even if the de-excitation occurred in successive stages.

Burcham and Smith⁴ have shown that in the bombardment of fluorine with protons an emission of α -particles of range 0.8 cm. takes place and that, for bombarding energies in the region of the first resonance of the γ -ray excitation curve, the α -particle emission exhibits similar resonant excitation.

A possible explanation of all of the foregoing facts may be obtained by assuming that the emission of a quantum of energy 6.0×10^6 ev. from the intermediate ${}^{10}\text{Ne}^*$ nucleus results in the formation of a less excited ${}^{10}\text{Ne}^{**}$ nucleus which afterwards disintegrates into ${}^{16}\text{O}$ and ${}^4\text{He}$ nuclei. The resonant features of the γ -ray emission might then have their normal explanation, whilst the observed resonant effect in the α -ray emission would be explained by the assumption that the ${}^{10}\text{Ne}^{**}$ nuclei which are unstable with respect to the emission of α -particles are only formed as a result of the γ -ray emission.

On this view, however, as also for the process (1), it is to be expected that the quantum energy of the emitted γ -radiation would increase by finite steps as the bombarding energy of the protons is increased to such values that the γ -ray emission occurs from the higher levels of excitation of the intermediate nucleus. By placing aluminium screens between a pair of Geiger-Müller counters, we have determined the maximum range of the secondary elec-

trons projected by the γ -radiation. The measured end-point values at bombarding voltages of 330 kv., 670 kv. and 860 kv. indicated values for the quantum energy of the γ -radiation identical within the experimental error of ± 50 kv. Further evidence that the quantum energy remains unchanged at these resonances has been obtained by the use of a recently constructed magnetic γ -ray spectrometer. By this method the relative values of the quantum energy were the same within the experimental error of 100 kv. The absolute value obtained for the quantum energy was 6.5×10^6 ev. In view of these facts, we suggest that the γ -ray emission is the result of the formation of excited ${}^{16}\text{O}^*$ nuclei according to the process:

the same excited state of ${}^{16}\text{O}$ (at 6.5×10^6 ev.) being produced for each resonance of the γ -ray excitation curve.

The total energy which is available, according to equation (2), as kinetic energy of the ${}^{16}\text{O}$ and ${}^4\text{He}$ nuclei is 8.5×10^6 ev. when the ${}^{16}\text{O}$ nucleus is formed in its ground state and resonant excitation of the α -particles of maximum energy is not therefore to be expected. When, however, the ${}^{16}\text{O}$ nucleus is left with an energy of excitation of 6.5×10^6 ev., the kinetic energy of the resulting particles is only 2.0×10^6 ev. and this value is sufficiently low to suggest that broadening of the resonant level due to this α -particle emission would not destroy the resonant features.

The resonant nature of γ -ray emission is usually explained by assuming that the proton is captured into a state from which de-excitation by the emission of an α -particle with the full energy of excitation is for some reason forbidden, the intermediate nucleus remaining excited until de-excitation by the emission of γ -radiation can occur. The above results show that these resonant states of ${}^{10}\text{Ne}^*$, from which the emission of an α -particle with the full energy is forbidden, decay by the emission of an α -particle of lower energy, rather than by the emission of γ -radiation, the residual oxygen nucleus being left in an excited state. It is probable, therefore, that the time required for this emission of a low-energy particle is considerably shorter than the time required for the emission of γ -radiation, but not so short that the resonant features could not occur. The delay needed for this latter condition may crudely be pictured as the time of leakage of the α -particle through the potential barrier of the excited ${}^{16}\text{O}^*$ nucleus. It has been shown that the height at which the penetration occurs is, for the resonance at a bombarding energy of 330 kv., about 2.0×10^6 ev. above the virtual ground state of the excited ${}^{16}\text{O}^*$ nucleus, and one might therefore reasonably expect a further energy range of about 2×10^6 ev. in which the breadths of the resonant

levels show a progressive increase with bombarding energy as the top of the potential barrier is approached.

It is interesting to notice that whilst resonant phenomena associated with the emission of particles from elements bombarded with α -particles have frequently been observed, such processes have hitherto, with one exception, not been found for bombardment with protons or deuterons.

Production of Neutrons by the Fission of Uranium

As a result of the discovery of the fission of the uranium nucleus after absorption of a neutron, we have made experiments to see if other neutrons are emitted in the process, and to measure their number. The results are comparable with those recently published by Joliot¹ and others.

Our apparatus consists of four concentric copper spheres (a), (b), (b'), (c) of radii 7.5, 10.5, 11.5, 12.5 cm., at the centre of which a source of radon plus beryllium of the order of 200 mc. was placed. The space between (b) and (b') was an air gap left for structural reasons. In the first set of experiments, the inner sphere (a) was filled with paraffin wax and the space between (b') and (c) with boron carbide. The apparatus was placed in a tank filled with water, and the activity detected by a dysprosium detector about 15 cm. from the surface of the outer sphere. Measurements were taken with the space between (a) and (b) empty, giving a count v , and full of uranium oxide (U_3O_8), giving a count u . In the second set of experiments the paraffin wax was removed, and the source surrounded with cadmium so that only fast neutrons were used. Again, experiments were made with, u_1 , and without, v_1 , the uranium oxide. Finally, experiments were made with the tank empty and the paraffin wax in place, but no boron carbide, to determine the absorption of the layer of uranium oxide for slow neutrons.

We considered that the production of neutrons might be due either to the slow or fast neutrons, or to both, and our experiments enable us to separate the two effects.

We found the following counts: $u = 0.81 \pm 0.015$; $v = 0.75 \pm 0.02$; $u_1 = 1.24 \pm 0.03$; $v_1 = 1.11 \pm 0.025$; while the absorption for slow neutrons corresponds to a cross-section of 5.9×10^{-24} , assuming a cross-section² of scattering of the order of 40×10^{-24} for these neutrons.

Let v be the number of fast neutrons produced by the fission of one uranium nucleus when caused by a slow neutron, and σ_f the cross-section for this process; and v^1 , σ_f^1 be the corresponding quantities for fission caused by fast neutrons; let σ_0 be the effective cross-section for all capture processes, including fission and resonance, for slow neutrons (for our purposes the resonance neutrons count as slow, but owing to their small 'numerosity' the effective cross-section for the resonance process will be considerably less than the

cross-section at resonance (25 volts)). Let σ_0' be the corresponding quantity for fast neutrons. We find the following results: $v^1 \sigma_f' - \sigma_0' = (4.0 \pm 1) 10^{-24}$ cm.²; $v \sigma_f = (2.1 \pm 1.6) 10^{-24} + 0.78 \sigma_0'$; $\sigma_0 = (5.9 \pm 1) 10^{-24}$. In calculating $v \sigma_f$ we have assumed that the number of fast and slow neutrons which reach the surface of our paraffin sphere are respectively 50 per cent and 20 per cent of the number emitted by the source³.

It will be seen that there is a net increase in the number of fast neutrons considered separately. As regards the slow neutrons the result is less certain there is apparently a decrease for these neutrons considered separately unless σ_0' is taken as at least 3×10^{-24} . We believe, however, that our method tends to give too large a value for σ_0 owing to scattering. It is in fact larger than that used by Joliot in his recent paper¹, $(8.7 - 1.2) \div 1.6 = 4.7$. If we assume Joliot's result is due to fission by slow neutrons, the value of σ_0' becomes at least 4×10^{-24} .

We hope shortly to make similar measurement with thorium.

Absorption Method for Determining the Range of Recoil Atoms

THE determination of the recoil ranges of atoms resulting from radioactive disintegrations has hitherto been restricted almost entirely to gases, on account of the extremely short range of recoil atoms in solids. In silver, for example, the range of α -particle recoil atoms is of the order of a few hundred angstroms whilst that of β -particle recoil atoms is many thousand fold less. It is clear, therefore, that absorption measurements and subsequent range determination in solids are possible only if the thickness of the absorbing layer can be varied by amounts corresponding to a small number of molecular layers. It occurred to us that the built-up molecular films prepared by the method of Blodgett and Langmuir¹ might serve as adjustable absorption screens of this kind; we have now demonstrated the feasibility of this idea and have obtained preliminary quantitative results.

In the first instance, we have confined our attention to α -particle disintegrations which immediately precede a β -particle disintegration, and have devised two methods, (1) suitable for thorium A, radium C and actinium A, and (2) convenient for thorium C radium C' and actinium C.

In method (1), a built-up film is prepared, containing a known number n of molecular layers of barium stearate deposited on stainless steel, and therefor having a known thickness. The film is exposed for a short time to a source of radio-thorium, when thorium A (half-life 0.14 sec.) is deposited on the outermost layer of the film and decays immediately into thorium B. Some of the recoil atoms are ejected downward

to the metal, the proportion actually reaching the metal being a function of n . This proportion is determined by comparing the β -ray activity of the specimen (measured with a Geiger counter) after dissolving off all the films in a suitable solvent, with the corresponding activity before dissolution. An absorption curve can then be obtained by varying n .

Method (2), which has been applied to thorium C, proceeds by trapping the atoms which recoil outwards: a deposit of thorium A obtained as in method 1) is 'blanketted' by covering with a number n' of barium stearate layers. Thorium B, formed by the decay of the thorium A, disintegrates into thorium C atoms, 35 per cent of which emit α -particles with the simultaneous production of recoil atoms of thorium C'. In the absence of blanket layers, a large fraction—nearly one half—of these recoil atoms are ejected out into the air and are lost. The blankets capture a fraction, dependent upon n' , of these atoms recoiling outwards, thus raising the β -ray activity of the specimen (due to thorium C') above its 'no-blanket' value. As the number of blanketing layers is progressively increased, the proportion of trapped recoil atoms, and consequently the β -ray activity, increases until it attains a saturation value corresponding to the capture of all the recoil atoms within the films. The value of n' at which this saturation value is just reached gives the desired recoil range.

Preliminary measurements show that the range of recoil atoms from thorium A is of the order of 60 layers of barium stearate—approximately 1500 Å. or 2×10^{-5} gm./cm.²—and that the range of recoil atoms from thorium C is somewhat less than this. The values are 10–20 per cent lower than would be expected from previously measured ranges in air and silver, which give for thorium A 2.2×10^{-5} and 3.5×10^{-5} gm./cm.² respectively, but it must be borne in mind that the built-up films are oriented whereas the substances previously employed were isotropic.

We are now engaged on accurate determinations for the elements mentioned above, and in addition are adapting the technique to α -particle disintegrations in which the product recoil atom also emits an α -particle. The method should yield information concerning the passage of heavy charged particles through solids and should serve to elucidate the phenomenon of aggregate recoil.

Mass and Mean Life-Time of the Meson

ACCORDING to the new field theory of nuclear forces and β -decay, the mesotron with the charge $-e$ (or $+e$) can transform into a negative (or a positive) electron and an antineutrino (or a neutrino) even in vacuum, the mean life-time of the former due to this process being proportional to the energy¹. In previous papers², the proper life-time τ_0 , that is, the mean life-time at rest, of the mesotron was calculated by assuming the interaction of it with the light particle, which was equivalent to that in Fermi's theory of

β -decay. The result was

$$\frac{1}{\tau_0} = \frac{g'^2}{\hbar c} \cdot \frac{m_U c^2}{\hbar} \left(\frac{2}{3} \lambda_1^2 + \frac{1}{3} \mu_1^2 \right), \quad (1)$$

where g' is a small constant with the dimension of the charge, m_U the proper mass of the mesotron and λ_1, μ_1 are dimensionless constants of the order of 1. Thus we obtained a value

$$\tau_0 = 1.3 \times 10^{-7} \text{ sec.}, \quad (2)$$

by taking $m_U = 200 m$, $g' = 4 \times 10^{-17}$, $\lambda_1 = \mu_1 = 1$. Similar calculations were made for the case equivalent to the Konopinski-Uhlenbeck theory of β -decay, but the value of τ_0 thus obtained was smaller by a factor of the order $(m/m_U)^2$ than (1).

On the other hand, the proper life-time has been determined by several authors³ from experiments on cosmic rays following the suggestion of Euler and Heisenberg⁴. Their results all point to a value

$$\tau_0 = 2 \sim 4 \times 10^{-8} \text{ sec.}, \quad (3)$$

which is in qualitative agreement with the theoretical value (2) corresponding to the Fermi interaction, but is in contradiction with that corresponding to the Konopinski-Uhlenbeck interaction. On account of the importance of the problem, it is worth while considering the former case more closely.

According to Kammer⁵, we assume that the interaction between two heavy particles at a distance r in the S state is given approximately by

$$V_{12} = \frac{1}{r} \left\{ \frac{1}{8} + \frac{5}{24} \left(\frac{\vec{\sigma}^{(1)} \cdot \vec{\sigma}^{(2)}}{\sigma^{(1)} \sigma^{(2)}} \right) \right\} \frac{g^2 e^{-\alpha r}}{r}, \quad (4)$$

where $\alpha = m_U c / \hbar$ and g is the constant with the dimension of the charge; $\vec{\sigma}^{(1)}, \vec{\sigma}^{(2)}$ are spin vector and isotopic spin vector of the i th particle respectively. The numerical values of the constant

$$a = g^2 M / \hbar^2 \alpha = (g^2 / \hbar c) (M / m_U), \quad (5)$$

which changes slowly with m_U , can be determined for several values of m_U by using the results of numerical solution of the deuteron wave equation with the potential of the form (4)', where M is the mass of the heavy particle.

Next, the constant g' is determined by comparing the mean life-time of the β -radioactive nucleus obtained in the previous paper² with the corresponding formula in Fermi's theory. The result is:

$$\frac{g'^2}{\hbar c} = \frac{\pi}{5} \frac{G^2}{a} \frac{M}{m} \left(\frac{m_U}{m} \right)^2, \quad (6)$$

for case (i) $\lambda_1 = 0, \mu_1 = 1$;

$$\text{and} \quad \frac{g'^2}{\hbar c} = \frac{\pi}{2} \frac{G^2}{a} \frac{M}{m} \left(\frac{m_U}{m} \right)^2, \quad (7)$$

for case (ii) $\lambda_1 = 1, \mu_1 = 0$;

$$\text{where } G^2 = 0.9 \times 10^{-4} \cdot \frac{\hbar}{m c^2} = 1.2 \times 10^{-22}$$

according to Bethe and Oritchfield⁶.

Hence, for case (i), (1) reduces to

$$\frac{1}{\tau_0} = \frac{\pi}{15} \frac{G^2}{a} \left(\frac{m_U}{m} \right)^4 \frac{m c^2}{\hbar}; \quad (8)$$

and for case (ii) to

$$\frac{1}{\tau_0} = \frac{\pi}{3} \frac{G^2}{a} \left(\frac{m_U}{m} \right)^4 \frac{m c^2}{\hbar}. \quad (9)$$

These expressions show that the proper life-time of the mesotron increases rapidly with decreasing mass m , the numerical values for several cases being summarized in the accompanying table.

m	100 m	125 m	160 m	200 m
τ				
Case (i)	10^{-8}	0.4×10^{-8}	1.2×10^{-8}	0.5×10^{-7} sec.
Case (ii)	0.2×10^{-8}	0.8×10^{-8}	0.2×10^{-7}	0.1×10^{-7} sec.

Thus the theoretical life-time is always a little too short to account for the cosmic ray phenomena. However, the discrepancy between theory and experiment diminishes if we take a value of m nearer 100 m than 200 m , and μ_1 large compared with λ_1^{-1} .

Diffraction of a Current of Chemical Molecules

A CURRENT of particles of mass m and velocity v , that is, de Broglie wave-length,

$$\lambda = \frac{h}{mv},$$

will be scattered at incidence on a diffraction grating; in the case of a line grating and of a normal incidence, the scattering will take place in such directions δ_μ that

$$\sin \delta_\mu = \mu \frac{h}{mva},$$

a being the grating constant.

Two currents of particles having masses m and m' , respectively, and the same velocity v , will be scattered in directions

$$\sin \delta_\mu = \mu \frac{h}{mva} \quad \text{or} \quad \sin \delta'_{\mu'} = \mu' \frac{h}{m'va}. \quad (1)$$

Let us assume that the particles m and m' are combined in pairs. When the bond is a strong one, the scattering of the pairs will probably take place in accordance with the limit value formula

$$\sin \delta'_{\mu'} = \mu' \frac{h}{(m + m')va}. \quad (2)$$

We do not know in what manner the passage from case (1) to case (2) is effected. Now if we consider

that work can be produced at the diffraction process, and that with very weak bonds we have to do still with case (1) for reasons of continuity, we can presume that these weak bonds will be broken by the grating.

From this it seems evident that weak chemical bonds ought to be capable of being broken up by the process of diffraction.

Presence of Less Common Elements in Rocks

ONE of the latest patterns of the Hilger spectro meter has just been installed in the Chemistry Department of this College, and a systematic search for certain of the less common elements, more particularly the rare earths, in various rocks has been initiated. Incidentally, the spectral lines of nickel have been detected from dark green inclusions in various calcites, notably those from Cannington Park near Bridgwater, and from Weston-super-Mare. The presence of the element was confirmed by the glyoxime test.

The Cannington Park calcite, given us by Mr. H. E. Balch, curator of the Wells Museum, proved particularly interesting. The nickel appeared to be present as carbonate, possibly as xaraitite, along with copper carbonates, malachite and azurite. The characteristic spectral lines of vanadium were also detected and the existence of both elements confirmed chemically. Several other elements appear to be present also, and these we are endeavouring to confirm chemically.

The nickel in the Weston calcite was associated with silica, possibly as garnierite or genthite.

Incidentally, tellurium was similarly detected in the insoluble residue left after digesting sulphur from Krisuvik, Iceland, with carbon disulphide. Its presence was confirmed by reduction and recognition of its characteristic appearance under the microscope.

The problem of the distribution of the less common elements in our rocks and soils is one of great interest; when further data have been accumulated, it may well become one of extreme importance.

'Intraglobular' Reaction in Protein Solutions

IN a letter¹ dealing with my hypothesis of 'intraglobular' reactions, Gralén and Svedberg state that the sedimentation constant of the product of the reaction of egg albumin with glycine ethyl ester measured by them remained practically the same as that of ordinary egg albumin, whereas the diffusion constant decreased to an extent corresponding to a 65 per cent increase of the volume of albumin globules. They believe that these results contradict the hypothesis of the existence of 'intraglobular' reactions.

Careful examination of Gralén and Svedberg's experimental results appears to me, however, to lend the best support to my hypothesis as well as to Wrinn's theory, although in my papers the necessary calculations have not been completed.

Without denying the fact that a portion of glycine ester must be bound to the surface of the albumin molecule (to test this point the adsorption of denaturated albumin at 0° C. was measured), it is necessary to establish that this reaction can take place only between glycine ester and free NH_2 -groups of the basic amino-acids, constituting the albumin, with the formation of a new peptide bond. If this were otherwise, the cyclization reaction of glycine ester would lead to the formation of peptides along with 2-5-dioxopiperazine, which is not observed in reality. Saline bonds between an NH_2 -group of glycine ester and free COOH groups of the albumin are excluded by the fact that they are very weak and are hydrolysed in the process of dialysis; such a hydrolysis has also not been observed.

According to data published by Bergmann and Hermann³, the number of basic amino-acids (arginine, lysine and histidine) in a molecule of egg albumin amounts to 28, while the number of amino- and carboxyl-groups in the side chains of these amino-acids is equal to 52. Hence it follows that out of the total number of glycine ester molecules which are bound to one molecule of egg albumin, only 52 are bound to the surface. This is, however, sufficient to create the surface of the albumin globule a spherical shell with a thickness equal to the length of one glycine molecule, that is, c. 4.5 Å., provided the glycine molecules are distributed symmetrically over the whole surface and are hydrated in the ordinary way. This corresponds to a 60 per cent increase of the volume of the globule, in excellent agreement with Gralén and Svedberg's measurements of the diffusion constant.

The invariability of the sedimentation constant is also explained very easily. If instead of determining the volume of the globule from the total volume of the albumin (as I did roughly initially), this volume is reduced, following Wrinch⁴, by 40 per cent, assuming the thickness of the globules to be equal to 3 Å., then the number of dioxopiperazine molecules that can be accommodated inside the globule will amount to 150 instead of 250. We have found that each albumin molecule is bound with 200 dioxopiperazine molecules. Since, however, 52 of them are bound to the surface of the globule, we find a good agreement in this case also. Owing to the fact that the density of dioxopiperazine differs very little from that of water supplanted by it, the sedimentation constant will remain the same, as has actually been observed by Gralén and Svedberg.

The Cyclol Theory and the Structure of Insulin

It has been proposed that the insulin molecule has the C_2 cage structure. This structure fits the chemical and physico-chemical facts and those relating to cell molecular weight, space group and cell dimensions¹. The view that this structure is inconsistent with certain experimental vector diagrams constructed afterwards has been advanced. Thus Crowfoot, for reasons nowhere stated, writes: "from the cyclol

structure one would expect many more peaks in the Patterson synthesis than do actually occur"². Alternatively, Bernal states that "the distribution of atoms in the cyclol skeleton is far too continuous to give rise to any definite peaks and no distribution of side chains can do other than increase the blurring of the picture"³. I can find no basis for either of these statements. The question of the vector map of the (C-C-N) units of the C_2 skeleton (the main features of which are readily appreciated by looking at very simple diagrams of certain idealized structures already published⁴) has been specifically raised by Bernal^{3,5}. This map has now been constructed by Riley and Fankuchen⁶, who use it to disprove two propositions, neither of which to my knowledge has been asserted, namely, (1) the insulin molecule consists of these 288 (C-C-N) units, and (2) these units and six points at the corners of a C_2 skeleton have the same vector map. This map cannot be regarded as a contribution to the study of insulin, since chemical requirements alone dispose of any idea that the insulin molecule has the composition (C-C-N)₂₈₈. However, the authors claim that it disproves also the hypothesis that insulin is a C_2 structure consisting of 288 ((C(OH)CHR)-N) units. To reach this result, they contend, following Bernal³, that a decision regarding all C_2 structures (which exceed 10^{100} in number) can be reached on the basis of a vector projection of their (C-C-N) units (which in the case of insulin represent 28 per cent by weight of the crystal) no matter what these 288 R groups may be, no matter how they may be arranged, no matter what may be the composition or arrangement of atoms in intermolecular spaces. This contention, in view of the fact that vector maps are not additive, can scarcely be correct. The issue raised, namely, my claim regarding the relation between the C_2 structure and the particular vector projection of insulin which they discuss, remains unchanged. This claim runs "the 18 peaks per molecule are given in the correct positions, on the assumption that there are concentrations of atoms at the six slits"⁷.

Apart from statements regarding uniqueness, dealt with in another place⁸, the remaining criticisms of interpretations of the experimental vector diagrams in terms of C_2 structures⁹ depend upon assuming definite intensities for groups of unknown chemical composition. Such intensities are necessarily arbitrary (cf. those given merely for purposes of illustration, but not made use of, in one of these investigations⁹). Crude maps based upon arbitrary intensities do not permit the assertion that the cyclol model leads to results incompatible with the X-ray evidence. On the contrary, C_2 not only fits all the deductions from this evidence the reliability of which has not been questioned¹⁰, but also it has provided the first hint as to a possible interpretation of the vector diagrams, previously left uninterpreted³, a hint which Bernal appears to have made use of in the 18-point model for insulin which he has since proposed¹¹. (This model has already been adversely criticized^{12,13}.) For with the C_2 structure in mind, it was seen^{1,9,14} that certain outstanding features of the diagrams can be interpreted in terms of the system of electron density deviations, $3s + 3s' = 0$, namely, six regions of high electron density at the corners of an octahedron of side 29–30 Å. and a low density region at its centre. Now it so happens that C_2 is a fabric cage with six special regions or slits which lie

approximately at the corners of an octahedron, and that this octahedron is of side $8\sqrt{6}a = 29.4$ Å. Thus "on the assumption that there are concentrations of atoms at the six slits", presumably belonging to special *R* groups or water of crystallization, the *O_c* structure, which necessarily has a low density region in its interior, gives a simple and unforced interpretation of certain features of the vector diagrams.

The investigations under discussion—and equally criticisms of them—have proceeded on the assumption that the experimental vector diagrams give a true representation of the situation in the insulin crystal. But it must be remembered that, quite apart from any lack of accuracy in the observations, the fact that the number of observations is incomplete means that the actual vector map prepared from them is necessarily a very distorted version of the true one. Further, in this particular case, the supply of data (59 relative measurements of amplitude) is certainly very meagre. Indeed the opinion has been expressed that "they are so inadequate that it is hardly worth while trying to make any kind of detailed analysis from the intensity data at present"¹⁴. In these circumstances, it is necessary to await more extensive data. Meanwhile, it may perhaps be wiser to limit deductions from the present X-ray data to the space group, the cell molecular weight and the dimensions of the unit cell. With these data, as with the general chemical and physico-chemical data, the *O_c* structure (as was shown at the outset¹) is in good accord.

History of the "Widmanstätten" Structure

My attention was recently directed by Dr. R. T. Gunther to a paper by G. Thomson (= W. Thomson, F.R.S.), which appears to have been generally overlooked, describing the Krasnojarsk meteorite, a pallasite containing abundant nickel-iron with about 10 per cent of nickel.

The particular interest of this paper, which is dated February 6, 1804, and published in the *Atti Accad. Sci. Siena*, **9**, 37 (1808), lies in the fact that Thomson studied the action of dilute nitric acid on the nickel-iron; the resulting etch figures are fully described and figured, and it is clear that Thomson anticipated the work of von Widmanstätten (or Widmanstatten), which was carried out in 1808 and published in 1812.

Active Form of Vitamin B₁ in Tissues

THOUGH there has been a strong indication since the work of Lohmann and Schuster¹ that the active form of vitamin B₁ in pigeon brain tissue is phosphorylated, the failure to obtain much activity with oocarboxylase in the catatorulin test with 'brei' (alices has made it impossible to make a firm decision². We are now able to report that with the use of two types of finely ground 'avitaminous' brain preparations (in presence of fumarate) we can get either (1) a preparation which shows good catatorulin effect with small amounts of oocarboxylase (0.26 γ max. and practically no effect with vitamin B₁, or (2) one which still retains some catatorulin effect with large amounts of vitamin B₁ (10 γ) as well as good effect with small amounts of oocarboxylase. Both preparations are rather unstable; the medium used is as in previous experiments.

As there can be little doubt that these ground preparations permit of better access to active centres and as synthesis of oocarboxylase can be found when vitamin B₁ is added to preparation (2), we consider it to be now proved that the active form of vitamin B₁ in brain is phosphorylated; the failure in the ordinary catatorulin test (as was previously suggested)³ is due to impermeability of the brei to oocarboxylase, the effect of vitamin B₁ being produced after phosphorylation.

Full details will be presented elsewhere.

Growth Activation of Cell Colonies *in vitro* by Extracts of Adult Tissues

AN extensive growth of cell colonies *in vitro* is only obtained if tissue extracts are added to the culture medium. It has been generally accepted (Levi¹, Verne², Willmer³) that extracts of growing tissues (embryonic and neoplastic tissues) and extracts of organs with active cell formation (for example bone-marrow) chiefly possess these growth-activating properties. Extract of embryonic tissue is considered to be the best growth activator (Willmer³).

Experiments were undertaken to determine whether the property of cell-growth activation is especially characteristic of proliferating tissue as opposed to mitotically inactive, stable tissue.

We investigated the growth-promoting effect of aqueous extracts from various tissues of adult chickens and compared the action of these extracts to each other as well as to extracts of seven-day-old chick embryos.

The stimulating effects of tissue extracts were quantitatively tested on fibroblast colonies in Carre flasks, prepared according to the standard technique. The growth of cell colonies was observed and measured over a period of seven days. During this time the added tissue extracts were not renewed.

Our experiments proved that extracts of tissues of adult animals including mitotically inactive tissues markedly increase the rate of growth of cell cultures

tracts from heart, smooth muscle, striated muscle, brain, lung, liver, kidney, testes, ovary, oviduct, and spleen proved to be very active. Extracts of spleen and bone-marrow are effective, but not more so than extracts of other tissues. Liver, and to a less extent kidney, differ somewhat in their growth-promoting action from other organs. Extracts from these two organs show a marked initial stimulation followed after three days by a slowing down of the rate of growth and degeneration of the cells resulting in a complete stoppage of growth by the fourth to sixth day.

The growth-promoting action of all extracts used with the exception of liver and kidney extracts varies somewhat within relatively small limits and is extremely pronounced. A comparison of the cell growth activating effects of adult tissue extracts with those of embryonic extract of the same concentration shows that under our experimental conditions the growth-promoting properties of extracts of adult tissues are definitely greater than those of embryonic tissues. Extracts of brain and heart, for example, increase the growth rates of fibroblasts two to three times as much as embryonic extract.

It can be concluded that the ability to stimulate growth of cell colonies *in vitro* is not a specific property of extracts of proliferating tissues, but that growth-stimulating substances are found in abundance in most animal tissues and organs.

We wish to mention here that our work confirms the earlier, much overlooked experiments of Carrel⁴ and Walton⁵ who already in the years 1913 and 1914 indicated that extracts of certain adult tissues stimulate cell growth somewhat.

Details of our experiments are being published elsewhere.

Pasteur Reaction in the Lactic Acid Bacteria

THE lactic acid bacteria show three well-defined types of Pasteur reaction which can be correlated with the respiratory mechanisms of the three main groups into which these bacteria (cocci and rod forms) can be classified.

	Group I	Group II	Group III
Catalase	0	0	0
Respiration	0	+	+
Cyanide inhibition	-	0	+
Hydrogen peroxide formation	-	+	0
Methylene blue stimulation	++	+	0
Glycolysis aerobic	+++	++	+++
" anaerobic	+++	+++	+

The experiments were made in the Barcroft-Warburg apparatus.

Organisms in Group I cannot use molecular oxygen to oxidize sugars, etc.¹, although 'protoplasmic respiration' (autoxidation) can be detected. There is

correspondingly no Pasteur effect. Lactic and pyruvic acid dehydrogenases are present in organisms of Group II² and an appreciable Pasteur effect is noticeable.

Group III (heterofermentative) types are peculiar in that apparently a negative Pasteur effect is present. This group grows almost equally well anaerobically and aerobically, so that its respiratory mechanism would not appear to be a very efficient means of obtaining energy for growth. Considerable amounts of acetic acid are produced aerobically, but in addition more lactic acid (estimated chemically) is produced aerobically than anaerobically. This is believed to be a very rare, if not a unique, phenomenon.

These findings form the basis of a classification which will be published shortly.

Mauicetus: a Fossil Whale

IN 1937, I published in the *Transactions of the Royal Society of New Zealand* an account of a portion of a skull of an extinct whale found in the Upper Oligocene of New Zealand. To this skull I gave the generic name of *Lophocephalus*. Soon after the appearance of the article, my attention was directed to the fact that this same title had been bestowed already on three animals of widely different groups, namely, on a gregarine, on a beetle and on a fish; hence it is necessary to substitute another generic name for this whale. I propose to use the name *Mauicetus*. This name definitely associates the whale with New Zealand, for the Maoris have many legends about that mythical demi-god Maui.

Ancient Egyptian Astronomy

IN a recent communication to NATURE¹, Dr. H. Chatley points out that in my former communication² I did not take account of a whole group of important papers of well-known scholars, and he adds some remarks on stars and planets in ancient Egypt. I think Dr. Chatley must have overlooked my first sentence, where I speak on "Egyptian calculating astronomy". We were, in fact, speaking on entirely different problems.

Dr. Chatley even makes statements concerning the historical estimation of the Egyptian "theoretical" astronomy (*sic venia verbo*). I want to take up this problem, for it seems to me of importance to prevent misstatements taking up a firm position also in this field from the very beginning. Dr. Chatley says: "It seems very doubtful if one can safely attribute much mathematical ability to the ancient Egyptians on the basis of the demotic texts to which Dr. Neugebauer refers. From the time of the foundation of the Museum at Alexandria, Greek methods appear to have been adopted." I do not know who attributed to the ancient Egyptians in this connexion "much

mathematical ability". In the letter of mine this statement is not made and in the paper quoted there on p. 116, note 1, concerning the Egyptian calculation of the new moons, I did say explicitly (p. 403): "Compared with the methods of the Babylonians and Greeks, this method here is very simple and shows no consideration of the anomalies of the motion of the moon and the sun, very carefully studied both by the Babylonian and Greek astronomers". It seems to me, indeed, to be the most important result of the discovery of an Egyptian "theoretical" astronomy, that it represents a state of development just as "primitive" as the Egyptian mathematics. Even the fact that those texts to which I was referring belong to the Roman period and for all that do not at all show the least influence of Greek methods, seems to me of the highest interest. This makes an exact parallel to an analogous position in mathematics, where the Egyptian mathematics, too, retains its primitive

character, quite uninfluenced by the Babylonian and by the Greeks. The striking recent investigation of Cumont on Egyptian astrology³ in this field proves also the splendid isolation of the work of the Egyptian astrologers from the world of the Greek masters—a fact evidently overlooked by I. Chatley, else he would not speak so securely of "purely Greek astrology".

I can also only repeat the conclusion of my preceding letter, that now it is possible for the first time to make a complete comparison of Egyptian, Babylonian, and Greek astronomy, as was possible in the history of mathematics a little earlier.

Points from Foregoing Letters

THE emission of gamma-rays of six million electron-volts energy when fluorine (mass 19) is bombarded with protons, may be explained, according to P. I. Dee, S. C. Curran and J. E. Strothers, by the formation of excited oxygen nuclei (mass 18). Excited neon nuclei (mass 20) are first formed, and these give up alpha-particles of low energy, thus changing into oxygen nuclei.

Experiments by J. L. Michiels, G. Parry and G. P. Thomson on the production of neutrons as a result of the fission of the uranium nucleus show that the processes of fission by fast and possibly by slow neutrons lead to a net gain in the number of neutrons.

E. E. Widdowson and S. J. Gregg have developed methods for obtaining the absorption curves and ranges of the recoil atoms from certain α -particle disintegrations, using built-up films of barium stearate to provide sufficiently thin absorbing screens.

The mean life-time of the meson due to spontaneous disintegration, according to H. Yukawa and S. Sakata, depends critically on its mass, and the discrepancy between theory and experiment becomes smaller as the mass decreases, although the theoretical life-time is always smaller than the experimental value $2 \sim 4 \times 10^{-6}$ sec.

From considerations of the work which can be produced when a current of molecules is scattered at incidence on a diffraction grating, W. Kroczy concludes that weak chemical bonds may be broken by the process of diffraction.

Spectroscopic analysis of various limestones and other rocks is being systematically undertaken in the Chemistry Department of the Central Technical College, Birmingham. Mention is made by J. Newton Friend and J. P. Alloh of the presence of nickel and vanadium in calcites from Cannington Park near Bridgwater and from Weston-super-Mare. Tellurium was found in sulphur from Krisuvik, Iceland.

D. L. Talmud re-interprets the findings of Gralén and Svedberg on the sedimentation constant of the product of egg albumin with glycine ethyl ester, and states that the experimental data do not disprove,

but rather support, the hypothesis of intraglobular protein reaction based upon Wrinch's cyclol model for proteins.

D. M. Wrinch discusses objections to the C_4 structure for insulin, which were brought forward; the strength of 'vector maps', and states that reliance can be placed upon such vector maps because the number of observations used in their preparation is incomplete.

Max H. Hey points out that a paper by V. Thomson, hitherto generally overlooked, shows that Thomson anticipated Widmanstätten's discovery of the etch-figures on meteoritic iron by some years.

I. Banga, S. Ochoa and R. A. Peters state that they have now obtained preparations from avian amniotic pigeon brain which show either catatorulin effects with coocarboxylase and not with free vitamin B_1 or with both. The catatorulin effect is the one given to the oxygen uptake induced in avitaminosis brain by vitamin B_1 addition. They consider it to be proved that the active form of vitamin B_1 in brain tissue is phosphorylated.

The aqueous extracts of the many adult tissues and organs investigated by R. S. Hoffman, J. Tenenbaum and L. Doljanski are said to stimulate growth of fibroblast colonies *in vitro* to a high degree. Under their experimental conditions, the stimulatory action of these extracts was in most cases greater than that of embryonic extract. It was concluded that the ability to stimulate growth of cells *in vitro* is, therefore, not a specific property of extracts of proliferating tissues, but that growth-stimulating substances are found in abundance in most animal tissues and organs.

Working on the metabolism of the lactic acid bacteria J. G. Davis has found that the three main groups into which these bacteria can be classified according to respiration mechanisms show correspondingly three different types of Pasteur reaction. Group III (heterofermentative) shows an apparent negative Pasteur effect.

Research Items

British Decorated Axes in the Early Bronze Age

A STUDY of the diffusion of British decorated axes of the Early Bronze Age by B. R. S. Megaw and Miss E. M. Hardy (*Proc. Prehist. Soc.*, N.S., 4, Pt. 2; 1939) indicates the importance of these axes in the material culture of the British and Irish Bronze Age and that of western and northern Europe. Fundamentally there are only two types: Type I, without flanges, ranging from 6 to 12 inches in length; and Type III, with strong cast flanges, normally from 6 to 8 inches in length. Type II, though in size following Type I, has straighter sides, and low flanges are absent. The ornament is wholly geometrical in character. Ornamented axes have been found only in the British Isles, south Scandinavia, Saxony, France and Holland. The greatest number occurs in the British Isles, being concentrated in north-east Ireland, east Scotland, Yorkshire, the East Anglian fens and the valleys of the Boyne, the Lagan and the Thames, all districts favourable to early settlement. Type I occurs most frequently in Ireland, Type III—though there is a considerable number in Ireland—concentrates in south-east England. Distributional study suggests the possibility that metal-working in the north and west may have started in the west and, carrying Type I, spread from Ireland and the 'highland zone' of Britain to the Continent, reaching Scandinavia via the Moray Firth, rather than via Caithness; while local development suggests the possibility that Irish craftsmen have settled in the Baltic. It is possible, or even probable that Type III originated on the Continent in northern Italy or Bohemia, whence it reached Scandinavia and Southern Britain and ultimately Ireland. This diffusional development illustrates the thoroughly cosmopolitan character of the Early Bronze Age, while a comparison of the character of the ornament with that of the schist plaques from Portuguese passage graves strengthens the attribution of an Iberian origin to Irish metallurgy. The practice of decorating the axe may derive from the spread of the cult of the sacred axe to the west and north.

Gold Pendant from Ancient Columbia

A GOLD object of unusual size and importance has been presented to the collections of the Ethnographical Department of the British Museum (Bloomsbury) by the National Art-Collections Fund. It is a pendant of ancient Colombian provenance in the form of a ceremonial knife with curved edge, similar in form to ancient copper knives from Peru and Ecuador; but the place of the handle is occupied by a highly conventionalized human figure, wearing an elaborate headdress with open-work geometric ornament. H. J. Braunholtz, who has figured and described the pendant (*Brit. Mus. Quarterly*, 13, 1, 1939), cites a parallel from gold objects of the Chimú period found in the Lambayeque Province of northern Peru in 1936. In the present example the headdress is flanked by smaller beaked figures, repeated below, while to the arms are attached animals resembling monkeys with birds' heads. The central figure wears a large circular nose-pendant and three bead necklaces. The legs are constricted below the knee with tight bands, a feature found in ancient Columbian

figure vases. Similar bands are still to be seen worn by living South American tribes. A peculiar character in the figure is the large number of fingers (fifteen on each hand) and toes (thirteen and fourteen). In general aspect the figure is unique, but it presents Peruvian and Panamanian affinity—additional evidence of the strong cultural connexions between north and south indicated in the Chimú period, if not earlier. Its date probably falls between A.D. 1000 and 1400. A record in ink on the specimen indicates its place of discovery as Popayan in the Cauca River valley. This is south of the area of the Quimbaya culture, which produced some of the finest gold work of pre-Columbian America. Though the entire surface is covered with gold, this is superficial only, and encloses a core of base metal with a specific gravity of 9.7, indicating a silver-copper alloy in equal parts. The method by which the pure gold was applied cannot be determined without minute microscopic analysis; but probably it was a form of amalgam plating.

Blood Groups in Man

PROF. R. RUGGLES GATES (*Z. Rassenkunde*, 9, 58; 1939) summarizes the data on the distribution of blood-groups A and B among the races of man. Blood group A is found in the chimpanzee and gorilla and in primitive races of man, but blood group B is not found in these relatives of man and to a very small extent in the primitive races. Since the proportions of A and B vary greatly in different races occupying similar environments, it is suggested that mutation, not selection, is the cause of the different distributions. Blood group B probably has arisen by mutation after the evolution of man, whereas A may have been derived from the early ancestors. As in plants and animals, parallel mutations at different mutation rates in different races may occur in man.

Sulphanilamide in Experimental Brucellosis

B. D. CHINN (*J. Infect. Dis.*, 64, 78; 1939) carried out experiments *in vitro* showing that sulphanilamide has a bactericidal and bacteriostatic effect on *Br. melitensis*, *Br. abortus* and *Br. suis*. He also found that the drug had a protective action in 100 per cent of guinea pigs inoculated with these organisms when treatment was started immediately after inoculation. Sulphanilamide had also a definite therapeutic effect in guinea pigs infected with *Brucella* when treatment was begun a week after inoculation. 50–100 per cent of the animals, according to the type of organisms injected, were negative pathologically and culturally after treatment, while untreated animals were all positive for *Brucella* and showed characteristic lesions. Infections in guinea pigs due to *Br. abortus* and *Br. suis* responded more satisfactorily to sulphanilamide than did *Br. melitensis* infections.

Anaphylaxis in the Rhesus Monkey

L. M. Kopeloff and N. Kopeloff (*J. Immunol.*, 36, 83; 1939) demonstrated the following anaphylactic phenomena in the rhesus monkey after intravenous

injection of horse serum: severe and fatal shock, Arthus reactions, and functional and pathological changes, including delay in clotting time of the blood, reduction in the number of blood platelets, emphysema, oedema and hæmorrhage of the lungs, oedema and hæmorrhage of the intestinal tract, and occasional hæmorrhage in other internal organs. Precipitins to horse serum were present after repeated injections. No correlation was found between the titre of the serum and the degree of sensitivity as measured by shock. The authors (*ibid.*, 38, 101; 1939) also produced severe and fatal anaphylaxis in monkeys by intravenous injections of egg-white. Repeated injections proved more effective for sensitization than single injections. Fatal anaphylaxis usually occurred within six minutes of the injection of egg-white, and was usually preceded by respiratory difficulty, unconsciousness and collapse. Post mortem, occasional emphysema of the lungs with petechial hæmorrhages was found. After shock the blood platelets were reduced to about a third or less of their original number and the coagulation time was appreciably delayed.

Adaptation of a Black Sea Fish to Changes of Salinity

THE Black Sea is inhabited by *Atherina pontica oichvaldi*, a teleostean fish, which is probably a descendant of the Mediterranean species *A. hepsetus*. If this phylogeny is correct, the Black Sea species already shows adaptation to very special conditions, for the average salinity there is only 18 per cent, and it is subject to sudden and serious changes, whereas the salinity of the Mediterranean remains steadily about 35 per cent. Eugen A. Pora has made tests to determine the limits of the adaptability of *A. pontica* to saline conditions (*Ann. Sci. Univ. Jassy*, 24, 319; 1938). He finds that it cannot survive in the salinity of the Mediterranean, its presumed original habitat, but is limited to a range from 12 to 20 per cent. In low salinities the smaller individuals die more quickly than the larger, in high salinities the order is reversed; and in both cases the incidence of death seems to depend upon the size of the gills in relation to body size. The smaller individuals have a large branchial area in relation to the body, the larger individuals have a relatively smaller branchial area; the former die more rapidly in low salinities from a loss of body salts, the latter die more rapidly in high salinities on account of histological changes in the gill filaments which bring about asphyxiation.

A New Mysid Crustacean from the Black Sea

At present only three species of *Hemimysis* are known from European waters: the deep-water *H. abyssicola* from Norwegian fjords, *H. larmannae*, a widely distributed littoral form ranging from north-west Europe to the Mediterranean and Black Seas, and the adaptable *H. anomala* confined to the Caspian and Black Seas, but penetrating even to the fresh waters of the latter basin. To that short series Mihai Băcesco adds a fourth species from the Black Sea (*Ann. Sci. Univ. Jassy*, 24, 425; 1938). It is a beautiful species with many chromatophores, brilliant red with yellow or orange markings, and the rapidity of colour change from full colour to almost clear transparency is remarkable, even under the local environmental change caused by agitating the water of the aquarium. The discovery of this

new species, *H. serrata*, raised the number of forms recognized from the Black Sea to three, out of known total of four, and the author makes the suggestion that the Black Sea basin, or more generally the Ponto-Caspian region, may be the evolutionary cradle for the genus *Hemimysis*, as it is for the related genus *Paramysis* and perhaps also for *Diamysis*. It cannot yet be safely said that the new species is endemic to the Black Sea for the mysid fauna of the eastern Mediterranean has been little studied and upon such study must await the determination of the relationship of the forms occurring in the close waters of eastern Europe.

Plant Behaviour

THE Masters Lectures of the Royal Horticultural Society for 1938 were given by F. J. Chittenden who chose "The Behaviour of Plants" for the title of his discourse (*J. Roy. Hort. Soc.*, 64, Pts. 2 and 3; February and March 1939). His first lecture dealt mainly with periodicity of development of garden plants. Shortening the normal period of dormancy of plant shoots can be accomplished in several ways. Mr. Chittenden reviewed the various methods with a combination of historical background, practical outlook and scientific exactitude, which is not often accomplished. He furthermore mentioned the simple expedient of plunging the dormant plant in a bath of warm water, a method of breaking the rest period which seems to have been forgotten of recent years. Dutch work upon periodicity of the common bulb was marshalled in such a way that many suggestive points of view emerge from the text. There are, however, many plants which could better represent the conception of 'short-day' flowering plants than the lecturer's choice of *Dahlia*, though his descriptions of earlier flowering in London than in New York are none the less interesting. The second lecture was chiefly devoted to a consideration of plant hardiness. The maidenhair tree, *Ginkgo biloba*, was cited as one of the hardiest plants under wide extremes of climate both recent and geological. *Primula nivalis*, on the other hand, has evidently such a narrow range of hardiness that it is extremely difficult of cultivation. Damage by early frosts in such southern plants as *Amaryllis Belladonna* is regarded as incomplete acclimatization in the northern hemisphere, but several interesting examples are given of quick adaptation to the reversal of climatic sequence involved in transplantation from north to south or vice versa. Many plants, as *Primula malacoides*, are also more variable in cultivation than they were in the wild state, whilst others are not. Generalisations are not possible between plant species; each one has its own innate characteristics, which must form the subject of separate experiments before adequate horticultural control can be expected.

Colchicine and Wheat Hybrids

E. R. SHARS (*J. Hered.*, 30, 38; 1939) describes the production of fertile polyploid generic hybrid by the aid of colchicine. The seeds resulting from the crosses *Triticum monococcum* × *Aegilops uniaristata*, *Ac. caudata* × *Ac. umbellulata* and *Ac. speltoides* × *Ac. umbellulata* were immersed in a solution of colchicine for twenty-four hours. As much as one third of some of the mature plants were found to be tetraploid $2n = 28$ and fertile, whereas the remainder of the plants was diploid and sterile.

Sex Chromosomes of *Cricetus auratus*

THE small rodent, the golden hamster, has an XY pair of chromosomes of equal size during mitosis but greatly differing in construction and appearance during meiosis (P. C. Koller, *J. Gen.*, 36, 177; 1938). This arises from the fact that the differential part of the X-chromosome remains during meiosis in a similar extended state to that of mitosis while the pairing segments of the X- and the Y-chromosomes are normally condensed. The centromere is localized in the pairing segments and chiasmata may be formed on either side of it. It is therefore to be expected that a number of characters may be controlled by genes on the sex chromosomes but may not show sex linkage. The differential segment of the X-chromosome shows 81.6 per cent pre-reductional segregation.

Effect of Pressure on the Rigidity of Rocks

THIS was the subject of a considerable amount of experimental work by Francis Birch and Dennison Bancroft of Harvard University (*J. Geol.*, 46, Nos. 1 and 2; 1938). They employed a method whereby a light circular cylinder of the specimen about 20 cm. long and 2 cm. in diameter was set into forced torsional oscillation by means of a driving armature at one end, and the resulting motion observed by another armature at the other end leading to an a.c. voltmeter. The whole was subjected to pressures of nitrogen gas varying between 1 and 4,000 kgm./cm². by placing it in a thick-walled steel tube. Using a water jacket, temperatures were varied between 30° C. and 100° C. Very large changes in rigidity were observed in many cases upon the application of the first few hundred atmospheres, but at high pressures the change of rigidity with pressure became nearly linear and small. Extrapolating from the results obtained, the authors discussed the materials and temperature conditions in the surface layers of the earth. The usually accepted values of the velocities of P and S waves in the granitic layer they suggested as being those in a granite with a low quartz content. For the intermediate layer they considered that their results were not inconsistent with some diabasic or gabbroic rock. In view of their small coefficients of decrease of rigidity with pressure and temperature, however, they found great difficulty in fitting in any of their rock types with the normal velocities of 7.8 m./sec. and 4.35 km./sec. respectively for the P and S waves in the underlying supposedly basic material.

Viscosities of Liquid Helium

SOME very puzzling results have been obtained for the viscosities of liquid helium. Some observers found a normal increase with decrease in temperature from 1.2° to 2.2° K. but below 2.2° K. the viscosity decreased rapidly. It has also been considered that at lower temperatures the viscosity fell below an experimentally determinable value. The suggestion has been made that a film is formed on a tube surface in which liquid helium is being evaporated under reduced pressure. W. F. Giauque, J. W. Stout and R. E. Barieau (*J. Amer. Chem. Soc.*, 61, 654; 1939) now describe some experiments which are very satisfactorily explained by the transfer of helium up the walls of the tube. Their own experiments indicate that the viscosity of liquid helium decreases from 2.0×10^{-4} poise at 2.266° K. to 1.0×10^{-7} poise at 1.468° K. The largest Reynolds number, which occurred at 1.468° K., was estimated to be about

200, instead of very much larger values formerly reported. At the lowest temperature of measurement the viscosity was found to be still decreasing rapidly, and it appeared to be approaching zero at the absolute zero of temperature.

Theory of Air-Conditioning Systems

AN instructive paper, by R. O'Neill Hobson, has recently reviewed the fundamental theory governing the operation of air-conditioning systems (*British Engineers' Export Journal*, April). These systems consist in the treatment, modification and control of all the physical and some of the chemical properties of air. They also involve the simultaneous control of temperature and humidity, purity and movement of the atmosphere within enclosed spaces. The demand in each industry varies from that of others over a wide range. The processing of cotton and artificial silk, for example, which requires a humidity point of at least 80 per cent, contrasts sharply with the manufacture of chocolates, where the maximum humidity should not exceed 25 per cent, or of match production, which needs no humidity at all. In the same way the temperature demands vary considerably. In a country where there is often a wide degree of temperature variation from dawn to dusk, as well as from day to day, ideal conditions can only be secured by a well-designed and efficient system. In those systems where both the temperature and the moisture content have to conform to set standards, the apparatus must be designed to duplicate as nearly as possible the changes which Nature makes on a large scale. Heat must be supplied to evaporate water, and heat must in turn be subtracted to effect the condensation of water vapour. It is essential to have the operation of the plant automatically controlled. Humidity control is of equal and sometimes of greater importance than temperature control. The large-scale air-conditioning and refrigeration installed in many South African gold mines enable gold companies to explore much greater depths.

Measurement of Radio Fields at Ultra-Short Waves

THE general development of the ultra-short band of wave-lengths below 10 m. for television broadcasting and for radio-telephone links, has given rise to a demand for accurate methods of measuring field intensity on these wave-lengths. The March issue of the *Journal of the Institution of Electrical Engineers* contains a paper by F. M. Colebrook and A. C. Gordon-Smith describing the design and construction of a measuring set developed at the National Physical Laboratory for wave-lengths of 7–11 m. (frequencies 27 to 43 Mc./s.) The apparatus consists of a high-gain intermediate-frequency amplifier (about 1 Mc./s.) associated with a signal-frequency and frequency-change unit of constant conversion efficiency. The e.m.f. of thermal agitation in the input tuned circuit of the intermediate-frequency amplifier is used as a standard signal for setting the amplifier to a known amplification. The whole apparatus is calibrated over its signal-frequency range by means of a small transmitter which gives a horizontally polarized radiation of calculable intensity. A loop aerial system is employed, coupled inductively through a suitable electric screen to the frequency-change circuit. The apparatus is suitable for measuring field intensities of any value down to about 1 microvolt per metre.

Location of Industry in Great Britain*

THE report on the location of industry which has now been issued by Political and Economic Planning (P.E.P.) is one of a series of contributions to this subject which has been made by P.E.P. since, in April 1935, it was decided to undertake a comprehensive study of regional development to provide a sound basis for the evolution of policy. Apart altogether from its recommendations, this report contains much that is new and gives by far the most comprehensive and scientific survey yet available of a problem which many factors besides those of the Special Areas and defence policy are forcing upon our attention.

After reviewing briefly the factors which led to the emergence of the problem, the report, by means of a series of diagrams, shows the recent changes in British industry and its present distribution by regions. The employment chart for all insured persons, including distributive and other workers, shows how, between 1923 and 1937, the south-east, Greater London, the south-west and the Midlands increased their proportion of total national employment at the expense of other regions, particularly Wales and the North. Since 1921, some 700,000 persons from other parts of Great Britain have migrated to Greater London. The net output figures show similar changes, with Greater London rising by nearly 50 per cent between 1924 and 1935 and South Wales declining almost as sharply. In 1935, Greater London had more workers actually employed than any other region, and at the same time a higher value of net output per head. Apart from their heavier burden of unemployment, the older industrial regions of the north-east, the West Riding and Lancashire have markedly lower net outputs per head than the south-east and east England or the Midlands. Between 1927 and 1937, the extractive group of industries reduced its use of labour by more than 30 per cent, textiles and clothing by 20 per cent, while heavy industry also slightly declined, but light and intermediate industries, building, transport, distribution and services expanded their personnel.

The region with fewest types of industry is south Scotland, in which 39 per cent of British industries are virtually unrepresented and a further 38 per cent have location factors below 0.45. Lancashire and Cheshire show most types of industry, while the West Midlands have the largest share of industrial concentration, nearly 20 per cent of their industries having location factors greater than 2. Between 1924 and 1935, Greater London maintained or increased its relative share of output in all industrial groups except two, and even in these its net output increased. Nevertheless, London is now getting no more than its proportionate share of new employment. In the last six years, the south-east and Midland divisions have made most advance, but the northern division has recovered nearly a third of the ground previously lost. Scotland, Wales and the north-east have held their own, the north-west continuing to lose heavily. The four southern divisions

now claim nearly 54 per cent of British employed workers as against less than 47 per cent in 1923, as London's employed population is now nearly half as high again as sixteen years ago.

Changes in employment in individual industries are also discussed, and the report then considers the factors which have determined the location of industries, including some discussion of the financing of new developments. A close survey of existing trading estates follows, while an analysis of the effect of the location of industry points out that about 43,000 acres of land are taken from the farms annually by industry, while at the same time the State has to spend large sums on cleaning up sites abandoned by industry in a derelict and unusable condition. Residential and university towns have their amenities ruined by new mushroom industries, while towns built for industry stand half idle. This analysis of social effects is followed by discussion of the different types of town in relation to industry, an analysis of the main considerations affecting industry and defence, of the need for balance in regional development and a discussion of the aims of national industrial policy.

The final chapter of the report outlines its proposal to meet the main needs not covered by existing machinery—the provision of a centralized research and information service and the effective co-ordination of action. The main proposal is the creation of a permanent Industrial Development Commission to guide the location of industry and advise the Government on the subject. The Commission would be charged with the licensing of new factories or extensions; where a licence was refused, it would be required to indicate broadly the areas and categories of industry in respect of which applications would not in principle be favoured. It would keep under review all factors affecting the efficient operation of industry or affecting economic development in different areas and the location of industry. Like the Commissioners for the Special Areas, it would have resources for giving limited financial help to overcome obstacles to industrial development in specific instances. The Commission would explore the problem of financing new enterprise, would take over the responsibility for supervising existing publicly owned trading estates and for the preservation or restoration of amenities.

The report also suggests that the Commission should take over the machinery for the Special Areas, and, particularly, that it should consider the problem of evacuation and re-settlement where necessary. Using Merthyr as an example, it is suggested that transfer as a community of such a town of 63,000 inhabitants at a total cost of £15 millions would represent a total cost to the State in interest and sinking fund of less than the £832,000 actually paid out in 1937–38 to keep much of Merthyr in idleness. It is proposed that the Commission should be responsible to Parliament through a senior Cabinet Minister without departmental duties, and its probable cost need not exceed that of the Special Areas Commissioners, whom the new industrial body would in time supersede.

Control of Metamorphosis in Lepidoptera

J. BOUNHIOL has recently published a detailed account of his experiments on this subject, some of which have been published from time to time during the last few years (*Bull. Biologique de France de Belgique, Suppl.* 24, 1-199; 1938). Three species of moths were used in this study: the silkworm moth *Bombyx mori*, the wax moth *Galleria mellonella*, and the gipsy moth *Lymantria dispar* in the order of their importance. The paper begins with a description of the life-histories and the methods of rearing. There may be either four or five larval ecdyses in *Bombyx mori*, but careful measurements of the head diameter will show to which instar the larva in question belongs, and whether it is of the four- or five-moulting type. Equally necessary for the correct interpretation of the later experiments was an examination of the effect on the occurrence of metamorphosis of simple starvation begun at various times after the last larval moult. In the case of *Bombyx mori*, the larva must be able to feed for at least seven days for metamorphosis to take place. This is liable to be a complicating factor in experiments in which the aim is to inhibit metamorphosis by an operative procedure. For example, the author finds that section of the ventral nerve cord prevents metamorphosis if the cut is made before the seventh day after the last larval moult; but this, he suggests, is due merely to an interference with the normal nutrition. The same sort of thing has to be taken into account in considering experiments where regions of a larva are separated off by ligatures with the view of finding their importance in metamorphosis.

Perhaps the most interesting part of the work is

that dealing with the function of the corpora allata. Dr. Bounhiol describes the delicate surgical method which he has devised for removing these bodies in the larva of *Bombyx mori*. He finds that loss of both corpora allata in the last larval instar has no effect on the occurrence of pupation; but if, on the other hand, the operation be performed in the instar before the last, then pupation takes the place of the normally ensuing larval moult and a premature metamorphosis is induced. The same is even true of a still earlier instar and in this way a pupa was obtained which weighed a fortieth of the normal.

The result of corpora allata removal in *Bombyx mori* and the comparable effects following the same operation in the stick insect *Dirippus* (Pflugfelder, *Z. wiss. Zool.*, 149; 1937) are interesting when compared with the results of Wigglesworth on *Rhodnius* (*Quart. J. Micro. Sci.*, 79; 1936). Wigglesworth suggested that the corpora allata secrete a hormone inhibiting metamorphosis and another initiating moulting. In *Bombyx* the corpora allata possess the first function but apparently not the second.

Dr. Bounhiol also reports that he repeated and confirmed the experiments of Kopeč, who found that removal of the cerebral ganglia before a certain critical period prevented metamorphosis. Lastly, he discusses the factors controlling metamorphosis in insects and maintains that the view which most experimenters on this line hold, that pupation is initiated by a hormone circulated by the blood, is still unproved. This must be so until someone makes at least a cell-free extract and induces metamorphosis with it.

E. T. BURR.

Portable Gas Producers

MR. BOSWORTH GOLDMAN and Mr. N. Clarke Jones, in a paper presented to the Institute of Fuel on December 8, 1938 (*J. Inst. Fuel*, 12, 63, February, 1939), pleaded for recognition of the value of portable gas producers as a means of supplying mobile power as an alternative to petroleum. In the event of world petroleum resources becoming exhausted or of their being restricted in times of national emergency, other fuel would have to be used for vehicular propulsion. Producer gas plants are claimed to be between two and three times as efficient as any oil-from-coal process and yet they can utilise the same cheap and easily available home-produced fuel.

The theory of producer gas practice is based on the conversion of carbon into carbon monoxide, which when mixed with further oxygen is combustible in an engine. To achieve this, five units are necessary: generator, coolers, scrubbers and/or filter, air inlet device and gas throttle. These units are disposed about the vehicle and connected by pipes. They can be fitted to existing vehicles by modification of the existing engine or alternatively incorporated into a specially designed chassis.

A variety of solid fuels, such as anthracite, charcoal, low-temperature coke and peat may be used in these plants, but their efficiency is dependent on factors

of reactivity, size and grading, moisture content, ash and volatile content. Actually there are ample resources of suitable fuel available in Great Britain, but their utilization is hampered by the relative difficulty of obtaining supplies as compared with liquid fuels.

As regards performance, figures obtained for certain types of converted vehicles show that for acceleration and hill climbing this type of fuel is but little inferior to petrol. Moreover, it has been proved that maximum power on gas is obtained at a mixture strength slightly weaker than that theoretically required. In the case of petrol, maximum power is only achieved with a richer mixture than is theoretically needed.

For some time past these and other advantages have been fully appreciated on the Continent, and a considerable number of producer gas vehicles are in use. In Great Britain, however, their utilisation has been impeded by the Government's refusal to adjust existing regulations in such a way as to place producer gas propelled vehicles on a similar footing to steam and electricity. Co-operation is required between producer gas plant manufacturers, suppliers of the requisite fuel and members of the automobile industry, if this technique is to be developed and full advantage taken of its potentialities as a substitute for liquid fuel.

Temperature-indicating Paints

THE use of special paints, such as those containing metallic iodides, for application to bearings and other parts of machinery liable to over-heating in order to indicate such temperature increase through change in colour of the paint, has been known for some years (Pinnock, *J. Soc. Chem. Ind.*, 38, 78; 1919). These earlier preparations were, however, only suitable for comparatively low temperatures, and also the colour change as a rule was not permanent. Paints or thermo-colours adapted for use under much more exacting conditions have been developed in Germany by the I.G. Farbenind. Akt. Ges. in connexion with its fuel research work at Oppau, including aircraft engine design (F. Penzig, *Z. des V.D.I.*, 80-74; 1939).

The method of indicating temperature change and distribution, especially in aircraft engine cylinders, etc., by means of thermo-colours offers many advantages over the usual laborious method of taking several individual temperature measurements in various parts of the cylinder, piston, etc.; and in the case of air-cooled engines it provides invaluable information in the optimum design of air guide plates. It is also of great value in other cases of temperature determination, for example, in hot plates, radiators, drying chambers, etc.

It was desired to discover paints which would not only undergo sharp, distinct, and permanent colour change at fairly definite temperatures, but would also possess good adhesion at these high temperatures, up to 450° C. It is hoped, indeed, to evolve thermo-colours for use up to 650° C. or even higher; but those so far discovered are sufficient for present-day aircraft engine research. In regard to sharpness of change, it is obvious that intermediate tones are to some extent unavoidable since the change is due to thermo-chemical reaction; but with sufficient time the change is definite and complete. On the other

hand, allowance must be made for the fact that the longer the time exposure the lower the temperature within reasonable limits, at which the change occurs. Curves are given in the original showing temperature change at intervals of 30 min. up to 120 min. for the various paints. The time effect is greatest at the higher temperatures: for example, a thermo-colour which by definite colour change indicates a temperature of 360° C. in 30 minutes, falls to 290° C. in 120 min., whilst the curves at 40-80° C. are nearly horizontal.

No fewer than three hundred different preparations have been investigated at Oppau; but only a very limited number have been found of practical use. These are tabulated by number in the original. The following are some of the colour changes: No. 1, rose to blue, 30°; No. 3, light yellow to violet, 110°; No. 8, white to light brown, 340°; No. 9, violet to white, 440°. No. 20 has two different colour changes at 65° and 145°; whilst Nos. 30 and 31 have three distinct colour changes at temperatures ranging from 65° to 220° (No. 30), and 155-275° (No. 31). The temperatures are indicated with an accuracy within $\pm 5^\circ$, which is sufficiently accurate for the purpose in view. Where exact measurement is required at any particular point this can be done in the usual way with thermo-elements.

The binding agent or medium used presented some difficulty; it was eventually discovered that synthetic resin soluble in alcohol is the most satisfactory. It is added in finely powdered form to the pigment, and a paint of any desired viscosity may be prepared by stirring this mixture with the correct amount of alcohol. These paints dry very quickly; the resin does not undergo any colour change which would affect the desired result, and the paint coating has practically no influence on heat transfer from the cylinder or other part under test.

Testing High-Voltage Cables

THE use of high-voltage cables for the underground transmission of electric power is becoming more and more important from the point of view of economy, and also because as the network extends the damage caused by the breakdown of a cable, generally due to over-voltage, may be very serious. For the last ten years constant research has been proceeding, dealing with oils, papers and the general physics of cables. In the development of a cable suitable for extra-high voltage transmission there have been four main methods of attack. The first is to use oil-filled cable, the second external gas-pressure cable, the third internal gas-pressure cable (gas-filled cable), and the fourth the cables most commonly used with solid insulation known as 'solid cables'.

In a paper read to the Institution of Electrical Engineers on January 18, by T. R. Scott and R. C. Mildner, the results are described of researches extending over several years on a 3-core 30 kv. solid

cable which has since, without any fundamental change, been manufactured in considerable quantities and has given extremely satisfactory service. Single-core cable manufactured on identical lines was somewhat inferior in performance. At 60 kv. this difference became very noticeable, although on the basis of standard acceptance tests there was little or nothing to choose between multi-conductor and single-conductor cables. It became evident, therefore, that some form of final check approximating to 'trial on service' was necessary to ensure that unsatisfactory types of cable were not issued for commercial service. In view of the destructive nature of the test that was visualized, it was considered impracticable to install the cable in the network of an operating company. It was considered feasible to design a testing plant to reproduce all the conditions under which cable operated, and yet give the facilities which such research requires. It was realized that such a method

ould be slow to produce results and expensive to try out; but its value has been amply proved by the practical results achieved.

Solid-core 60 kv. cable was originally selected as the basic type. It was considered that this type of cable would always be able to compete on an economic basis with the other forms of cable that have been proposed, provided that it could be proved that it was capable of operating at a conductor temperature not more than 65° C. for a life not appreciably less than that of solid cables operating at lower voltages. Work on solid-type 60 kv. cables also provided an excellent basis not only for effecting improvements in the performance of similar cables working at 30 kv. and lower voltages, but also for extending the investigation to 132 kv. All experimental cables were 'processed' in the factory under closely observed, but essentially practical, conditions, and their characteristics have been watched carefully throughout their useful life. The paper gives a preliminary survey of the work carried out to date.

It is hoped that the results obtained will assist in allaying certain fears which obviously influence cable users. The authors state that as the result of the experience gained in their tests the successful operation of solid-type cable at 60 kv. has been firmly established. The employment of this form of cable in preference to the other types which have been proposed, should rest on a purely economic basis in which the cost of the installed line and its maintenance is added to the charges to be attributed to the electrical losses involved in operation. In this latter respect the stability of the dielectric need be in no way inferior to that of other types. It is pointed out that the deterioration due to the electric discharges in vacuum spaces (gas pockets) can be reduced to negligible proportions at the proposed working stresses by drawing attention to the quality of manufacture. In this matter the authors' experience suggests that 'uniformity of impregnation' is the main object to be aimed at rather than getting the purest material. As the 'geometric factor' of the cables tested varies widely, it is concluded that the maximum electric stress in the cable is the crucial factor in its behaviour in operation.

University Events

BIRMINGHAM.—The following honorary degrees are to be conferred at the degree congregation on July 1: LL.D. on Mr. A. C. Beatty, Lord Porter, and Sir Charles Grant Robertson; D.Sc. on Dr. E. B. Bailey, and Sir William Bragg; D.Litt. on Prof. Arnold J. Eynon.

CAMBRIDGE.—The tenth course of Scott Lectures is being given in the Cavendish Laboratory by Prof. M. S. Blackett, at 4.30 p.m. on May 4, 5 and 8. The subject of the lectures is "Cosmic Rays—New Results and Further Problems".

W. S. Tai, research student of Gonville and Caius College, has been elected to the Sheepshanks exhibition.

LONDON.—The Farnham House Laboratory of the Imperial Institute of Entomology, at Farnham Royal, Bucks, has been approved as an "Institution having recognised Teachers" for the instruction of students pursuing courses of advanced study or research.

Science News a Century Ago

Ptolemy's Catalogue of Stars

At a meeting of the Astronomical Society held on May 10, 1839, Francis Baily, in a paper bearing the above title, said: "The catalogue of stars, which goes under Ptolemy's name, will always be interesting to the astronomer, as containing the first record of the state of the heavens. The point to which, in the present view of the case, I am most desirous of directing attention is, how far the existing edition of this work may be considered as faithful transcripts of the catalogue as it issued from Ptolemy's hands. This important question can only be decided by a careful examination of various manuscripts, and by comparing the discordant readings with the actual positions of the stars, as determined by modern observations." Having referred to the five sources of information, he went on: "Having carefully compared the position of every star, as given in each of the several copies alluded to, I have found that out of 1,028 stars, of which the catalogue consists, there are above 780 (or more than three-fourths) of them that are discordant, either in longitude or latitude, and this not merely in 10, 20, or 30 minutes, which is no uncommon difference, but sometimes to an amount involving whole degrees."

The Atlantic Voyage of the *Ironides*

In October 1838, Airy, at the request of the owners of the iron sailing ship *Ironides*, had made improvements in the method of correcting her compasses. Shortly afterwards, the ship sailed for South America. After her return, the *Mechanics' Magazine* on May 11, 1839, said: "Thus, the first sailing vessel constructed of iron which has ever been dispatched to encounter the risk of a transatlantic voyage, and which left Liverpool some five months since, for the Brazils, entered the Mersey on the 1st of May. The homeward passage from Aricati was accomplished in forty days, which is considered to be no despicable achievement, as during the whole trip light winds prevailed. The return of the *Ironides*, has completely established the practicability of navigating the ocean safely and surely in ships constructed of iron. The compass, whose action it was predicted would invariably be deranged, worked correctly; and the superiority of the material of which she is built is proved by the fact, that from the day on which she sailed for Pernambuco, during the time she remained at the Brazils, and in the course of her voyage home, on no one occasion was it necessary to use the pumps; in fact her hull is absolutely and literally water tight."

The Asiatic Society

Among the reports read at the sixteenth anniversary meeting of the Asiatic Society on May 11, 1839, was one by the Right Hon. Holt Mackenzie referring to the work of the Committee of Commerce and Agriculture. It commenced by acknowledging the valuable services of Dr. Royle (secretary) and Mr. Solly (chemical analyst). Attention, it said, had been given to the introduction into India of improvements in cotton cultivation; the value and quality of various oil seeds grown in India and the vegetable tallow of Canara; and information had been collected regarding cocutcheon, kino, hemp, tea, iron, cochineal, timber, wool, silk and other things.

Societies and Academies

Paris

Academy of Sciences (C.R., 208, 953-1060, March 27, 1939).

M. ROY: Diagram of the flow of a gas through a rotary tuyere.

J. KUNTZMANN: Classes in a multigroup.

T. PRYOVITCH: Value at infinity of the integrals of certain differential equations.

W. BARRETT: Certain discontinuous groups of displacements.

R. MOINEAU: The autopropulsive and hyper-sustaining flapping wing.

D. BELORIZKY: Collisions in the problem of three bodies and in space.

G. PETIAU: Electromagnetic magnitudes of the theory of the photon.

J. MARIANI: Quantum of length and the spin of elementary particles.

J. GUASTALLA: Surface manometer with pendulum suspension [for the measurement of the pressure of surface films].

M. JOLY: Existence of two forms of superficial protein films. Very stable films of low viscosity, and very viscous films which 'age' with time are distinguished.

P. VERNOTTE: Convection of heat, from a plane in which there is any distribution whatever of temperature, by an indefinite fluid of two dimensions in which there is any distribution of velocities: application to the law of natural convection.

G. DUYOURET: Specific heats of iron between 1.5° and 20° K.

R. GUILLIEN: Dielectric constant of ammonium sulphate in the neighbourhood of the λ -point. Dielectric constant and electric absorption have a maximum at the λ -point.

F. CARBENAY: High-frequency radio communication along power lines.

R. AUDUBERT and R. RALBA: Photogenic effect and electronic activation of the radical $N \equiv N$.

L. ABONNENC: Diamagnetism of the rare gases of the atmosphere—argon, krypton, xenon.

A. DUFOUR and F. PRUNIER: An effect observed with a Sagnac disk in rotation when a part of the optical circuit is not in rotation.

A. PINKABA: Influence of molecular interaction on the magnetic birefringence of polar liquids.

J. VERHAEGHE and M. VAN EYCK: Circular magnetic dichroism of cobalt sulphocyanides.

A. COTTON: Note on the preceding paper.

M. DODÉ, H. VON HALBAN, JUN., F. JOLIOT and L. KOWAREKI: Energy of neutrons liberated in the nuclear partition of uranium. The experiment described, while showing the neutrons produced are distinct from the incident neutrons, does not demonstrate the possibility of chain reactions.

M. BRUTZOUS: Thermochemistry of combinations of nitrogen.

MILN. M.-L. DELWAULLE: Study of the Raman effect of equilibrium reactions in the formation of mercuric chlorobromide and bromocyanide.

F. FRANÇOIS: Study of the system mercuric cyanide, mercuric chloride and methyl alcohol. Formation of an addition compound of mercuric chloride and methyl alcohol and evidence by the Raman effect of a chlorocyanide.

E. TOPOBESCU: New method of studying the polarization of galvanic piles.

H. VOLKRIINGER, MMRS. M. FREYMANN and FREYMANN: Influence of temperature on the Raman spectrum of ammonium nitrate and sulphate.

(To be continued.)

Amsterdam

Royal Netherlands Academy (Proc., 42, No. 2, 1939)

F. K. TH. VAN IJERSON: The pressure of the rock on the coal near the coal face. A mathematic consideration of the problem by the methods of the theory of elasticity.

L. S. ORNSTEIN and W. DE BRAAF: Remarks on the paper of V. Zwetkoff, "Ueber die Lichtzerstreuung in anisotropen Flüssigkeiten".

R. FÜRTH, L. S. ORNSTEIN and J. M. W. MILAT: On the theory of liquids. A provisional mathematic treatment of the theory of liquids regarded as quasi-crystalline structures containing many 'holes' faults.

A. J. KLUYVER and E. L. MOLT: On the production of acetylmethylcarbinol by *Bacterium coli*. The bacterium has been shown capable of producing small amounts of acetylmethylcarbinol under the conditions of the Voges-Proskauer test, so that the theoretic basis of the latter test for distinguishing *B. coli* from *B. aerogenes* loses much of its significance.

E. DUBOIS: On the insignificance of cranial vault-height in phylogenetic brain growth.

B. G. ESCHER: Moon and earth. Geologic considerations on the development of continents and oceans, the limitation of granitic magma to the continents, the composition and morphology of the moon.

H. FREUDENTHAL: New continuation and mapping theorems.

O. S. MEYER: Integral representations of Whittaker functions.

J. TEGHEM: On a type of Diophantine inequalities.

P. G. MOLENAAR: A complete system of differential co-variants of the first order of the binary cubic differential form.

H. D. KLOOSTERMAN: On the singular series in Waring's problem and in the problem of the representation of integers as a sum of powers of primes.

I. LIFSCHITZ: On dissymmetrical synthesis in the case of complex metallic salts (3).

W. P. POSTMA: Some remarks on the influence of nitrate reduction on the respiration of roots.

F. C. J. ZEIJLMAKER: Carboxylase and α -carboxylase in the germination of *Avena*. The total amount of co-carboxylase remains constant during germination.

J. C. MOOI: On the enzymes taking part in the conversion of alanin and of asparaginic acid by *Aspergillus niger*.

C. J. JARSKI: An oestrus cycle in *Lobelia reticulata* (Petus).

W. RIMM: The hemispherical wall of the newborn bear and the evolution of the nerve cell.

G. P. FRITS: (1) The growth curves of the dimerizations and of the weight of the seeds of *Phaseolus vulgaris*. (2) A second group of observations regarding dimension and form with the growth of the seeds of *Phaseolus vulgaris*.

Moscow

Academy of Sciences (C.R., 21, Nos. 1-2, 1938).

S. FENIKOFF: Deformation of a surface with the tension of lines of a family.

A. G. PINSKER: Extension of semi-ordered spaces.

M. S. EIGHENSON: Surface brightness of the light sky and the infinity of the astronomical universe.

M. N. PODASHEVSKY and A. M. POLONSKY: Luminescence of alkali-halogenid crystals.

J. S. SHUB: Influence of heat treatment in a magnetic field upon the distribution of the spontaneous regions of a ferromagnetic monocrystal.

D. BLOKHINTSEV and B. DAVYDOV: Some contributions to the theory of solid rectifiers.

K. S. WULFSON and M. I. LOMBERT: Dispersion of light in crystals of quartz.

A. I. ALIOZHANIAN and S. J. NIKITIN: β -ray spectrum of RaC and energy-levels of excitation of αC^1 nucleus.

D. IWANENKO: Simple applications of the Proca potential.

A. SOKOLOV: Nature of heavy electron.

D. I. MIRLIS and A. I. GLUCHOVA: Kinetics of etching and the linear-selective corrosion of metals in polyphase systems.

W. STERN, B. KRAVETZ and A. SOKOLIK: The action of carbon dioxide on self-combustion of the mixture hexane-air.

M. G. KREIZMANN: Isolation of the enzyme transferring the amino-group of glutamic acid.

A. V. VLADIMIROV and G. V. LIASKOVSKAJA: Age and daily variations of citric acid content in leaves of *Nicotiana rustica*.

G. D. AFANASSIEV: Indications of rare metal mineralization in the south-east of the Altai mountains.

A. I. ZUTIN and M. T. PAVLOVETZ: Age differences in spontaneous mutation in males of *Drosophila melanogaster* of different origin.A. I. ZUTIN: (1) Influence of a change of thermal regime upon the frequency of lethal mutations in *Drosophila melanogaster*. (2) Combined effect of a change of thermal regime and subsequent temperature contrast upon the frequency of lethal mutations in *Drosophila melanogaster*.

G. D. KARPECHENKO: New tetraploid barleys—he hulled and the naved.

V. I. PATRUSHEV: Blood-value of cross-breeds between the wild *Ovis Polii Karelini* Sew. and the domestic sheep.

A. SOKOLOVSKAJA and O. S. STRELKOVA: Polylloyd in the high mountain regions of the Pamir and the Altai.

L. M. DOBOKHOV: (1) Dynamics of carbohydrate accumulation in plant leaves as influenced by different content of carbon dioxide in air. (2) Effect of carbon dioxide upon transpiration and stomatal apparatus in plants.

V. G. ALEKANDROV and O. G. ALEKANDROVA: Structure of the furrow in wheat kernel.

L. M. DOBOKHOV: Alteration of physiological processes in tomato under the influence of *Cladosporium fulvum* Oke.

V. I. PATRUSHEV: Blood value of Yaroslavl cattle in correlation with body weight and yield of milk.

K. K. FLEROV: Remains of Ungulata from Betpak-dala.

Forthcoming Events

[Meeting marked with an asterisk is open to the public.]

Monday, May 8

ROYAL SOCIETY OF ARTS, at 8.—Prof. E. C. Dodds: "Modern Chemistry, Modern Medicine and Modern Food" (Cantor Lectures. Succeding lectures on May 15 and 22).

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Dr. D. Thomson: "Journeys in Arnhem Land".

Tuesday, May 9

ST. MARY'S HOSPITAL, LONDON, W.2, at 5.—Dr. V. D. Allison: "The Mode of Spread of Acute Streptococcal Infections".

UNIVERSITY COLLEGE, LONDON, at 5.30.—Sir Philip Hartog: "The Newer Views of the Work of Priestley and Lavoisier" (succeding lecture on May 16).*

ILLUMINATING ENGINEERING SOCIETY (at the Institution of Mechanical Engineers), at 7.—Annual General Meeting.

P. Good: Presidential Address.

Wednesday, May 10

INSTITUTE OF METALS (at the Institution of Mechanical Engineers), at 8.—Dr. Olaf Bloch: "The Photographic Emulsion and its Contribution to Science and Industry" (Annual May Lecture).

Thursday, May 11

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Annual General Meeting.

Captain B. S. Cohen: "The Long-Distance Telephone Call—A Triumph of Engineering and Co-operation" (Faraday Lecture).

Friday, May 12

ROYAL ASTRONOMICAL SOCIETY (in the lecture room of the Royal Society), at 5.—M. Bernard Lyot: "Study of the Solar Corona and Prominences without Eclipses" (George Darwin Lecture).

ROYAL INSTITUTION, at 9.—Prof. J. Garstang: "Discoveries in Cilicia".

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

LECTURER IN METALLURGY AND CHEMISTRY in the Oxford Schools of Technology, Art and Commerce—The Chief Education Officer, City Education Office, 77, George Street, Oxford (May 8).

JUNIOR LECTURER IN ELECTRICITY ENGINEERING and JUNIOR LECTURER IN METALLURGY in the University of the Witwatersrand—The High Commissioner for South Africa, South Africa House, Trafalgar Square, W.C.2 (May 13).

LECTURER IN BIOLOGY in the Kingston-upon-Thames Technical College—The Principal (May 15).

WOMAN EXAMINER in the Metallurgical Section of the A.I.D. Test House, Cardington, Beds.—The Under-Secretary of State, Air Ministry, Berkeley Square, London, W.1 (Ref. ICS/R&O. 88. May 16).

LECTURER IN ELECTRICAL ENGINEERING in the Croydon Polytechnic—The Education Officer, Education Office, Katharine Street, Croydon (May 18).

PROFESSOR OF ELECTRICAL ENGINEERING in the University of Birmingham—The Secretary (May 23).

JUNIOR SCIENTIFIC OFFICER in the Forest Products Research Laboratory—The Establishment Officer, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (May 23).

JUNIOR SCIENTIFIC OFFICER in the Road Research Laboratory—The Establishment Officer, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (May 23).

ASSISTANT LECTURER IN MATHEMATICS in the University of Manchester—The Registrar (May 23).

ASSISTANT LECTURER IN ELECTRICAL ENGINEERING in the Manchester Municipal College of Technology—The Principal (May 21).

ASSISTANT IN MORPHOLOGY AND ASSISTANT IN CLINICAL PATHOLOGY in the British Post-graduate Medical School, Duane Road, W.12—The Dean (June 5).

ASSISTANT CHIEF (male) in the Engineering Department of the General Post Office—The Engineer-in-Chief (Staff Branch), General Post Office, Alder House, Aldersgate Street, London, N.C.1 (June 9).

Establishment of New Industries

THE major proposals of the report on the location of industry recently issued by Political and Economical Planning (P.E.P.) have already been outlined in these columns (NATURE, May 6, p. 770). From discussions of the report and its contents, however, it is apparent that a number of points raised by it are being overlooked. Among such matters of special interest to scientific workers is the suggestion that the proposed Industrial Development Commission should be empowered to advance money for the promotion of new industrial enterprise. This problem is discussed in some detail.

To a large extent the provision already made by the Special Areas (Amendment) Act of 1937, the Nuffield Trust and the Special Areas Reconstruction Association, Ltd., meets the need of new industry enterprise which is concerned with the manufacture of an established product or of a product not already made in Great Britain. The manufacture of an entirely new product or the establishment of a novel process is another matter, and the comments of the report on this subject may well raise doubts as to whether the Committee on Industrial Development, in its report issued in 1932, was not much too confident that there was no gap in our existing structure for the finance of development and research.

The present report does not consider that the difficulties in the way of developing entirely new processes or inventions are altogether the fault of financial institutions. Moreover, the few companies which have been formed specially to deal with new inventions do not appear to have had any great measure of success; the necessary link between invention and finance has not yet been bridged.

One of the major difficulties is the aggregate cost of 'vetting' new propositions, which frequently exceeds the profits to be anticipated on the small proportion of successful ones. The high cost is due to the difficulty of finding any firm or organization capable of dealing with the wide range of industries into contact with which a concern attempting to finance new processes is usually brought. The difficulty has been recognized, of course, for many years, and in November 1935 the Chancellor of the Exchequer made an important statement putting the Department of Scientific and Industrial Research, the Medical Research Council and the Agricultural Research Council at the disposal of banks, issuing houses and brokers to furnish them with reports on the scientific merits of the methods or substances for the development of which it might be proposed to make a public issue.

While, however, the three research organizations in question could undoubtedly be of far greater use to industry and finance, it is at least open to doubt whether they possess invariably the necessary combination of commercial and technical outlook. The nature of their responsibilities limits them to making a complete and exhaustive report on a technical subject. What is often required, however, is a quick opinion based on sound judgment and wide knowledge as a basis for a decision whether to proceed with further investigation or to reject the project at an early stage. The commercial prospects as well as the technical soundness of the process must be taken into account, and the appreciation required must consist not merely in the verification of technical claims but also in forecasting the demand for the new product, and the forces which determine it,

the output of competitive products, the location of manufacture, the areas or industries in which they are sold, relative costs and selling prices, patent aspects, and other economic and technical factors.

At least it may be held that the establishment of the information service recommended in the P E P report should assist in dissipating the very serious lack of technical knowledge in financial circles, which may be regarded as responsible for its failure to restrain or check the excessive over-capitalization of new companies. Moreover, if the view is correct that the evolution of better facilities for the finance of new industries would be an important contribution to the problem of the Special Areas, it should be of no less service to areas which are in danger of becoming depressed through their dependence on a limited number of industries. It is therefore considered that stimulation of private enterprise in co-operation with Government enterprise may offer a solution. The proposed Industrial Development Commission accordingly should explore with business men the possibilities of setting up one or more specialized institutions to deal with the financing of new enterprises generally, and should be empowered to subscribe a proportion of the capital of any such institution. If the machinery then erected became effective and wide enough in its scope, the necessity for direct financing by the Commission of individual enterprises would be materially reduced and might eventually disappear.

There is yet another direction in which the report suggests the need for investigation by the proposed Commission. Any truly scientific policy of industrial development must take account also of both the preservation and restoration of amenities. Even with the examples of the depressed areas in front of us, as well as the encroachment on amenities which on a smaller scale is taking place all over the country, it is no simple matter to decide just how best to provide the necessary safeguards without unduly hampering industrial expansion.

The report itself recommends that the Commission should be given discretionary powers to attach conditions to licences, obliging manufacturers to provide for the safeguarding of local amenities or their restoration, if damaged or destroyed. This is one of the most important services that the Commission could render to the community; the widespread destruction which has resulted in the past from unrestricted development

by private enterprise is sufficient indication of the need for preventing such destruction in future.

The mere institution of licensing powers should assist, for the Commission would consider this factor along with others in handling applications for licences. The efforts of public authorities to preserve amenities through town planning regulations should be substantially reinforced by this factor alone. Public policy, however, can do little or nothing to deal with the root cause of such nuisances as arise from the decline of the industry or enterprise itself and its eventual abandonment. It is possible, nevertheless, to take steps in advance to prevent the repercussions on local society as a whole from becoming too drastic. The report suggests that one way of dealing with this problem would be by means of a sinking fund.

This again is a matter for investigation by the Commission. Any such fund should be earmarked for the restoration of local industrial and social amenities, where necessary, in the future transfer or liquidation of any factory. The other aspect of this question—the extensive salvage operation which are already necessary to restore certain areas to a condition in which they can again become usable for industrial and social purposes—equally falls within the orbit of the Commission. Restoration of such areas should have an early claim on any Government funds available for general public works purposes, and the Commission would be the most suitable body through which the planning of restoration projects and the distribution of funds to local authorities could be carried out. In this respect, indeed, it would develop the pioneer work of the Commissioners for the Special Areas.

The suggestions of the report regarding these two problems, which are by no means so far separated as might appear at first sight, well illustrate its admirable balance. The care for industrial development is never allowed to overshadow the fact that the efficient utilization of the resources of the nation involves safeguarding the health and social well-being of its citizens and the natural amenities of the country. The exposition given in the report of the need for further scientific investigation in these matters, no less than the vision it gives of the possibilities if industrial development and the erection of new towns are viewed in their true perspective as creative social enterprise, will be widely welcomed. Nor does the report leave scientific workers in any doubt that they may well be called to make a decisive contribution, if these possibilities are to be realized.

Agricultural Development in Great Britain

Policy for British Agriculture

by the Rt. Hon. Lord Addison of Sittingborough.
p. 304. (London: Victor Gollancz, Ltd., 1939.)
6d. net.

THE agricultural policy of the Labour party, as presented in Lord Addison's book, has as its objective the restoration of British agriculture. In the case of Lord Astor and Mr. Seeböhm-Treutwein, Lord Addison believes that agricultural production in Great Britain should be stimulated by the adoption by the Government of a policy of improved nutrition. Recent reports on nutrition are quoted to show that the poorer sections of the population are inadequately fed, and it is calculated that in order to bring the food standard of the community up to a reasonable level it would be necessary to double our production of milk and to increase our production of eggs, fruit, vegetables and meat by 60, 78, 60 and 40 per cent respectively.

Quoting Scandinavian experience, Lord Addison considers that livestock production in Great Britain should be based on arable rather than pasture farming, and recommends that there should be a large extension of arable acreage (back to the total of the 'seventies) including a large additional home production of wheat. In fact, he considers that our wheat acreage should be doubled, although how this is to be achieved at a guaranteed price he recommends—37s. 6d. a

quarter instead of the present figure of 45s.—does not emerge.

All these increases in production would, on Lord Addison's hypothesis of an adequate standard of nutrition, leave unaffected our existing imports of food, and would, in fact, call for a considerable addition to our present importation of animal feeding stuffs.

Other recommendations include the nationalization of the land, the fixing of guaranteed prices to farmers, the re-organization of marketing and the payment of higher wages to agricultural workers.

Little is said about the cost of Lord Addison's proposals, but he is critical of the present "mixture of tariffs, quotas and quantitative regulation" which "is now being sought to be atoned for by a system of subsidies". He considers that the only self-respecting and permanent procedure is to have a price system under which the consumer is given an adequate income to pay a reasonable price to the producer.

Much contained in Lord Addison's book is controversial and many of his pronouncements are statements of belief rather than of fact. The methods by which his various proposals are to be put into operation are largely omitted, and the reader may be left with the impression that, although Lord Addison is undoubtedly sincere in his efforts to help British agriculture, he is inclined to over-estimate the benefits and to under-estimate the dangers of the policy he proposes.

God or Mammon?

Christianity and Economics

by Lord Stamp. Pp. xii+194. (London: Macmillan and Co., Ltd., 1939.) 5s. net.

THE purpose of Lord Stamp's book is "to review the contacts between the ideals of Christianity and the working of the economic machine". He begins with a chapter on the economic condition of Palestine at the time of Christ, and draws a far from idyllic picture "of over-population, intense industry to keep going, heavy taxation and much discontent". From a careful examination of His recorded teaching, Lord Stamp establishes the conclusion that "Christ did not condemn the institutions and relationships of His day". His teaching is thus for the modern no ready-made guide, with easy application to the

economic life of his own age". The vital link between Christianity and economic life is rather to be found "in the logical extension or consequence of certain germinal, and even explosive, ideas of conduct and interrelationship which Christ taught"; and the essence of those ideas is that they are "personal and voluntary, and not prescribed by any external system or laws".

But Lord Stamp does not confine his treatment of the subject to a study of Gospel precepts and background. His chapter on "Christian Doctrine on Economic Affairs in the Past" gives the history of the actual relationships between Christianity and economics as these have developed and existed in the past. Amongst other things, he shows how the authoritarian economic ethics of the Middle

Age was subjected to intolerable strain by the sudden rise in prices consequent upon the flow of precious metals into Europe on the discovery of the New World. During the second half of the sixteenth century, the total stock of gold and silver was quintupled.

Passing on to Christian principles and their practical application, Lord Stamp enumerates the following: (1) the brotherhood of man; (2) the principle of stewardship; (3) the doctrine of the good neighbour; and (4) the equality of the value of each individual soul. On the application of these fundamental principles to the conditions of modern life, Lord Stamp gives much valuable guidance.

Lest his work should be regarded too much in the light of a merely personal view, Lord Stamp includes a careful examination of three recent representative pronouncements of organized Christian bodies: first, the Encyclical *Quadragesimo Anno*; second, the findings of the Conference of

Protestant Churches on Church, Community and State, held in Oxford in 1937; third, a pamphlet published by the Industrial Christian Fellowship on "The Church and the New Economic Order." He finds in them "a common basis of criticism and condemnation, despite differences of emphasis".

In his final chapter, Lord Stamp raises some significant questions. If we can only avoid poverty by exploiting the machine and by organizing men in industrial subservience to it, "it seems as if material abundance and spiritual poverty are inverse related", as Christ virtually taught. We then confidently assume "that we can have all the material riches that a pagan society teaches us to produce, equally from a truly Christian order. So is it really possible to make the best of both worlds?"

Lord Stamp has given us a good book with a clear grasp of facts, principles and values.

The Flora of North-east Ireland

A Flora of the North-east of Ireland

By Samuel Alexander Stewart and Thomas Hughes Corry. Second edition. Flowering Plants, Vascular Cryptogams and Charophytes, by Dr. Robert Lloyd Praeger; Mosses and Liverworts, by William Rutledge Megaw. Pp. lix + 472. (Belfast: The Quota Press, 1938.) 10s. 6d.

THE great botanical interest of the flora of Ireland is due not only to the position of the island as a western outpost of the Eurasian continent, but also to the peculiar elements of which the flora is composed and to the differences shown by the flora and vegetation when these are compared with the botanical features of Great Britain. North-east Ireland is, in some respects, less interesting botanically than the western districts but there are compensating features. The matter is stated thus in the introduction to the work at present under notice: "The position of the area is such that it is removed from the regions occupied by the most marked plant-groups to be found in Ireland—the flora of the south-west and west, with its fascinating admixture of Mediterranean, Pyrenean and North American plants; the Central Plain, with its rich assortment of lime-loving and swamp-loving species; and the south-east and east coasts, which connote the presence of species, mostly of southern facies, favouring sandy and gravelly soils. But as will be seen, certain members of all these groups

penetrate into the north-east. On the other hand, as a glance at a map might suggest, this region is rich in plants of Scottish type, which here reach their maximum in the country."

The introduction to this new edition makes instructive and pleasant reading. It contains many facts regarding the ecological distribution of the more distinctive species, and the contents are arranged as to facilitate the researches of botanists desiring to visit the best botanizing areas for special studies. There is also much information regarding the historical development of botanical knowledge of north-east Ireland. The bulk of the book is arranged after the style of "county floras", the sequence of species being that of the Bentham and Hooker system. Valuable historical and distributional notes are included and many references to literature are given. The value of including the critical species of *Rubus* with the proviso that probably the names "cannot all hold permanently" may be doubted. An appendix gives a list, with comments, of casual plants and of those recorded in error.

The inclusion, as Part 2, of the mosses and liverworts is a welcome innovation in Irish county or district floras. A topographical index is also a very useful scheme which might well be widely adopted by authors of similar works. There is an index to plant names and black and white maps of the counties of Down, Antrim, and Londonderry.

W. B. TURBILL.

A Guide to Plant Genetics

Recent Advances in Plant Genetics

by Dr. F. W. Sansome and Dr. J. Philp. Second edition, revised and rewritten by Dr. F. W. Sansome. Pp. xii + 412. (London: J. and A. Churchill, Ltd., 1939.) 18s.

WHEN this book first appeared, it filled a gap by providing a valuable summary of the more modern aspects of plant genetics. The new edition, which has been revised and partly rewritten by Dr. Sansome, preserves the main features of the previous one. There is an entirely new chapter on variegation and chimeras, and the first two chapters have been rearranged with considerable gain in coherence and clarity. Though not designed as a text-book, and in spite of the limitations imposed by the authors in their preface, it forms a very satisfactory introduction for the student of genetics. Through a logical sequence it succeeds in giving a proper perspective of the principles of modern genetics. The new edition should be even more useful than the first.

Within the limits set, the student of genetics and the general biologist have a very fair guide to inheritance in plants. But the field of study is enormously wide and varied and it is obviously impossible to give the substance of every recent addition to knowledge of it within the limits of the book. The student is aided by a bibliography containing about 1,500 titles and a "Key to literature" in which the more important papers and review summaries are classified under subject headings. By means of the "Key" the uninitiated can rapidly trace the literature on, for example, corn seedlings, cotton genetics or chromatid segregation.

The predominant role in modern genetics of the cytological method is reflected in this book. Nuclear behaviour is described first, the results of pedigree breeding afterwards. This applies to each of the sections dealing with the broad mechanical aspects of heredity, namely segregation, linkage, polyploidy and structural change. The correlation achieved is rather better than that in the previous edition.

Attention is directed also towards physiological aspects of genetics. A consideration of factor interaction leads on to a useful discussion of the biochemical work on flower pigments. Later we are introduced to the balance theory of gene action and interaction.

The continued omission of any treatment of selection or of population mechanics is to be regretted. These form by far the best introduction to a study of evolution, only specialized aspects of which are covered in the present book. The evolutionary approach is principally through the results of interspecific hybridization and in relation to polyploidy and structural hybridity (especially as in *Oenothera*).

The chapter on the constitution of the gene now includes sections on the position effect, gene size estimations and the effects of X-rays. Somatic crossing-over and mosaicism in maize endosperms are also given a place here, but scarcely seem at home with the rest of the company. There is no mention of reverse mutation, and the account of the effects of X-rays is very defective and inaccurate. It is without a reference to the contributions of Timoféeff-Ressovsky, Zimmer and Delbrück on the mechanism of spontaneous and radiation-induced mutation. They have shown that a spontaneous mutation must be regarded as a chance chemical change which has a very low reaction rate and consequently a very high van t'Hoff coefficient.

A few errors have crept in. The most serious is a confusion (p. 18) between character and factor. The statement "that the immediate products of meiosis are qualitatively different in respect of one pair of alternative (allelomorphic) characters" is clearly unsound. Moreover, it contradicts the (correct) statement on p. 16 "that the chromosomes carry determiners . . . which control the transmission and behaviour of inherited characters". This tendency to a looseness of phraseology sometimes leads to an untrue statement. For example, that "Beaded wing in *Drosophila* is a dominant lethal" (pp. 69 and 275). Two of the constitutions for linkage in autotetraploids (p. 192) are wrong, namely those for asymmetrical coupling and for triplex coupling.

The final chapter evaluates the newer work on genetics. Further attack on the nature and action of the gene seems likely to lead more and more into physiological by-ways. No one can predict how advances will be made; but it is interesting to reflect that our present understanding of gene action has come from such varied experiments as the implanting of *Drosophila* eye-buds into larval abdomens, the crossing of radishes with cabbages and the regeneration of diploid moss-plants from injured capsules. D. G. CATCHELSEA.

The Claims of Logical Positivism

The Logical Syntax of Language

By Prof. Rudolf Carnap. Translated by Amethe Smeaton (Countess von Zeppelin). (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvi+352. (London: Kegan Paul and Co., Ltd., 1937.) 25s. net.

An Examination of Local Positivism

By Dr. Julius Rudolph Weinberg. (International Library of Psychology, Philosophy and Scientific Method.) Pp. vii+311. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., 1936.) 12s. 6d. net.

THE analysis of mathematics has given rise to important schools of philosophical thought in recent years. Progress has indeed been such that it is now almost impossible to discuss certain fundamental problems of knowledge without taking into account their results. The various phases of the epic controversies between them are highly technical: hence their interest for the mathematician as well as for the philosopher.

Until recently, three irreconcilable doctrines concerning the relationship between logic and mathematics were in the field. The logicist thesis, which is illustrated mainly by the monumental work of Russell and Whitehead, makes pure mathematics a branch of logic. For the formalist school, pure mathematics is the science of the formal structure of symbols; and all inferential systems can be treated as games played in accordance with certain rules, provided the expressions used are stripped of their meaning and considered in their structural relationships. The intuitionist thinkers, who follow mainly Brouwer and Weyl, maintain that pure mathematics is founded on a basic intuition of the possibility of constructing an infinite series of numbers, with the consequence that a large portion of higher mathematics is beside the universe of logical theory.

Logical positivism goes beyond logicism and metamathematics, in considering that the logical characteristics of sentences and the logical relations between them are solely dependent upon the syntactical structure of the sentences. In this way, logic becomes a part of syntax, provided that the latter is conceived in a sufficiently wide sense and formulated with exactness.

This claim is developed technically in the standard work of Prof. Rudolf Carnap; while Dr. J. R. Weinberg's book may serve both as an

introduction and as a critical analysis of various theories connected with this new movement, which may be considered as one of the striking intellectual developments of our time. Indeed, its revolutionary character has given rise to violent controversies which still divide philosophers into rival camps.

The fundamental position of logical positivism is its stand against all forms of metaphysical, transcendental thought and expression. In this aggravates the empirical strain which is noticeable in the works of Bacon, Berkeley, Hume and Mill. The main difference of this school from the more traditional views of logic, is that the latter are concerned not only with sentences, but also with the relations of meaning between sentences whereas the former contends that logic has nothing to do with meaning, and is concerned only with the formal treatment of sentences.

According to logical positivism, there are only two kinds of significant statements: matters of fact, which have an empirical content and which are verifiable in principle, and necessary truths, tautologies which follow from definitions regulating the use of symbols. Outside these two kinds of statements, all propositions are meaningless, however attractive their intrinsic depth or complexity may be. What makes it difficult at first to expose the real nature of a proposition is the fact that it is usually expressed as a grammatically correct sentence; thus grammar leads to a host of verbal obscurities and pseudo-problems which, it is contended, have often passed as profound philosophical utterances. By inquiring into the meaning of propositions, confusions, paradoxes, misleading terminology which implies the existence of certain entities corresponding to words, are solved analytically and thus are given their proper value.

As Dr. Weinberg points out, logical positivism has first striven to give a careful analysis of two types of propositions: those of physical science (and their common-sense counterparts), and those of mathematics, which are shown to be reducible to logical statements free of intuition. The minute and exhaustive elucidations of concepts and expressions by Moore, Russell and various other logicians, and the outline of the work of Russell and Whitehead ("Principia Mathematica") and Wittgenstein ("Tractatus Logico-Philosophicus") are then given a methodical and critical exposition. Dr. Weinberg shows the shortcomings of logicism and explains how Wittgenstein's views lead to

lipism. His treatment of probability and induction is less convincing: thus, he says that the three main types of probability are species of a simpler one, but he does not state it.

The portion of the book devoted to logical syntax forms an excellent introduction, though perhaps not a convincing one, to the standard work of Prof. Carnap, which we may, however, consider on its own merits. A word should be said, first of all, about the excellence of the translation made by Countess von Zeppelin of a most difficult and intricate text. This translation has on the occasion of improving many points of the original German work. The publishers also have spared no efforts and ingenuity in presenting such a book, with its host of complicated symbols, in a clear and attractive way.

The starting point of Prof. Carnap's system is at the distinction between the usual syntactical rules and the logical rules of deduction is that between formation rules and transformation rules, both of which are formulated, it is claimed, in syntactical terms. Prof. Carnap is thus led to build up the syntax of two languages: what he calls 'language I' covers a narrow field of concepts and shows how the syntax of a language may be formulated within that language itself; 'language II' is richer in modes of expression, and helps to formulate all the sentences of classical mathematics and classical logic. In both 'languages', the investigation is not limited to the mathematico-logical part of language, but is also concerned with empirical sentences (protocol-sentences ultimately). Finally, the treatment of the syntax of these two languages leads to an outline of a general syntax applicable to any language whatsoever; though it is admitted that this attempt is very far from attaining the desired goal.

The theoretical value of these constructions is to be found in their attempt to reach the most general forms of reasoning, and to express them as accurately as possible. But such a purpose, which is apparent in the material treatment of logical syntax, is formally defeated by the adoption of the principle of tolerance, according to which the business of logical syntax is not to set up prohibitions, but to arrive at conventions (p. 51). Thus we are told that "everyone is at liberty to build up his own logic, i.e., his own form of language, as he wishes. All that is required of him is that, if he wishes to discuss it, he must state his methods clearly, and give syntactical rules instead of philosophical arguments" (p. 52). Now, common sense could admit the form of such a aim, if it be made for a game. But it is difficult to allow it for the study of logic proper, which goes beyond the actual use of any specific language, whether natural or artificial.

However great the skill and ingenuity displayed by Prof. Carnap in the construction and defence of his 'languages', one cannot help questioning their practical use. For example, the artificial character of 'language I' (pp. 58-78) is shown by the fact that it introduces a number of new symbols and expressions which increase the burden of ordinary language; and that it still has to justify their meaning and use with a series of 'explanations' bristling with words of everyday usage. Again, the comparison of the primitive sentences and rules of 'language II' with those of other systems (p. 96) shows fully how relative and conventional this language II, as well as other systems, can be. The fact that 'language II' is able to give an interpretation of the fundamental notions of classical mathematics, such as the real numbers (p. 147) and classical physics (p. 149) scarcely dispels any feelings about its artificiality: for after all, it is difficult to justify an abstract construction which is totally devoid of meaning, with the simple excuse that it would provide a means of translating into a coherent system of symbols the main achievements of the positive sciences.

Such a construction might be accepted if it were final both with regard to consistency and generality, or if it could be justified on strict psychological as well as ontological grounds. But such can scarcely be the case of logical syntax, though it is bound to find outside itself the justification of its principles and development. For this reason, "Principia Mathematica" is considered as old-fashioned; and Prof. Carnap himself seems already to have moved further than the position outlined in his "Logical Syntax of the Language": there is no reason why progress should not be continuous, the more so as novelty is implied in the very process of analysis itself.

Without prejudicing the permanent logical interest of logical positivism, we cannot help thinking that the ultimate basis of its difficulties lies in its rather discouraging philosophical implications. The zest with which the extreme formalists develop their technique urges them to throw overboard the whole body of values which has so far justified philosophers in undertaking their arduous journey across the stormy seas of the mental sciences. Thus the major branches of philosophy are made to melt down to logic alone: metaphysics is bundled out into the expanse where lyrical verse already occupies a place of honour; while psychology is forced to find refuge with the empirical sciences. If logical positivism had its own way in the active field of the mental sciences, logicians alone would survive the catastrophe which would befall philosophy.

THOMAS GREENWOOD.

South-West Africa in Early Times

Being the Story of South-West Africa up to the Date of Maharero's Death in 1890. By Dr. Heinrich Vedder. Translated and edited by Dr. Cyril G. Hall. Pp. xvi+525+12 plates. (London: Oxford University Press, 1938.) 15s. net.

ALTHOUGH this book, originally published in German, is in name a history, the author's conception of the scope of his subject has necessitated a very full treatment of the ethnology and racial movements of the native peoples, Bushmen, Herero, Nama, Bergdama and Ovambo. Full use has been made of much valuable, but unpublished and inaccessible material, especially the remarkable collection in twenty-seven volumes of records of the "Sources of the History of South-West Africa", which has been taken into safe custody by the Administration.

The author's sifting of the material provided by his authorities is cautious and thorough. His discussion of the famous rock-engravings and cave paintings deserves attention. In the light of his experience of the native peoples, and his tests of their reactions, he is of the opinion that, while the engravings are the work of an ancient and vanished race, the paintings are relatively modern, and in all probability the work of the Bushman.

The English edition omits certain quotations of original documents, and curtails accounts of the development of certain vanished mission stations, while adding illustrations and maps. As a summary and critical account of unpublished material, the book is of considerable value to the student of the history of the South African native peoples and their relations one to another, as well as to the white man.

A Catalogue of Vertebrates of Japan

By Yaichiro Okada. Pp. vi+412. (Tokyo: Maruzen Co., Ltd., 1938.) 12s.

THIS valuable work presents every appearance of careful compilation to show the composition and range of the components of Japan's vertebrate fauna. It indicates, by the way, the intensity of systematic work in Japan since von Siebold's "Fauna Japonica" was completed in 1860, for the fauna at present contains 3,823 vertebrates, whereas in 1860 only 646 were known. The classes were represented now and then as follows: mammals 375 (57); birds 873 (201); reptiles 158 (18); amphibians 76 (11); cephalocorda 1 (0); cyclostomes 7 (0); fishes 2,251 (359). A rough glance through the contents shows that of non-migratory land forms, mammals, reptiles and amphibians, a very high proportion of the subspecies are peculiar to Japan and the neighbouring Korea and Formosa, whereas aquatic species and birds are more widely distributed. But it is surprising to find that among the mammals and birds only three mammals, the common house mouse, the mongoose and a deer, and three birds, are regarded as having been introduced from other countries. All the cosmopolitan rats are listed as original natives of Japan. The thoroughness of Prof. Okada's work is suggested by the extent of the index, which itself occupies 93 pages.

J. R.

J. Chr. Fabricius Systema Glossatorum

Im Anhang: K. Illiger, Die neueste Gattung Eintheilung der Schmetterlinge aus den Linnéischen Gattungen Papilio und Sphinx; J. Chr. Fabrici Rechenschaft an das Publicum über seine Classification der Glossaten. Herausgegeben von Felix Bry (Sammlung naturwissenschaftlicher Facsimile-Druck Band 1.) Pp. xii+112+13+4. (Neubrandenburg: Gustav Feller, 1938.)

THE "Systema Glossatorum" was the last work of the great Danish taxonomist, J. Chr. Fabricius, and is of fundamental importance to those who are concerned with the nomenclature of butterflies. It is, furthermore, a publication of the greatest rarity, and apparently only two examples exist of the original in the Latin language (1807). The present work reproduces in facsimile the original text of Fabricius, which is thus now rendered accessible to all and sundry who are concerned with taxonomy. As supplements there are also included facsimile reproductions of Illiger's "Gattungs-Eintheilung der Schmetterlinge" and Fabricius's brief *Rechenschaft* his classification of Glossata.

A. D. I.

Faunistischer Führer durch die Coleoptere Literatur

Die wichtigste Käfer-Literatur nach geographisch Gebieten geordnet. Von S. Schenckling. Band Europa. Lieferung 1. Pp. 64. 6 gold marks. Lieferung 2. Pp. 65-128. 6 gold marks. (Neubrandenburg: Gustav Feller, 1938.)

THIS work aims at being a guide to the most important faunistic literature on the Coleoptera which is arranged according to the geographic regions. Volume 1, it is announced, will consist of about ten *Lieferungen* and these are concerned with the general Palearctic region and with Europe. Volume 2 is to treat of the literature referring to Palearctic Asia and Africa together with the Indian, Malayan region; Volume 3 with Ethiopia, Austral and Oceania and Volume 4 with America.

A specialized work of this kind should prove a valuable aid to the taxonomist and especially to students in the great museums. A survey of the two parts already published makes it evident that the "Führer" will simplify the task of searching the literature in any particular group of these insects inhabiting a specified country or region.

Einführung in die theoretische Physik

Von Prof. Dr. Clemens Schaefer. Band 3, Teil 1 Quantentheorie. Pp. vii+510. (Berlin und Leipzig: Walter de Gruyter und Co., 1937.) 26 gold marks

THIS substantial volume forms one part of a comprehensive "Introduction to Theoretical Physics" written by Dr. Schaefer of Breslau, and concerned with quantum theory, treated mainly from a mathematical point of view. About one half of the book relates to the theory of Bohr, for the author considers that this is historically correct and also represents the best approach to wave mechanics. The final chapter deals with Dirac's theory of the electron and positron.

Plastics and Some Recent Applications

By H. V. Potter

CONSIDERABLE progress has been made in the practical application of plastics in every where since the author's review which appeared in *NATURE* of March 9, 1935. Moulded radio cabinets were then just being introduced, and these were regarded as a great step forward since they represented by far the largest mouldings which had at that time ever been made. The advent of these large mouldings meant far more than capturing the radio cabinet market. Their introduction entailed the installation of larger and more powerful presses in moulding works, and more presses of this type had been purchased. Efforts were made to find uses for them, and larger mouldings followed as a natural corollary.

Probably the largest mouldings ever made are the standard-sized coffins or caskets which are now in experimental production. These require a press of approximately 4,000 tons capacity, and each casket uses nearly 95 lb. of moulding material in its production. Although the consistent increase in size of mouldings is an indication of progress, improvement is primarily noticeable in the materials from which the mouldings are produced.

It is proposed to confine attention in this review to those synthetic resinous plastics which have already attained an important position in industry. A brief perusal of the patent literature will disclose that hundreds of new plastics have been proposed in recent years, most of which will progress no farther than publication of the patent. From the industrial point of view, the two most important synthetic resins are the phenol-formaldehyde and urea formaldehyde types, both of which are thermo-setting. From each of these, moulded materials and laminated materials are produced, while they are also employed in paints and varnishes in place of natural resin.

A brief outline of the manufacture of phenol products—better known, perhaps, as 'Bakelite' materials—may assist those who are not familiar with the process. Basically, the production of urea materials, once the resinoid has been made, is similar to the methods adopted for manufacturing phenolic moulding powders and laminated sheet.

By mixing phenol and formaldehyde in a heated reaction vessel together with a suitable catalyst, a reaction occurs which results in the formation of a heavy viscous mass at the bottom of the vessel with a layer of water above it. When the upper

layer has been removed by evaporation, the remaining material is tapped off and allowed to cool. It is then a brittle, amber-like solid which can be softened by heating. Continued application of heat, however, causes this 'resinoid', as it is termed, to become permanently hard and insoluble. Moulding powders are made by pulverizing the initial resinoid and mixing with it various fillers, pigments, mould lubricants, plasticizers, etc. The ultimate result of this processing is a powder from which the moulder produces the finished moulding by charging pre-determined quantities into heated steel moulds which are then closed under pressure. The properties of the mouldings can be varied by changes in the resinoid formula and by differing types and proportions of filler. In this manner the moulding material manufacturer can ensure, within limits, that any desired characteristic shall be present in the finished moulding. Good dielectric properties, low power losses at very high frequencies, resistance to heat, water or chemicals are typical examples of the many grades of material which have been developed to meet some specific requirement.

In a similar manner, the properties of laminated materials can be varied, but within much narrower limits, since the manufacturer is restricted in his choice of fillers. These laminated materials are built up by impregnating sheets of paper or fabric with resinoid and forming many such sheets into a solid board under heat and pressure. The material is produced ranging from a few thousandths of an inch in thickness for some types of electrical insulation up to a maximum thickness of 4 inches for gears. Yet another grade of laminated material is employed for decorative purposes. Veneers and wall panels are now in regular production and are used for the surfacing of walls and furniture in the home, hospitals, offices, hotels, restaurants and all types of public buildings. A surprisingly wide range of beautiful colours—pastel shades, black, white, mottles and wood grain patterns—is available, and the materials also embody unusual and valuable properties. They are unaffected by steam or moisture and are resistant to heat, fruit-juices and alcohol. Their surface does not corrode and, being non-hygroscopic, is hygienic and easily kept clean.

The range of present-day uses of plastics is so wide and so important that it is impossible fully to describe their applications in the space of this

article. Since engineering uses are now very much to the fore, some of the more interesting developments in this sphere will be outlined. The aircraft industry finds many uses for plastics. Phenol plastics are mechanically strong and their weight is only half that of aluminium. This fact, combined with the ease with which moulded parts can be produced, provides a tempting prospect for the aircraft engineer, and it is reasonably certain that moulded fuselages, wings, etc., will be pressed out of plastic material in the not too distant future. The size of mouldings has hitherto been a drawback but, as mentioned earlier, moulded coffins have been made and moulded sheets of laminated paper and wood have been manufactured up to 20-ft. in length. For large structures, such as an aeroplane fuselage, wood reinforced with synthetic resins has an important future. The latest developments here follow closely along the lines of laminated

material practice, that is, veneers of wood are treated with 'Bakelite' resins, built up into boards of required size and consolidated under heat and pressure. Another recent development is the moulded airscrew blade shown in the photograph opposite. This is probably the largest moulding yet made in which continuous lengths of fabric have been used. The threads at the root end forming the flange are unbroken throughout the whole

length of the blade except where necessitated by the gradually decreasing cross-section. A core accurately located in the centre of the blade and around this the reinforced material is moulded and compressed. A high-frequency furnace employed to melt the core metal without damaging the blade.

An organic glass, obtained from methyl methacrylate, which is one of the thermoplastic resins, is replacing ordinary glass for wind shield observation turrets, etc., in aircraft. It is light in weight, has a good refractive index and will not splinter on impact.

Many small components in aircraft construction are produced from plastics, including barrel supports for variable pitch airscrews, shims, chafing rings, etc. There is no doubt, too, that if a synthetic resin having much greater physical strength and elastic properties could be developed, the field of application for plastic

would be far wider. Research is continually proceeding in an endeavour to attain this object and it must eventually be achieved. The limit has almost been reached for increasing the mechanical strength of plastic materials by differing types of filler. Synthetic resins have made possible a great improvement in plywood, which is of particular importance for aircraft work. Phenolic resin incorporated on paper are employed as the

APPLICATION OF PLASTICS IN DECORATIONS. THE WALLS AS WELL AS THE DESK ARE SURFACED WITH 'BAKELITE' VENEERS.

material practice, that is, veneers of wood are treated with 'Bakelite' resins, built up into boards of required size and consolidated under heat and pressure.

Another recent development is the moulded airscrew blade shown in the photograph opposite. This is probably the largest moulding yet made in which continuous lengths of fabric have been used. The threads at the root end forming the flange are unbroken throughout the whole

would be far wider. Research is continually proceeding in an endeavour to attain this object and it must eventually be achieved. The limit has almost been reached for increasing the mechanical strength of plastic materials by differing types of filler.

Synthetic resins have made possible a great improvement in plywood, which is of particular importance for aircraft work. Phenolic resin incorporated on paper are employed as the

hesive for the various plies of a plywood board. The paper is of tissue thickness and is merely a vehicle for providing a resin film in convenient form. The plies with the impregnated paper interlaved between them are formed into a solid board in a hot press, the heat causing the resin film to flow, penetrating the wood and finally polymerizing. In contrast to ordinary plywood sheets, the strength of the synthetic resin bond is actually increased by immersion in water. This remarkable water resistance, and the fact that the adhesive is impervious to insects and fungus, greatly enhances the prospects of plywood for aero construction.

Two important applications of phenolic laminated materials in engineering are for the production of gears and bearings. The material is easily machined by standard workshop methods, and gears transmitting up to 300 h.p. are now made from it. One or more of these plastics gears in a gear train results in a considerable reduction of noise and they have other advantages due to their chemical resistance. Wherever bearings of phosphor bronze, white metal or lignum vitae have been used previously, consideration may advantageously be given to the synthetic resin bearing. A longer life is frequently obtained and the sole lubricant required is water. The material is not, of

CONTROL PULLEYS, BARREL SUPPORT AND UNDER-CARRIAGE PISTON USED IN MODERN AIRCRAFT, MACHINED FROM PHENOLIC LAMINATED MATERIAL.

course, suitable for use for components in high-speed engines.

The applications of plastics to-day are extraordinarily diverse. Thousands of mouldings are made daily and are used in almost every industry. More than seven million insulating components punched from laminated material may be used in a single telephone exchange. Matrices for printing stereotypes are made from a phenolic material, dentures are made from the pure resinoid, and, in the form of lacquers, varnishes and cements, synthetic resins are assisting industry in many ways. Yet despite the progress which has been made in the past four years, it is not too optimistic to forecast that progress in the next four years will be even more rapid.

The resins more recently developed, such as vinyl and polystyrene, are slowly making headway for uses to which they are better suited than the earlier resins. These materials can be moulded by the injection process, that is, forcing the resinoid (which has previously been plasticized by heat) through an orifice into a closed mould, in place of the older method of using the resinoid in powdered form. The vinyl and polystyrene resins have valuable properties some of which are not possessed by the other resinoids. They have a water-white transparency, good electrical properties and excellent water resistance. They are, however, thermoplastic and can, therefore, be softened repeatedly by heat while, as already noted, the phenolic and urea resinoids are permanently hardened by heating.

There has been a good deal of development in connexion with the equipment for injection moulding, and machines are now available which work almost automatically except for switching on the electric current and keeping the feeding hopper filled with the resinoid. Further important advances in the mechanization of press operations will undoubtedly be seen in the future.

Hydrocarbons in Industry

SINCE the structures and classical methods of synthesis of the aliphatic hydrocarbons serve as an admirable introduction to systematic organic chemistry, it is perhaps natural that these early chapters should be soon ignored and then forgotten. In those countries, however, fortunately endowed with natural sources of liquid hydrocarbons, their chemistry has become a subject of vital technical and national importance, whilst countries which have to rely on imported or synthetic products are even more dependent on methods by which cheapness of production and economy in utilization of fuels of high octane number or of lubricants can be achieved.

A general discussion was held by the Faraday Society on April 17-19 at the Imperial College of Science and Technology, London, under the title "Hydrocarbon Chemistry", with the object of ascertaining how far present scientific inquiry into the reactions of the hydrocarbons could serve in interpreting the somewhat complex processes already operating in industry. The discussion divided itself naturally into four sections: homogeneous thermal reactions, catalytic reactions, synthetic hydrocarbon production and, finally, olefine polymerization.

It is admitted that the mechanism of the thermal cracking process is a complicated one, but that it involves chain mechanisms at some stage, a hypothesis first advanced by Prof. R. O. Rhee and now generally accepted. There is, however, no unanimity of opinion as to the actual chain processes involved in the reactions. Hydrocarbon free radicals can be prepared by a variety of methods and their properties have been described. It has also been shown that they can initiate chains of reaction when admitted to the saturated hydrocarbons at suitably elevated temperatures. Much of the discussion centred around the questions as to how the reaction centres originate, what were the relative rates of such reactions as

and

and by what mechanisms admission of nitric oxide cuts down the velocity of decomposition.

From the technical point of view, the problems to be solved in connexion with the synthesis of fuels such as iso-octane or aromatic hydrocarbons are how to utilize two straight-chain hydrocarbon

fractions, one from C_6-C_8 and the other from C_1-C_4 . It appears clear that owing to the high temperatures involved in thermal cracking, which leads to loss of control, the method of attack is thermal decomposition of the C_6-C_8 fraction. C_6-C_8 and re-synthesis of isoparaffins is not in favour, and alternative methods are being sought. Three avenues of attack on this problem are being explored, each involving catalytic reactions. The most direct involves catalytic cracking to C_6-C_8 fraction followed by re-synthesis of isoparaffins, the second catalytic ring closure, or the third attempts to bring about directly catalytic isomerism to isoparaffins as has already been found possible in the shorter members of the series. The discussion made it clear that the *modus operandi* of any one of these processes is by no means clear. This is exemplified by the fact that in one of the simplest reactions, namely, the exchange reaction of deuterium with an unsaturated hydrocarbon, such as ethylene, or a saturated one, such as ethane, three different mechanisms have been advanced. These may be depicted as follows:

A similar diversity of opinion was noted when the mechanism of ring closure was discussed.

When heptane is passed over a dehydrogenation catalyst either of the oxide or metal type to produce toluene, a mono-olefine is found to be present. The third mechanism described above for the exchange reaction is likewise applicable to the process of olefine formation, but we note that the half hydrogenated state is an intermediary in the reaction. The answer to the question whether the cyclization proceeds through the olefine or through the half hydrogenated state awaits further experiment. It is also interesting to observe that both (2) and (3) provide us with mechanisms by which the double bond in a olefine can travel towards the end of the chain, a

at cyclization may result. Cyclization in the gas phase involves a large change in entropy, since the difference in the internal mobilities of the straight chain and ring is so pronounced; it is clearly important to devise some method by which the position of the molecule adsorbed on the catalytic surface at the temperature of ring closure may be examined.

On the synthesis side, discussion was devoted to the interesting reaction which occurs between saturated tertiary hydrocarbon and an olefine in the presence of a variety of catalytic agents, especially sulphuric acid. Whilst considerable progress has been made in elucidating the structure and energies of reactions involving conjugated double bonds, it would be very desirable if calculations on reactions of the type

are made. In the technical synthesis of liquid fuel, it is clear that processes of coal hydrogenation are extremely complex and that the identification and examination of the various reactions involved would be a matter of great

difficulty. Whilst very complex products can be made by the Fischer-Tropsch process, the initial reactions which the carbon monoxide and hydrogen undergo in building up the complex hydrocarbons are much simpler, and some success has already been achieved in identifying and examining the successive reactions which are involved. It was clear from the discussion that it may be possible to synthesize many other products in addition to the straight-chain hydrocarbons by means of this elegant reaction.

The last section of the discussion was devoted to the polymerization of the olefines. Here dimerization of short-chain olefines to produce fuels, and polymerization to produce long-chain macromolecules suitable for plastics, are at present the two important technical objectives. No less than nine papers were devoted to this aspect of hydrocarbon chemistry.

The Faraday Society always attempts to emphasize the international character of its discussions on scientific subjects, and it is worthy of comment that this meeting was a truly representative one in spite of the present political situation.

ERIC K. RIDGAL.

Growth of Induced Plant Tumours

By László J. Havas, Institute of Pathological Anatomy, Brussels

A COMPARISON between the malignant tumours of animals and the plant tumours, commonly called 'crown gall', is beyond the scope of the present article*. It may be pointed out, however, that characteristic histological and cytological differences can be observed—obviously enough—between these two pathological structures, such differences being inherent in the two types of host organisms themselves. It may be added further that the analogies of response of plants and animals, to be described, were obtained *in spite of* their structural differences.

Inspired, no doubt, by the experimental induction of tar tumours in animals, discovered by Yamagata and Ichikawa, Komuro¹ exposed the root tips of *Vicia Faba* and *Pisum sativum* to suspensions of coal tar. He obtained by this method well-characterized neoplastic structures termed by him 'phyto-tartumours'. Most of the cellular abnormalities described by Komuro in these swellings, such as giant and multinucleate cells, hypernucleolated, lobed, vacuolized and fragmented

nuclei, amitotic divisions, chromosome aberrations, etc., were also observed by Mottram, Picon, Levine and Bergmann² and others, in onion and bean roots treated with coal tar and also with Scharlach Red. Such effects, as the systematic investigations of Levine^{3,4} and Chargaff⁵ have shown, were not limited to the particularly sensitive root tips, for swellings macroscopically comparable to crown gall, and presenting similar cytological abnormalities, were also produced by them on the stems of the most heterogeneous annuals, and even woody plants, subjected to local treatments (painting) with the above and a variety of other chemicals.

The discovery of the active factors in coal tar responsible for tumour production in animals (Bloch and Widmer), and the isolation and synthesis of these and other highly carcinogenic hydrocarbons (Kennaway; Clar; Cook *et al.*⁶, Fieser, and others), gave an added impetus to the study of the etiology and of the experimental induction of chemical cancers in animals. One of these compounds, 1:2:5:6:dibenzanthracene, was tested by Levine⁷, and was shown

* See for reference on this subject the excellent review of A. J. Baker and T. O. Berge, *Amer. J. Cancer*, 26, No. 2, 310-356.

to produce marked overgrowths when applied locally (painting) on the stems of a great variety of plants. A similar application of benzpyrene and of methylcholanthrene provoked, however, only an unlocalized thickening and bending of the stems of roses and tomatoes (Havas), although the carcinogenic potency of these compounds is known to be far superior in animals to that of dibenzanthracene. On the other hand, a definite increase in the size of the neoplasms was observed by Havas⁷ when crown gall tumours of the tomato were painted with benzpyrene at an early stage of their development. Such divergencies are natural, as the degree of sensitivity of different plants, and even of individuals within the species, varies in a great measure^{8,9}.

But the faculty of inducing neoplasms in plants is not limited to the above-mentioned polycyclic hydrocarbons. Thus, Auler¹⁰ was able to demonstrate that lactic acid also has such properties, while the role of this substance in the carcinogenic sensitization of animals was shown by Parventjev¹¹ and others. The influence of the different amino-acids on the development of the tar tumours and the spontaneous tumours of rodents has been studied by a great number of workers (Vles¹², Coulon, Suzuki¹³, etc.). While some of these acids seem to inhibit cancerous growth, L-cystine and glutamic acid are generally regarded as carcinogenic sensitizers¹⁴ in animals. An analogous effect of these two chemicals is reported by Levine¹⁵, who induced by their local application neoplasms in plants. Similar parallelisms of action were obtained by such widely different organic and inorganic substances as copper, alcohol, ethylene, etc.¹⁶.

While in the preceding examples the method of the experimental approach to the problem consisted in the attempted *induction* of tumours in normal plants, the experiments to be reported now were designed to test the effects of the various carcinogenic and carcinolytic sensitizers of animals on the incremental *growth* of plant tumours already induced by inoculating the plants with *Bacterium tumefaciens*, the causal agent of 'crown gall'. The technique applied in these experiments was also different, the substances having been introduced (unless otherwise mentioned) directly through a cut in the stem or through a petiolar stump, using the negative pressure in the water stream to pull up the solutes in the plants¹⁷.

The carcinogenic power of the oestrogenic hormones seems to be now rather convincingly established in animal experiments (Leo Loeb¹⁸, Lacasseagne, Fodor *et al.*¹⁹, Gardner, McEuen, and others). Comparable effects of the follicular hormone were shown by Havas¹⁸ on the incremental growth of the crown gall of the tomato, an increase in the weight of the tumours, amounting to 70–80

per cent, having been obtained as a result of treatment. The stimulating effect of this hormone on the tumours of the tomato was also observed by Stapp²⁰; but on *Bacillus*, and using a different mode of administration, Verona²¹ was unable to confirm such an action. Although apparently less active than the follicular hormone, an increase in the weight (23 per cent) of the above phytoecanoma could also be recorded by treatments with the hormone of the anterior lobe of the pituitary (Havas).

The experimental evidence furnished by the majority of workers (Fodor¹⁹, Hayaashi²², Engel-Reiss *et al.*²³, Jones, and others) seems to confirm the similarity of action of this endocrine product in animals. The role of the active principle of the thyroid gland in the carcinogenic sensitization of animals is still under discussion (Suzuki, Engel¹³, Forsell, Jones, and others). It may be mentioned, however, that a definite increase (10 per cent) in the weight of the above neoplasms of the tomato was obtained under the influence of thyroid extracts²⁴. Effects to the contrary, namely a 20 per cent reduction in the weight of the tumours, were also observed by Havas¹⁸ on plants treated with the hormone of the thymus gland which according to Engel²⁵, Arzt, Fichera, and others increases the cancer resistance of animals.

In spite of the many contradictory views expressed by cancerologists as regards the influence of the different vitamins on malignant growth (Gordonoff and Ludwig²⁶, Caspari, Biseglie, Geré, Fodor and Kunes²⁷, and others) there is now fairly general agreement that an excess in the vitamins C and D increases the receptivity of animals to cancer. Vitamin C was tested by Havas²⁸ on tomato plants, inoculated as above, and it was found that the weight of the tumours exceeded by 29 per cent that of the controls. Still more striking were the results obtained with the vitamins A and D tests on a variety of *Opuntia*, which, after several hundred inoculations, had proved to be highly immune to *B. tumefaciens*, as only about 1.5 per cent of the inoculations have taken. When, however, the site of the inoculations was painted with solutions of vitamin A or D, 80 per cent of the inoculations yielded large intumescences^{29,30}.

Colchicine, which has come recently to the fore, thanks to the important investigations of A. P. Dustin³¹, was shown to have encouraging carcinolytic properties by Dustin and Amorós Peyron³² claims even a "complete sterilization" of the experimental and spontaneous tumours of different animals. A parallel action of this alkaloid was described by Havas³³ on the growth of the crown gall of the tomato, the weight of the neoplasms of the treated plants having been reduced to half that of the controls.

Finally, an example may be given when the recovery of a carcinolytic substance of plants has exceeded the experimental evidence of the similarity of its action in animals. This agent is the p of the mistletoe (*Viscum album*) which, according to the mode of its extraction and administration, produced tumour resolutions ranging from 66 to 1000 per cent on tomato and *Ricinus* plants (Havas¹). But no clear-cut results were obtained by the author in animal experiments. Thanks to an apparently more adequate preparation of the *viscum* sap, Koeh² could report, however, a surprisingly high percentage of amelioration and complete healing of the Ehrlich tumours of the mice.

In conclusion, it seems desirable to emphasize that, in spite of the suggestive analogies of response ascribed, the *specificity* of action of the agents responsible for such reactions is by no means suggested. The diversity of the chemical structure of the substances used and the fact that similar parallelisms of response can be obtained by purely physical intervention speak for themselves against

such a concept. The connecting link between the phenomena observed is, therefore, more likely to be found in analogous endogenous factors present in both the animal and plant protoplasm.

Obituary Notices

Prof. W. Cramp

THE sudden death of Dr. William Cramp, at Llandudno on April 20, at sixty-three years of age, will be a severe blow to his many friends and especially to his old students at the University of Birmingham. He had a great gift of sympathy with his students. He readily understood their difficulties, took great pains to clear them up and so endeared himself to them all.

Cramp was educated at King Henry VIII Grammar School, Coventry, and at the University of Manchester. From 1892 until 1897 he served his apprenticeship with Rotherham and Sons, Coventry, and from 1897 until 1901 was an engineer with Arranti, Ltd., Hollingwood. At the age of twenty-five he was appointed lecturer in electrical design at the Central Technical College, South Kensington, under Prof. Ayrton. He then set up in practice as a consulting engineer in London and Manchester, giving, at the same time, lectures to his old University. In 1908 he was transferred to full membership of the Institution of Electrical Engineers; he communicated many papers to it and was awarded several premiums for them. During the Great War he was twice commissioned to do special work for the Board of Trade in Italy. In 1919 he was appointed professor of electrical engineering at the University of Birmingham, where he did much valuable research work. He always enjoyed showing his friends the original work that is being done in the laboratories under his direction. Cramp took an active part in the meetings of the

British Association. In his presidential address to Section G at Blackpool on "The Engineer and the Nation", he took a sombre view of the world as a whole and of the little recognition given to the work done by the engineering profession. He controverted the popular criticism of the use made of scientific discoveries for war purposes. He stood as a devotee of pure science that had no moral obligations and no ethics. If the engineer were left undisturbed by the politician, he visualized the power he might exert to make war impossible. A few months later, Prof. Cramp lectured before the Royal Institution on the future of power supply, and he pointed out some of the difficulties that would have to be overcome before the 'grid' system of supply could be regarded as ideal. In 1931 Prof. Cramp gave the Faraday Lecture to the Institution of Electrical Engineers at London and at several of the local centres, the subject chosen being "Faraday and his Contemporaries".

Several treatises which have proved useful to students of engineering were written by Prof. Cramp; in particular, his books on "Armature Windings", "Continuous Current Machine Design", and, in conjunction with O. F. Smith, "Vectors and Vector Diagrams". He also contributed many scientific papers to various journals.

He was the inventor of the 'Cramp single-phase motor', a self-exciting alternator, apparatus for the production of nitric acid from the air, and a new system of coal-face lighting. It was only a few weeks

ago since his special knowledge of the use of electricity of mines was recognized by his appointment to the chairmanship of the committee set up by the Secretary of Mines to consider what amendments are required to the general regulations governing the use of electricity in mines under the Coal Mines Act, 1911.

Cramp took an active part in the activities of the British Broadcasting Corporation. He was largely responsible for founding the Engineering Club in Manchester in 1913 and the 'Children's Concert Society' in Manchester in 1914. His interests were very wide and he had been looking forward to many plans for the future when the end came. He was a widower and leaves two daughters, to whom the sympathy of his many friends will be extended.

Prof. F. J. Cheshire, C.B.E.

THE death of Prof. Frederic John Cheshire, on March 24, at seventy-eight years of age, removes one who had a very considerable influence on the development of the optical instrument industry in Great Britain, more especially during the War of 1914-18 and in the following years. His main interests lay in the fields of experimental science, and his true vocation was to the life of a teacher.

Cheshire was born on June 8, 1860, being the son of the late Mr. George Cheshire of Leeds. He was educated at Birkbeck College, and at the Royal School of Mines. After some early training in engineering at the works of Messrs. Greenwood and Batley, Leeds, he entered the Customs and Excise Service in 1880, and thence went to the Government Laboratory as a chemist. In 1885 he secured an appointment by open competition on the examining staff of the newly instituted Patent Office, where he served until 1915, when he was transferred to the Ministry of Munitions and became deputy director-general of the Optical Department. On the formation of the Optical Engineering Department at the Imperial College in 1917, he accepted the post of director, and held this position until his retirement in 1925. He was awarded the C.B.E. in 1918. Even this busy career had not exhausted his abundant energies, and he afterwards acted as consultant to various commercial firms.

In the course of his early teaching work, Cheshire became well known for the interesting experiments with which his lectures were illustrated. He had a great desire to give practical assistance to students from industrial firms, and on one occasion had been invited to give a course of lectures on sound under the auspices of the London County Council for the benefit of workers in piano factories. At the beginning of the course he was asked, "What do you know about making pianos, Mr. Cheshire?" "Nothing at all," he replied, "but I do know some things which every maker of pianos should know."

With this outlook, it is natural that Cheshire's main publications were concerned with the improvement of apparatus for teaching and lecture demonstration. Early papers described optical projection apparatus of an improved description including a

polariscope. He also took much interest in the design of microscopes, especially petrological type and apertometers. His papers appeared generally in the *Transactions of the Optical Society* and the *Journal of the Royal Microscopical Society* between 1907 and 1923. In 1917, it was difficult to purchase teaching apparatus, and he designed various ingenious optical benches and similar apparatus which could be constructed in the College workshop, in addition to sundry pieces of apparatus of an original character including 'focimeters' and 'squaring-on eyepieces' for the equipment of the laboratories.

Cheshire insisted that technical optics was essentially a branch of engineering, and changed the name of the section to the "Optical Engineering Department". He considered that the mechanical design of instruments needed attention, and the provision of instructional courses, equally with purely optical design. His experience at the Patent Office and contacts with the staff of Messrs. C. Zeiss had, however, shown him the importance of thorough-going computational work in optical design and the appointments made to his teaching staff reflected these ideas.

Cheshire was a man of charm, and had a natural capacity for leadership. From 1916 until 1920 he was president of the Optical Society, and in 1922-1923 president of the Royal Microscopical Society. He was a founder fellow of the Institute of Physics. He was a sportsman of parts, and designed a well-known golf-club. In 1886 he married Mary, daughter of the late Mr. George Richardson of Huddersfield, and had a son and a daughter.

PROF. FRANTIŠEK NAČHTIKAL, a distinguished Czech physicist, died in Prague on April 12 at the age of sixty-five years. He was the author of several monographs on electrotechnics and applied physics. He served on the Czechoslovak patents council and was an authority on wireless transmission technology.

WE regret to announce the following deaths:

H. Coote-Lake, treasurer of the Royal Anthropological Institute, on April 22, aged sixty years.

Dr. Marguerite Kettle, assistant editor of the *Lancet*, widow of Prof. E. H. Kettle, F.R.S., on May 5, aged fifty-one years.

Mr. Henry Marsh, C.I.E., known for his engineering work, especially in connexion with irrigation in India and South America, on April 25, aged eighty-eight years.

Engineer Vice-Admiral Sir Henry Oram, K.C.I. F.R.S., formerly engineer-in-chief of the Fleet, and president of the Junior Institution of Engineers and of the Institute of Metals, on May 5, aged eighty years.

Prof. C. S. Plumb, emeritus professor of animal husbandry in the Ohio State University, on March 10, aged eighty-eight years.

Mr. Daya Ram Sahni, C.I.E., formerly director-general of the Archaeological Survey of India, aged sixty years.

NUCLEAR PHYSICS

Control of the Chain Reaction involved in Fission of the Uranium Nucleus

It has recently been shown that the number¹ of neutrons liberated² in the nuclear fission of a uranium nucleus is sufficiently high to make the realization of a self-perpetuating reaction chain seem possible. The danger that a system containing uranium in high concentration might explode, once the chain is started, is considerable. It is therefore useful to point out a mechanism which gives the possibility of controlling the development of such a chain.

We form an expression which is characteristic for the behaviour of the chain:

$$v'' = \frac{A_f}{A} v (1 - \alpha), \quad (1)$$

A_f being the product of the cross-section for nuclear fission for a thermal neutron of the uranium nucleus with the concentration of the uranium; A_i the product of the absorption cross-section for thermal neutrons of the nucleus of kind i multiplied with its concentration; A the sum of all A_i 's, which is to be taken over all kinds of nuclei present in the solution; v is the average number of neutrons liberated in one fission, α the average probability for a neutron to diffuse out of the system before being absorbed.

The energy liberated by the chain will be

$$E = NF, \quad (2)$$

F being the energy liberated in one fission and N the number of fissions produced by the chain. We have

$$N = v' + v'^2 + v'^3 + \dots \quad (3)$$

The chain gives thus a quantity of energy, which is increasing rapidly with time, if v' is greater than 1. Let us consider the case of a chain which is due to fission produced by thermal neutrons; that is, a chain propagating itself in a system containing sufficient hydrogen for the slowing down of the neutrons.

If the cross-sections for capture or fission of all nuclei present follow the $1/v$ law, v'' will not depend on the velocity of the neutrons and therefore not on

the temperature of the system (since α will in practice be small and since it depends in the first place on the distance necessary for slowing down the neutron; the temperature has, of course, an effect, although it will be very small).

Let us, however, introduce an absorbent, such as cadmium, the cross-section of which does not depend on the neutron energy in the thermal region. We will have, instead of (1),

$$v'' = v \frac{A_f}{A' + A_0} (1 - \alpha), \quad (4)$$

where A' is the sum of all A_i 's following the $1/v$ law and A_0 is a constant, the term due to the newly added absorbent. v'' will now decrease with increasing temperature. At a temperature, which will be characteristic for the composition and the geometrical constants of the system, v'' will become smaller than unity and the system will stabilize itself somewhere near this temperature; the equilibrium being determined by the fact that the amount of energy given out per unit of time by the system (in the form of heat and nuclear radiation) is equal to the energy produced by the system. Similar questions have been discussed by F. Perrin³.

Added in proof: In the case of a chain propagating itself by thermal neutrons, the time necessary for the slowing down and for the absorption of a neutron, that is, its mean life, is of the order of 10^{-4} sec. If one makes v'' as small as 1007, it needs 100 times the mean life of a neutron or about 10^{-2} sec. to double the number of neutrons, and with that the energy liberated per unit of time. It is therefore possible to control the development of the chain by a periodical interaction of absorbers which break up the chains by entering the system.

Decay Curves of Uranium and Thorium Fission Products

It has been suggested by Bohr¹ that the rare isotope ^{235}U is responsible for the fission produced in uranium by slow neutrons, while the fission produced by fast neutrons is to be ascribed to the abundant isotope ^{238}U . In this connexion it is of interest to see whether any differences can be detected between the shapes of the resulting decay curves for the fission products of uranium bombarded with fast

obtained with 100 minutes exposure; each curve represents two series of measurements. The shape of the curve is the same for fast and for slow neutrons. This was also the case in the experiments with 3 minutes exposure and 20 seconds exposure, where several series of measurements were taken and the decay was followed for 30 minutes and 5 minutes respectively. In no case did the ratio of the activity for fast and slow neutrons change during the decay a change of 10 per cent would have been noticed.

DECAY CURVES FOR THE DISINTEGRATION OF URANIUM BY FAST AND SLOW NEUTRONS, AND FOR THE DISINTEGRATION OF THORIUM

and slow neutrons, and also to compare these curves with those obtained with thorium. Some experiments by F. Joliot² indicated that slow neutrons were relatively more effective in producing the longer period activities than the shorter.

We have made similar experiments using neutrons from a lithium target bombarded with 50 microamperes of 750 kilovolt deuterons. The fission products were collected by recoil on a collector plate placed 1 mm. below a glass plate painted with uranium or thorium oxide. In the fast neutron experiments, these plates were surrounded with cadmium sheets and placed immediately below the lithium target. In the slow neutron experiments a 4 cm. slab of paraffin wax was interposed between the target and the plates, which were resting on another block of paraffin wax, 8 cm. thick. In the latter case 75 per cent of the activity obtained was due to slow neutrons (only 25 per cent remaining when the plates were shielded with cadmium).

In three series of experiments, uranium was bombarded for 20 seconds, 3 minutes and 100 minutes, respectively, care being taken to keep the neutron intensity constant during the irradiation. In the first two cases the collector was of lead, while in the 100-minute experiment paper was used. Afterwards the activity of the collector plates was measured with a Geiger counter connected through a Neher-Harper circuit to a 'scale of eight', which had been tested for linear counting up to 5,000 particles per minute. The accompanying graph shows the decay curves

As regards the thorium fission products, the shape of the decay curve is again indistinguishable from that of the uranium fission product for the same time of exposure. In order to avoid contamination with the active deposit from thorium emanation, the thorium oxide layer was sealed up behind a celluloid foil of 0.4 mm. air equivalent. In the case of the 100 minutes exposure this was, however, not sufficient and only when the emanation was continuously blown away during the exposure was this contamination avoided.

From the measurements just reported, it thus seems impossible to decide whether different uranium isotopes are responsible for the fission produced by slow and fast neutrons. Although some of the periods for the fission products from different nuclei must be different, the abundance of periods of any duration seems to be so great that these differences are smoothed out in the resulting decay curve.

We wish to thank Prof. Niels Bohr for suggesting the problem, and Prof. L. Meitner and Dr. O. R. Frisch for help and advice.

Tracks on Photographic Plates of the Recoil Nuclei of Disintegration of Uranium

UNDER the bombardment of uranium by neutrons, recoil nuclei of great mass and high ionizing power are produced. According to the measurements of Frisch¹, the ionization which they produce along their tracks attains 70 Mev. Their range in air, measured by Joliot², is nearly 3 cm.

For these reasons, it was to be expected that the tracks of such recoil atoms would be observed on photographic plates with a thick coat of emulsion. Our first experiments³ suggested this assumption. On a plate, 2 cm. x 3 cm., some thick and short tracks were obtained, which can be attributed to the uranium recoil nuclei. A preparation of radiothorium plus beryllium being taken as a source of neutrons, besides the recoil tracks a considerable background of γ -rays was also observed on the plates.

In order to avoid the background in further experiments, irradiation was effected by the neutrons obtained from a cyclotron by means of the reaction $n + D \rightarrow n + D$. The experiment itself was carried out in the following manner: a photographic plate was placed above a thick coat of metallic uranium powder at the distance of 2–3 mm. The plate was turned with the nucleus coat toward the uranium. The irradiation lasted 10 minutes. As a result, we obtained on the plate tracks of uranium α -particles and other tracks almost identical with them in range, but thicker and more continuous, which we believe to belong to the uranium recoil nuclei. The character of these tracks is shown on the accompanying figure, which shows a photograph of two tracks in the emulsion especially prepared for these experiments.

One of these tracks, continuous and thick, with a range corresponding to 1.6 cm. of air, belongs to a recoil nucleus. Another track, 5 cm. long, belongs to an α -particle of uranium. In the second track, separate grains can be discerned, and it can also be seen that its track is thinner. Although the composition of the emulsion was especially chosen in order to facilitate discrimination between recoil nuclei tracks and α -particle tracks, in many cases it is very difficult to do this, chiefly because many of the tracks are directed most perpendicularly into the emulsion and therefore they cannot be examined in detail with the microscope. Moreover, the greater number of tracks come from the anterior layers of the uranium and have therefore small ranges.

If the counting is limited only to the tracks of range 5 cm. and more in air, then the plate of area 6 cm.² receives nearly six hundred recoil nuclei in a minute.

Although in our experiments the source of neutrons is nearly thirty times as powerful as that used by Risch, our results agree fairly well with his data (5 particles in 1 minute from 300 mc.). Our data differ, however, greatly from the results of Roberts, Meyer and Hafstad⁴ (30 particles in 1 minute from a source equivalent to 10 curies). It is possible that this contradiction may be explained by the fact that Roberts and co-workers counted only the impulses of energy 75–150 Mev.; however, according to our experiments, the action of the uranium recoil nuclei on the photographic plate is not expected to differ much from the action of α -particles. This would accord with the assumption of Joliot⁵, who believes that the average energy of the recoil nuclei is only 5–35 Mev., and not 75–150 Mev. as Meyer and co-workers thought.

In conclusion, it is to be noted that after irradiation for three hours of bismuth, gold and platinum with neutrons from a cyclotron, no recoil nuclei were observed.

Short-Range α -Particles from Oxygen, Nitrogen and Fluorine Bombarded with Protons

THE bombardment of fluorine by protons leads to the emission of a strong γ -radiation, for which the excitation curve shows well-defined resonances¹. In a letter by Dee, Curran and Strothers², in which the nature of this γ -radiation is discussed, strong reasons are given for expecting the emission of a short-range α -particle group in the same transmutation, and it is pointed out that this group should show the same resonance excitation as is found for the γ -radiation. Assuming the γ -ray energy³ to be 5.8 Mev., the calculated mean range of the α -particle group is 1.1 cm.

In some earlier work⁴ on the transmutation of fluorine a search was made for this group, but no evidence of its presence could be obtained, although with a bombarding voltage of 450 kv. the measurements were extended to a range of 1 cm. Recent unpublished work in this laboratory on the energy of the γ -radiation has, however, shown that the figure of 5.8 Mev. is probably too low, and the calculated range of 1.1 cm. for the α -particles is thus too high. In order to investigate ranges of less than 1 cm., the bombarding voltage must be reduced to less than 450 kv. in order to prevent scattered protons from entering the ionization chamber.

Experiments at these low voltages have recently been carried out, and the emission of a group of α -particles of mean range 0.8 cm. from a thin barium fluoride target bombarded with 330 kv. protons has been established. (We understand that these short-range α -particles from fluorine bombarded with protons have also been discovered at Pasadena by McLean and Becker, using a cloud chamber.) A rough excitation curve for the production of these particles is given in Fig. 1 (curve A), and shows that they follow approximately the same resonance curve as that obtained for the γ -rays (curve B). The

RECOIL NUCLEI. $\times 410$.

FIG. 1.

FIG. 2.

resonance character of the group makes its observation difficult, as it does not appear at bombarding energies below 300 kv. and is obscured by scattered protons above 400 kv. There is, however, a definite γ -ray resonance between these two voltages, and the occurrence of this peak in the α -particle excitation function indicates that these particles must be associated with the γ -radiation. A further discussion of the interpretation of the γ -ray process has already appeared².

In the course of this work, the emission of groups of α -particles of mean ranges 2.07 ± 0.05 cm. and 2.57 ± 0.05 cm. at 500 kv. bombarding energy was also observed from fluoride targets. These groups were also obtained from a carbon target, and it was suspected that they were due to nitrogen and oxygen contamination. Confirmation of this view was obtained by passing the proton beam from the accelerating tube through a thin aluminium window into a mixture of nitrogen and oxygen. The range distribution of the disintegration particles was investigated with a shallow ionization chamber. Curve A of Fig. 2 shows the α -particle groups obtained from air, and curve B those from a mixture of 20 per cent nitrogen and 80 per cent oxygen. The intensity ratio changes in the manner expected assuming the 2.07 cm. group to be due to the transmutation of oxygen and the 2.57 cm. group to that of nitrogen. These groups have therefore been interpreted as due to the disintegration of the rare isotopes of oxygen and nitrogen in accordance with the reactions

and

The observed energy releases are $Q_1 = 3.96 \pm 0.15$ Mv. and $Q_2 = 5.00 \pm 0.15$ Mv.

The mass of ^{15}N has been determined by Bainbridge and Jordan³ from the mass-spectrograph doublet $^{15}\text{N}^1\text{H} \rightarrow ^{15}\text{N}$ and is given as 15.0050 ± 0.0003 ,

assuming that the mass of ^1H is 1.0076 ± 0.0001 . This value of ^{15}N agrees with that obtained from disintegration data⁴, and combining it with the observed value of Q_1 , we obtain a value of 18.0050 ± 0.0004 for the mass of ^{16}O . The mass of this isotope has been given by Aston⁵ as 18.0057 ± 0.0002 and by Mattauch⁶ as 18.00376 ± 0.0002 , and the present determination thus tends to support an intermediate value.

There is considerable discrepancy between the various values which have been obtained for the mass of ^{16}O ; Aston gives 12.00355 ± 0.0001 , Bainbridge gives 12.00402 ± 0.00017 and from disintegration data given by Cockcroft and Lewis⁷ for the reactions:

a value of 12.0043 is obtained using Aston's value for the masses of ^4He and ^1H . From the observed Q_2 we calculate that the mass of ^{16}O is 12.0038 ± 0.0004 , assuming Bainbridge's mass of ^{15}N . Our value for the mass of ^{16}O is thus based ultimately on Bainbridge's mass of ^{15}N , which is in agreement with the value obtained from reaction (3). The energy release found by Cockcroft and Lewis for reaction (2) enables the mass of ^{16}O to be calculated directly from that of ^{17}N , and this gives a value of 12.004 in good agreement with our value.

The Meson and its Transformation into Heavy Particle

THE meson or mesotron was first introduced by Yukawa to serve as the connecting link between β -ray disintegration and the forces responsible for nuclear binding. Subsequent work has identified it with the penetrating component of the cosmic rays but the meson has not so far been observed in nuclear reactions (apart from cosmic rays), for the necessary energy of about 100 Mev. has not been available except in the recent experiments on the fission of the uranium nucleus, which, however, have not so far been investigated in sufficient detail to make a definite conclusion possible.

Following Yukawa, the meson is assumed to obey the Bose statistics. This is necessary if the neutron-proton interaction is brought about through the meson only; but if the existence of neutral particles called neutretos¹, be also postulated, then the proton-neutron interaction will be brought about through the exchange of a meson and a neutretto, and will lead to two alternatives for the statistics obeyed by the intermediate particles: (1) both the meson and the neutretto obey Bose statistics; or (2) both obey Fermi statistics. Case (1) corresponds to that studied in detail by Bhabha, Heitler, Kemmer and others but possibility (2) has not been fully explored, and therefore, the statement that the meson obeys Bose

statistics can at the present stage be regarded only as an assumption.

The spontaneous transformation of a meson into an ordinary electron and neutrino has been discussed theoretically¹, and the 'decay period' has been found to be in reasonable accord with observations on the meson absorption anomaly for cosmic rays. We have considered the possibility of a meson being transformed into two heavy particles, a proton and a neutron. The initial energy of the meson must of course exceed about $2Mc^2 \sim 2 \times 10^6$ ev., M being the proton mass, to provide the proton and neutron rest-masses. The transformation probability is proportional to g^2 , where g is the usual constant (dimension, electric charge) characterizing the strength

of the nuclear field surrounding a neutron or a proton. This probability comes out to be very high, and it seems that the protons and neutrons found in cosmic rays are possibly due to the spontaneous transformation of mesons of very high energies.

PHYSICS AND CHEMISTRY

Preliminary Report on the Masses of ^{12}C and ^{14}N

WITH a newly constructed mass-spectrograph of Bainbridge and Jordan type¹, we measured the mass differences of $^{12}\text{CH}_4 - ^{16}\text{O}$ and of $^{12}\text{CH}_4 - ^{14}\text{N}$. These ions were produced by electric discharge through a mixture of methane, carbon dioxide and air in a cylindrical discharge tube of the usual type. In addition to these doublets, lines of NH_3 , NH_4^+ , CH_3 , H_2O , H_2O^+ were also simultaneously obtained on the same plate. Photographic plates employed in this work were prepared from the commercial process plates by Schumannization, 10–20 seconds being sufficient for photographing spectral lines on these plates.

By measuring every interval of these lines with $\lambda = 1.008$, a dispersion coefficient at every point on the plate was determined empirically as accurately as we wanted.

Since difference in dispersion coefficient at various parts of the plate was found to be very slight, and moreover no systematic error took place during the measurement, the determination of dispersion coefficient with our method can be quite justified, and the following results were obtained:

Doublet	Number of doublets measured	Difference of mass
$^{12}\text{CH}_4 - ^{16}\text{O}$	16	0.03642 ± 0.00009
$^{12}\text{CH}_4 - ^{14}\text{N}$	88	0.01257 ± 0.00006

From these results and Aston's $^1\text{H} = 1.00812 \pm 0.00004$ ², isotopic masses of ^{12}C and ^{14}N can be calculated as follows:

$$^{12}\text{C} = 12.00394 \pm 0.00018.$$

$$^{14}\text{N} = 14.00761 \pm 0.00021.$$

A full account will be published elsewhere.

Discrepancies in the Isotopic Weight of ^{12}C

OF some forty isotopic weights so far determined by the doublet method, more than half depend on that of ^{12}C as a substandard. As chairman of the International Committee on Atoms, I am anxious that some agreement should be reached on this isotopic weight to enable a satisfactory table to be adopted. Ill-health has prevented me making any further measurements for the past year, but Mattauch has recently published results¹ indicating that my value 12.00355 ± 0.00015 is too low. He gives as his own 12.003876 ± 0.000032 , closely agreeing with Bainbridge and Jordan's latest value, 12.00398 ± 0.00009 . Much as I regret being compelled to criticize the results of other workers, I feel it may be well to explain some of the reasons which prevent me accepting the high value with entire confidence.

My first criticism concerns the accuracy claimed. My own figure corresponds to an uncertainty of position of a line on the photographic plate of 0.0075 mm., Bainbridge's to 0.0045 mm.; Mattauch's, owing to the much smaller dispersion of his apparatus, to 0.0003 mm., which seems very small for photometric measurements. My second and more important criticism is the possibility of some systematic error in the instruments. The fundamental discrepancy in the doublet $\text{O}-\text{CH}_4$ could be explained by supposing that my apparatus gives the mass of the molecule too low relative to that of the atom, or that the other types give it too high. What evidence is there for either of these possibilities? Suspicious of the first, I checked the mass of ^{12}C by as many different methods as possible². One, the doublet $\text{CO}-\text{C}_2\text{H}_4$, only used molecules and others only used atoms; all gave results consistent with my low value, which was further supported by more measurements of the doublet $^{44}\text{A}-\text{C}_2\text{H}_4$ ³ and by work on ^{46}Ti ⁴.

The three doublets $\text{CO}-^{14}\text{N}$, $\text{C}-^{10}\text{BH}_3$, and $^{22}\text{Ne}-\text{CD}_4$ quoted by Mattauch to check his high value are neutral in their evidence, for it so happens that if my values for all the atoms concerned are put in, the agreements are equally good.

To use a loose optical analogy, Mattauch and Bainbridge's double focusing is related to my single focusing as a lens to a pin-hole. The lens gives greater sharpness, higher resolution and in most cases higher accuracy, but it may on the other hand

produce distortion not likely with a pin-hole. In connexion with such possible distortion, several points may be noted. The first is the asymmetry of the lines in the O—CH₃ doublet which caused Bainbridge to reduce his first estimate of 0.0369 ± 0.0002 for the difference in mass⁸ to 0.03649 ± 0.00008 , which was very nearly halfway to mine, 0.03601 ± 0.00016 . Then Mattauch⁹ states that in his measurements of the N—CH₃ doublet his plates were unaccountably inconsistent, some agreeing better with my value of this doublet than with Bainbridge's.

Two other cases are of interest. Mattauch⁹ measured the doublet ¹⁸O—¹⁸OH, obtaining a value for the mass of ¹⁸O of 18.0037 ± 0.0007 . My own measurements⁸ of this doublet indicate a higher value, 18.0057 ± 0.0002 , in much better agreement with the best optical determination of Babcock and Birge¹⁰ of 18.0065 ± 0.00018 .

In 1937 Mattauch, in collaboration with Hahn, demonstrated the formation of ⁸⁷Sr in rubidium material. In connexion with this piece of work, which I consider one of the most beautiful ever made in the application of mass-spectra to chemical problems, he measured¹² the doublet ⁸⁷Sr—⁸⁶SrF, and found a difference of packing fraction of 9.0 ± 0.5 . It is now known that the packing fraction of the comparison molecule is very exactly zero, but from Dempster's packing fraction curve¹¹ and the measured value for the isobare ⁸⁶Kr², which is -7.40 , or -7.13 if we use the high value of ¹³C, it seems reasonably certain that so large a negative value as -9.0 is inadmissible. It will be noted that both these discrepancies are of the same sign and suggest the same explanation.

Considerations such as these make me doubt the wisdom of adopting a value depending on measurements of one doublet only. I checked my value with the doublets CO—C₂H₄, ⁴⁴A—C₂H₄, ⁴⁴A—C, and ⁴⁴A++—OH₂. Measurements of these with a double focus mass-spectrograph would be of great help in the present uncertainty. In the meanwhile, it is a matter of some satisfaction that the whole difference remaining amounts to 27 parts in a million—only twice my estimated error.

Rigidity of Liquids

As was reported by us in a recent note¹, the monochromatic radiations of the zinc arc, namely, 4680, 4722, 4810 Å., diffused longitudinally by liquid glycerine at 26° C., revealed, on either side of the primary lines, the presence of sharply defined displaced components in the spectrum of the scattered light. The spectral shifts of these components is 0.52 cm.^{-1} , corresponding to a modulation frequency of $1.53 \times 10^{10} \text{ sec.}^{-1}$.

On the basis of the usual Brillouin formula, the velocity of the acoustic waves giving rise to the components comes out as 2500 metres per sec. This is considerably higher than the ultrasonic velocity of 1910 metres per sec. as determined for glycerine at the same temperature for longitudinal waves of frequency 10^7 sec.^{-1} , generated by the piezo-electric method. That sound waves of such high frequency as 1.53×10^{10} should be observable at all in liquid so highly viscous as glycerine is unintelligible on the classical hydrodynamics. It appears to me that Clerk Maxwell's concept² of fluid viscosity as fugitive elasticity resolves this difficulty and, in addition, offers a ready explanation for the observed great difference between the velocities for 'hypersonic' and 'supersonic' waves.

SPECTRA OF 4046 Å. MERCURY RADIATIONS SCATTERED BY LIQUIDS.

It is clear that if a liquid possesses rigidity, the velocity of propagation of the longitudinal wave of sufficiently high frequencies would be $\sqrt{\frac{k + 4/3}{\rho}}$

instead of $\sqrt{\frac{k}{\rho}}$, k and n being the bulk modulus and

rigidity modulus respectively of the liquid. Taking these two expressions as giving the velocities of sound in the hypersonic and ultrasonic ranges of frequency respectively, the bulk modulus comes out as 4.6×10^{10} and the rigidity modulus as 2.4×10^{10} , the former agreeing closely with the reciprocal of the directly observed adiabatic compressibility.

The foregoing explanation of our results finds strong support from the fact that the time of relaxation calculated from the viscosity and the rigidity of glycerine, by using the Maxwell formula $\eta = n \cdot \tau$, comes out as $3.5 \times 10^{-10} \text{ sec.}$, which is much larger than the actual value of the time period, $0.65 \times 10^{-10} \text{ sec.}$, of the observed Debye waves. Further, we have found that with rising temperature, the divergence between 'hypersonic' and 'ultrasonic' velocities of glycerine diminishes, as is to be expected from the rapidly falling viscosity and the consequent diminution of the relaxation time.

Our observations thus seem to establish, experimentally, the thesis that for mechanical disturbances of sufficiently high frequencies, a liquid behaves essentially as a solid. On the basis of this thesis, becomes easier to understand the general relation

between light-scattering and fluid viscosity, illustrated in the accompanying spectra of light scattered by four liquids of increasing viscosity, namely, benzene, acetic acid, salol, and glycerine, all of which depolarize light strongly. It will be noticed that in the spectrum of glycerine the rotational 'wings' accompanying the Rayleigh line, which are so prominent in feature with the more mobile liquids, are almost completely absent, thus indicating that, in respect of light-scattering, glycerine is practically indistinguishable from an amorphous solid.

Anomalous Properties of some Anhydrous Salts of the Iron Group at Low Temperatures

It has been established in the Leyden Laboratory¹ that the susceptibility of nickel, cobalt, ferrous and chromium chlorides at the temperatures of liquid hydrogen depends on the intensity of the magnetic field.

It has been found in our laboratory² that all these substances show jumps in the specific heat similar in shape to those exhibited by ferromagnetics. These facts have led to the view that the anomalies observed, namely, dependence of the susceptibility on the field and the jumps of the specific heat, might be due to a transition of the salts from the paramagnetic to the ferromagnetic state. A detailed investigation of the temperature dependence of the susceptibility, carried out by us, showed that the ferrous and cobalt chlorides and cobalt iodide exhibit at the temperature of the specific heat jump a maximum of susceptibility the position and sharpness of which depends on the intensity of the magnetic field, and in such a manner that on increasing the field the maximum shifts to the lower temperatures. This fact does not fit in with the usual notions of ferromagnetism. The low value of the susceptibility and the absence of signs of saturation in these salts are likewise inconsistent with the hypothesis of ferromagnetism.

It seems possible to explain the dependence of the susceptibility on the field, the anomaly of the specific heat and the temperature dependence of the susceptibility by the 'quenching' of the orbits of metallic ions in the electric field of the crystal, a concept introduced by Stoner. The dependence of the susceptibility on the field is then accounted for by the external magnetic field forcing out the orbits from their quenched states, that is, increasing the effective number of the carriers of magnetism. The temperature influences the quenched orbits in the same sense, namely, increase of the temperature diminishes the effectiveness of the crystalline field. The existence of the maximum of susceptibility is accounted for by the increase of the effectiveness of the electric field due to the lowering of the temperature, and its location is determined by the internal electric field, the temperature and the external magnetic field. As the latter two are disturbing factors with regard to the quenching of the orbits in the crystalline field, the increase of one of them,

say, of the magnetic field, diminishes the temperature of the maximum. The jump in the specific heat is due to the orientation of the orbital moments in the crystalline field.

Investigations of the magneto-caloric effect and the specific heat of ferrous and cobalt chlorides in magnetic field, carried out by G. Miljutin and S. Shalyt, show that at temperatures below that of the susceptibility maximum the magneto-caloric effect is negative, that is, the salt cools when the magnetic field is applied and vice versa. The position and magnitude of the specific heat jump depend on the intensity of the magnetic field. These new facts support the hypothesis of the quenching of the orbits and cannot be explained by the ordinary transition to the ferromagnetic state.

A detailed description of the results obtained will appear in the *Journal of Experimental and Theoretical Physics* (Russian).

Experiments on Pumping Liquid Helium to Low Temperatures

TEMPERATURES sensibly lower than those usually attained by pumping liquid helium are accessible now that the design of apparatus can take into account the known characteristics of the creeping film phenomenon¹ of liquid helium II. In a previous paper² it was shown that temperatures below 0.8° K. could be reached very simply by constricting the lower part of the pumping tube, to restrict the creeping of the helium II film. We suggested that still lower temperatures might be attained by using a membrane pierced by a small hole instead of the constriction tube. The advantage of this design is that it reduces the film flow while offering the minimum impedance to the flow of gas evaporating from the surface of the liquid owing to the normal heat influx.

Experiments in which the hole was 0.15 mm. in diameter have confirmed this suggestion: using an ordinary laboratory pump of speed 10 litres/sec., we obtained a temperature of 0.73° K. in a vessel of 4 c.c. capacity. The temperature was measured magnetically using chrome alum as thermometer, and calibrating its magnetization (corrected to that of a sphere³) against temperature between 4° K. and 1.5° K., as given by Keesom's 1932 vapour pressure curve⁴.

There is at present an uncertainty of some hundredths of a degree in the value of the temperature reached. If Keesom's 1937 vapour pressures⁵ are used in the calibration, the figure for the temperature becomes 0.76° K. Some of the values on the 1937 curve are probably in error, however, for application of the Clausius-Clapeyron equation leads to improbable thermal properties of helium gas. Also, careful measurements of vapour pressure against the susceptibility of paramagnetic salts (which form a more adequate thermometer in this region than can a gas thermometer) indicate that there is some inconsistency in both vapour pressure curves. (This question is being further investigated in the Clarendon Laboratory.) The same uncertainty, of course, applies

also to previous experiments⁴ on the lowest temperatures attained by pumping liquid helium (0.71° on the 1932 scale), so we can state that the region of temperature hitherto available only with the elaborate apparatus of these earlier experiments is now accessible with the simple means described.

As the pierced membrane used in the above experiment offers an appreciable resistance to gas flow, we are now engaged on experiments to determine the size of membrane hole best suited to different conditions of heat influx to the apparatus. For this purpose the normal heating (that is, by gas conduction and radiation) to vessels less well insulated is simulated by enclosing an electrical heating coil in the helium vessel. These experiments have shown that a hole of 0.15 mm. diameter is too small unless the heat influx can be reduced below 1 millical./min. For example, a heat influx of 3.5 millical./min., which is roughly that occurring in our ordinary 30 c.c. vessel for demagnetization experiments, gives a temperature of 1.06° K. with a 0.15 mm. hole, while with a bigger hole it is again possible to reach below 0.8° K.

A complete account of these experiments will be given later.

Polymorphism of the Micas and Diffuse X-Ray Scattering of Layer Silicate Lattices

THE first significant work on the structures of the micas was that of Mauguin¹, who measured the units of structure and discussed types of isomorphous replacements. Pauling², on the basis of his co-ordination theory, proposed general structures that were shown by Jackson and West³ to be correct in some detail for muscovite. Mauguin noted that the lattice dimension along the *c* axis of a biotite crystal was apparently one half that of muscovite, and he further observed diffuse scattering of X-rays from several crystal zones.

Muscovite contains close-knit layers approximating $[(\text{Al}_2)\text{AlSi}_3\text{O}_{10}(\text{OH})_2]^+$ in composition that are joined across the cleavage plane by potassium atoms having twelve-fold co-ordination. The unit of structure chosen by Jackson and West is crossed by two such layers related by a glide reflection plane, the crystal symmetry being monoclinic holohedral. Phlogopite results from replacing (Al_2) with octahedral co-ordination by (Mg_2) , which completely fills the octahedral positions; in biotite, (Al_2) is replaced by magnesium and iron.

Examination of many micas now brings to light a great variety of structure. Biotite, phlogopite, lepidomelane, zinnwaldite and lepidolite often have a single layer structure, the crystal symmetry being monoclinic hemihedral. A pseudohexagonal three-layer structure is also frequently found for lepidolites and zinnwaldites. Two-layer structures, similar to but not identical with that of muscovite, have been found for four of the fifty biotite-like samples examined. Several biotite samples were found in which the unit of structure apparently was crossed by six,

eight and ten layers. In the last case, the lattice periodicity is more than 100 Å. in a direction normal to the unique monoclinic axis, which introduces some question about the extent of an element in the crystal mosaic. Twenty samples of muscovite including seven specimens associated with biotite (lepidolite (zoned crystals), all had a two-layer structure, and none showed diffuse reflections.

Many of the biotite-like samples give diffuse scattering of X-rays in $[h, k, l]$ zones for which the *l* index is not a multiple of three. This is a result of random combinations of the various structure. Thus if some elements of the three-layer arrangement are replaced by a two-layer structure, the periodicity along the *c* axis will be destroyed for those planes with the *l* index other than a multiple of three, and reflections from such planes will be broadened. Random elements in the single-layer structure give rise to diffuse scattering but do not prevent close agreement between observed and calculated intensities. In structures of higher layer multiplicity, few random elements make intensity calculation impossible by introducing an indeterminate phase shift, but do not necessarily lead to diffuse scattering as is shown by the layer minerals dickite, talc and pyrophyllite as well as by the micas.

The uniqueness of the muscovite structure is result of its departure from the ideal arrangement proposed by Jackson and West. This departure which is considerable, is shown by the relatively high intensities of reflections from (06 $\bar{l}$) with *l* odd, which should be absent for the ideal structure as they are for the biotites. Incomplete filling of the octahedral co-ordination positions in muscovite leads to distortion of the co-ordination and therefore of the layer. As a result, there is but one way in which the twelve fold co-ordination of potassium between layers can be obtained. In the biotites, complete filling of the octahedral positions gives a regular arrangement within a layer and thus permits various combination of layers. Even the two-layer biotite structures have (06 $\bar{l}$), *l* odd, reflections absent.

The distinction between muscovites and biotites from mineralogical data, has partially been recognized by Winchell⁴. Diffuse scattering of X-rays from the micas has features in common with the phenomenon described by Preston⁵ and Guinier⁶ for alloys. Considerable time will elapse before detailed analyses of the many structures observed can be published.

Interrelation of Dissociation Energy, Internuclear Distance and Bond Order for Carbon-Carbon Linkage

Fox and Martin¹ have found that the heat of dissociation (*D* kgm.-cal.) for different carbon-carbon linkages (organic compounds, graphite, diamond) follows smooth curves when plotted against either the internuclear distance (*r*, angstroms) or bond order *x*. When the assigned values of any pair of the three magnitudes *D*, *r*, *x* are plotted against each other

logarithmically, approximately linear relations are obtained, from the slopes and intercepts on the axes of which it may be deduced that the following relations could hold very approximately:

$$Dr_s^2 = 282 \quad (1)$$

$$x^2/r_s^2 = 3.7 \quad (2)$$

Fox and Martin¹ have independently deduced the relation Dr_s^2 equals a constant, by a semi-empirical method, as consistent with a potential energy function of a simple form recently proposed by Sutherland, and with a modified Morse-Clark relation connecting bond constant k_s with r_s . It is of interest to note that the latter type of relation, originally devised for spectroscopic diatoms only, is found to have application to molecular linkages. This has also been shown by Thompson and Linnett².

In the last two columns of the table below, r_s is calculated from D , and x from r_s (calc.), using (1) and (2).

C—C link oethylene and spectrum	D	r_s	x	Dr_s^2	x^2/r_s^2	r_s (calc.)	x (calc.)
ethylene	161	1.204	2	281	3.03	1.205	3.07
ethylene	126.8*	1.208	2	284	3.55	1.305	2.15
ethylene	125.1	1.23	2	294	3.74	1.31	2.10
ethylene	105.3	1.40	1.02	289	3.78	1.39	1.02
graphite	100	1.42	1.45	286	3.67	1.41	1.50
diamond	76	1.54	1	274	3.65	1.55	0.98
hydrocarbons	71.8	1.56	1	270	3.76	1.58	0.91

* Approximate assignment for C_2 by Mulliken³ (5.5 volts).

It should be mentioned that the data involve the uncertain heat of sublimation of carbon (S kgm.-cal.). The D values above depend partly upon the estimate of Sidgwick and Bowen⁴, $S = 150$. If we follow Fox and Martin and take the true value to be $S = 150 + q$, where q is unknown, it is found that the slope and degree of linearity of the logarithmic Dr_s^2 lines are little affected by changes in q over a wide range from $q = -20$ to $+100$. The best exponents for r_s in (1) range from about 2.9 to 3.4 as q changes from -20 to $+40$, with corresponding changes in the constant term of (1). If we adopt Herzberg's⁵ value $S = 124$, the r_s exponent in (1) is 2.8, so that the form of the relation is practically unaffected. The value $S = 140$ makes Dr_s^2 as nearly constant as possible, and the constant in (1) takes the general form $282 + 2.13 q$. The relation (2) is independent of S .

Fox and Martin have obtained good additive relations for the heats of formation of various organic compounds on the basis of their assignments to individual linkages on the assumption that the C—C (and C—H) single bond energies are constant. The accurate work of Rossini⁶, however, indicates that even in paraffin hydrocarbons, C_nH_{2n+2} , these linkages differ slightly in D values, and that only for n greater than 5 is the increment in D for each CH_2 added constant. It is hoped that the present work may assist in the task of assignment of individual linkage contributions more accurately than is at present possible.

Demonstration of Optical Interference Figures

It is not generally known that by using 'Polaroid' filters of sufficient size (1½ in. to 2 in. diameter), optical interference-figures afforded by crystals in convergent polarized light—most difficult subjects to project satisfactorily on a screen—are obtained in a simplified manner with results exceeding in clearness and brilliance those got by the older apparatus.

As shown in Fig. 1, the left-hand side consists of the usual source of light, L , either arc or coiled-filament lamp, W , a water-cell, Ab , an ordinary Abbe condenser and S , the stage. P is the polarizer,

Fig. 1.

SKETCH OF PROJECTION APPARATUS USING 'POLAROID'. NOTE SIMPLIFICATION OF THE R.H.S.

large enough to give full scope to the width of the Abbe. This is standard practice, except that a 'Polaroid' filter may be used for P . The departure from the usual practice is in having no lenses whatever between crystal and screen, in fact, nothing but the largest available 'Polaroid', A . A large, even interference figure results, and if A is placed close to the specimen, the full aperture of the Abbe is made use of. Actually, the optic axes of Rochelle salt can just be brought in ($2E = 120^\circ$). For intermediate optic axial angles, for example, mica, sanidin, borax, etc., the results are excellent. With uniaxial figures, up to 36 rings have been counted, under optimum conditions. Figs. 2 and 3 are from actual photographs of the screen itself with the figure projected on it. The screen should not be more than a foot from the

Fig. 2.

PHOTOGRAPH OF SCREEN WITH UNIAXIAL FIGURE FROM KH_2PO_4 PROJECTED ON IT.

Fig. 3.

PHOTOGRAPH OF SCREEN WITH BIAxIAL FIGURE FROM MICA CLEAVAGE.

analyser for large $2H$ values, but may be any distance for uniaxial crystals. A translucent screen, with the glass on the far side, is better for a 'front' view.

The apparatus used by me was a microprojector, supplied by Flatters and Garnett of Manchester, a 3-ft. circle being well illuminated with a 48-watt, low-voltage lamp. Cheaper grades of 'Polaroid' are also effective.

Measurement of the Amount of Steam Escaping from Areas of Volcanic or Solfataric Activity

ON the slopes of Mt. Tongariro in the Tongariro National Park, New Zealand, there is a remarkable area of solfataric activity called Ketetahi Hot Springs. One of the most noteworthy features is the column of steam arising from the vigorous fumaroles of this area. This column of steam has

cloud, and the velocity of ascent in calm weather or of sideways dispersion by wind, were determined in various ways. From the Ketetahi hut, about $\frac{1}{2}$ mile distant, the steam appears as two columns, which at about 80 per cent humidity are 100 metres and 50 metres in diameter respectively. The rougher measurement was that of the size of the cloud. I had to be assumed that the cloud was circular in cross-section. For vertical ascent the diameter was estimated, and in a strong wind the diameter of the horizontal cloud could be determined with the aid of an inclinometer. The velocity in calm weather could be found from the observation from the hut of the time for the cloud to rise to the height of the summit of Te Mari, and in a wind, from the time to blow over the face of Tongariro. Measurements were also made at the active area with an anemometer. Here, on the driest day, the size of the cloud from the individual fumaroles was estimated on the field and from a photograph. A final assumption was that the temperature in the cloud was the same

CRATER OF WHITE ISLAND.

[Photo by Dr. P. Marshall]

been noted by Hochstetter¹, who gave a drawing of the volcanic peaks from Ongarue, 36 miles away, and in this the column was clearly shown. Thomas² stated that it was visible for fifty miles, and although it has not been possible to check this, the statement is probably still correct in favourable circumstances.

In March 1935, I attempted, among other physical and chemical investigations at this area, to estimate the amount of steam escaping. The method was based on the fact that the actual amount of water in the droplets forming a cloud is small in comparison with the water present as vapour in saturated air. The droplets, however, define the extent of the air saturated with water vapour from the fumaroles. If the original humidity be known, and the cross-sectional area and velocity of the cloud be observed, it should be possible to calculate the output of the fumaroles. The water present as droplets is of importance only if the original humidity be high. In observations by Köhler³ on ordinary clouds, the amount ranged from 0.12 gm. to 0.96 gm. per cubic metre. As a mean, an addition of 0.5 gm. was made to allow for the visible droplets.

Observations were made at humidities from 60 to 96 per cent, determined by wet- and dry-bulb thermometers in an improvised screen. The size of the

as in the surrounding air. This should be approximately correct at a sufficient distance from the fumarole. In calm weather, the rise of the column is assumed to be due to the lower density of saturated air, and not to a difference of temperature. The results of various estimates ranged from 30 lb. to 120 lb. of steam per second. The best value was taken as 50 lb. per second or 180,000 lb. per hour, which is about the yield of a small steam well in Tuscany or California. For comparison, it may be mentioned that the steam required to heat the water in the hot stream flowing from the area was only 0.6 lb. per sec.

In November 1938, Dr. P. Marshall made arrangements for a visit to White Island, the active volcano in the Bay of Plenty, and invited me to assist him on the chemical side. To reach White Island, a launch trip of fifty miles on the open sea is necessary, and the bad landing made possible a stay of only $1\frac{1}{2}$ days. In this short time, with much other work to be done, only very rough observations could be made. Four main columns of steam, 120, 60, 30 and 20 metres in diameter were observed. From the humidity and the time to rise to the level of the crater rim, the output was estimated as 1,000 lb. per second. This would make the area twenty times as active as Ketetahi, a not unreasonable estimate.

In view of the great importance of water vapour in all volcanic phenomena, it was thought desirable to direct attention to this method of estimating the activity of solfataric and volcanic areas. With suitable instrumental aid, and more time for thorough observations than was available, the method might be used for comparing the activities at different localities and recording changes in the activity of areas under observation at intervals.

Benzil—a Skew Molecule?

THE values of the dipole moments of benzil and phenanthraquinone in various solvents, determined by us, and summarized below, suggest that the former molecule has a skew configuration in which the two $\text{C}_6\text{H}_5-\text{O}=\text{O}$ units lie in planes which are nearly mutually perpendicular (see figure).

Solvent	Benzil	Phenanthraquinone
n-Hexane	3.4 D.	—
Dioxan	5.7 D.	5.6 D.
Carbon tetrachloride	3.6 D.	—
Benzene	3.7 D.	5.5 D.
Carbon disulphide	3.4 D.	5.5 D.

This is seen if a certain structural similarity between benzil and phenanthraquinone be assumed, because then the moment of the latter can be taken as that of the completely *cis* form of the former, whence the component moments acting in the directions of the $>\text{C}=\text{O}$ links are each of 3.2 D. magnitude. Knowing this, the effective degree of departure of benzil from a co-planar model can be calculated, since, from symmetry, during rotation of the two benzoyl groups, only those resolved acting at right angles to the axis of rotation will contribute to the experimentally measured resultant; hence—if the two rotatable halves of the molecule are set in planes making an angle χ° with one another—this resultant is given approximately by $\mu = 3.2 \cdot \cos 30^\circ \sqrt{2(1 + \cos \chi)}$, from which values of χ between 90° and 100° are obtained by substitution of the results in the accompanying table.

If this conclusion is correct, benzil is the third molecule for which a 'skew' configuration seems to be necessary, the previous two¹ being hydrogen peroxide and hydrazine. We think that the reasons advanced by Penney and Sutherland¹ for the last cases, however, cannot apply to benzil, which is probably a molecule the shape of which is set by

the superposition of electrostatic and steric repulsive forces (tending to produce a *trans*-structure) and van der Waals' attractions (tending to produce a *cis*-structure). In connexion with this point, it is relevant to note that published data² show that diacetyl, for which the van der Waals' attractions must be weaker than for benzil, has a definitely greater χ angle (130° – 140°).

The Vector Map of the Cyclol C₃ Molecule

THE vector map of a projection of the cyclol structure O_3 , prepared by D. P. Riley and I. Fankuchen¹ provides elaborate illustrations of the rudiments of map theory. Particularly it is to be noticed that the weaker of the two peaks in the map is not the projection of a peak which could be observed in an equally coarse vector map of the skeleton in three dimensions. In this respect, the diagram illustrates a distinction between dominant features of a crude map and precise details of a complete map: in a complete map of a projection, every point against which there is an entry is necessarily the projection of some point in space against which there is an entry in the complete three-dimensional map.

If vector maps are to be utilized in science, care must be taken that the assurance proper to the realization that the nature of the relation between a point structure and its vector map is a problem in pure mathematics is not transferred to assertions which have no mathematical basis. When Riley and Fankuchen say that their projection "could reasonably be expected to bear some resemblance to that due to the whole molecule", I can only point out, by way of warning, that if the four triangular faces of the O_3 skeleton were omitted, much more than one third of the skeleton would remain, but the peaks of Riley and Fankuchen's own map would no longer emerge.

Again, there are no mathematical grounds for the statement by Riley and Fankuchen that side-chains roughly perpendicular to the plane of projection "cannot alter the fundamental pattern of the vector map". Even a few side-chains perpendicular to the plane can easily alter the intensity of every entry and therewith alter the shape of every contour and destroy or create recognizable peaks.

I am not, of course, presuming to suggest that Riley and Fankuchen's expectations may not be justifiable somehow for the particular case with which they are dealing, or to deny that when the structure of insulin is known the effect of the side-chains in the vector map may turn out to be as slight as the writers affirm. I am concerned only to protest, in view of the setting in which they have been displayed, that neither expectation nor affirmation can claim the support of general mathematical theory.

BIOLOGY

Effects of Veiling Glare in Binocular Vision

T. Murray Martin and R. W. Pickford have reported an experiment on the effects of veiling glare on size perception in monocular vision^{1,2}. A differential veiling glare is often present in fog vision, when one object is seen through more fog than another. The present experiment, which was on binocular vision, dealt with size and distance perception when two similar objects were seen through a veiling glare greater over one object than over the other.

A box blackened inside was divided into two sections by a milk glass panel. Eyeholes in one wall and an opening opposite gave the subject an unbroken field of vision about one metre by two, at three metres distance. In the right-hand section were two 60-watt lamps. Light from either of these, passing the milk glass, produced a veiling glare in the subject's eyes, by reflection from a piece of plate glass set across the left-hand section at 45° to the line of vision. The lamps were set apart so that either produced a glare about twice as intense at one side of the visual field as at the other. The subject saw two white disks 11 cm. in diameter standing about 60 cm. apart on a blackened table, against a black background, lit by a 40-watt lamp above his head. He could vary the distance and apparent size of the disks by pulling strings. They varied slightly in relative height but not in apparent distance apart. Either disk could be used as a standard at 300-cm. distance. The greater glare could be on the right or left. The variable disk could be set initially too far away or too near. The eight possible combinations of conditions were used in turn and an equal number of readings taken for each.

Subjects 1 and 2 were instructed to move the variable until it seemed at the same distance as the standard. They often made a rather wide adjustment, were then dissatisfied and made a narrower adjustment. They said the wide difference represented apparent equality of distance, but left apparent inequality of size. If these attitudes to size and distance alternated unconsciously in fog vision in everyday life it might give rise to serious accidents. The remaining subjects were tested twice, first for distance and then for size perception. All agreed that equality for apparent distance left inequality of apparent size and vice versa.

Subject	Method	Mean reading cm.	Number	S.E. cm.	p.
3 m.	Distance	- 4.1	80	1.20	< 0.01
6 f.	"	+ 7.5	40	1.86	< 0.01
9 f.	"	+ 4.1	40	1.04	< 0.01
5 m.	Size	+ 2.4	24	1.06	0.05-0.02
8 f.	"	+ 0.2	24	2.16	< 0.01

For five of the nine subjects the differential veiling glare had a measurable effect. This is shown in the accompanying table, where the mean positions chosen for the disk under greater glare, measured from the other disk, are given for these subjects. The sexes of the subjects, numbers of readings, standard errors and probabilities of the means are shown. Subject 3 tended to see the veiled disk as if

farther away than the other (working by distance). Subjects 6 and 9 saw it nearer (by distance); subjects 5 and 8 saw it as if larger (by size).

Examination of the results by the analysis of variance enables us to draw the following conclusions: (a) The eight conditions, taken together, produced significant differences for all subjects but 4 and 7, working by distance. (b) The time order, indicating practice, produced no appreciable effect. (c) Change from variable-near to variable-far produced significant effects in subjects 3, 5 and 9, and doubtful in 7 and 8, working by distance; but only in 3 and 6 by size. (d) Change from variable under more to variable under less glare produced significant effects for subjects 3, 6 and 9 working by distance; but only for subject 8 by size. (e) Change from variable left to variable right produced significant effects for all but subject 7 (doubtful) working by distance; and for subjects 3, 6, 7 and 9 by size. (f) The smallness of variances due to interactions of conditions indicates that the factors mentioned above were effectively independent.

All subjects consistently over- or under-shot the mark when working for distance; by size all under-shot it but subject 9, who was inconsistent.

Changes of Average Maternal Age

In a report in NATURE of March 18 of an address delivered by Dr. L. S. Penrose to the Industrial Section of the British Psychological Society on February 8, the following sentence occurs: "When the birth-rate is falling, the average maternal age [average age at child-birth] will probably become greater". In support of this view it is stated that Dr. Penrose estimates the average maternal age in England at the present time at 29 years, whilst, in Japan (with a much higher birth-rate), it is said to be 26 years.

In the case of England and Wales, on account of defectiveness of birth registration prior to the passing of the new Population (Statistics) Act last year, it is unfortunately impossible to estimate accurately the average maternal age for any past period, except perhaps 1921 and 1931, for which certain approximate figures derived from census data are available. For certain European countries, however, the average maternal age at various periods may be readily calculated from published data. The following estimates are derived from figures found in Kucynski's "The Measurement of Population Growth".

It will be seen that, contrary to Dr. Penrose's conjecture, the average maternal age falls along with the birth-rate. Reverting to Great Britain, it happens

TABLE 1. AVERAGE MATERNAL AGE.

Period	Average maternal age	Birth-rate (approximate)
Sweden		
1871-75	32.23	30.7
1891-95	31.78	27.4
1911-15	30.38	23.5
1926-30	29.67	15.9
Denmark		
1878-84	30.84	32.2
1901-05	29.93	29.0
1911-15	29.55	26.1
1926-30	28.93	18.6
France		
1892-97	29.08	22.5
1908-13	28.58	19.5
1928-31	28.10	17.9

That in the year 1855, the first year of compulsory birth registration in Scotland, the information required was relatively complete, and included age of mother. It is, therefore, possible to compute average maternal age for that year. Recently we have made an estimate of specific total fertility rates for Scotland for 1931 (based on the specific legitimate fertility rates published by the Registrar-General for Scotland in the Report for the year 1937) from which the average maternal age for 1931 may be obtained. The resulting figures are shown in Table 2, which also includes figures for England and Wales, 1921 and 1931, based on estimates published by the Registrar-General in the Statistical Review for 1932.

TABLE 2. APPROXIMATE AVERAGE MATERNAL AGE.

Period	Approx. average maternal age	Birth-rate
Scotland		
1855	30.2	31.3
1931	29.3	19.0
England		
1921	30.1	22.4
1931	29.6	15.8

These results show the same trend as the more accurate figures for Sweden, Denmark and France already quoted. There would seem, then, to be little doubt that in England and Wales and in Scotland, as in other European countries, the fall in the birth-rate has been accompanied by a fall, and not a rise, in the average maternal age. Closer examination shows that, in general, the fall in fertility first affects the older married women, and gradually spreads, usually in a remarkably regular fashion, to the younger age groups¹. The effect of this in lowering average maternal age is evidently more than sufficient to balance any rise in the average age of marriage which may have occurred.

It follows that the remarks of Dr. Penrose relating to mongolian idiocy have a significance exactly opposite to that suggested in the article. With the fall in the birth-rate we should expect not an increase, but a fall in the incidence of this congenital abnormality.

Variations in Follicle Population Density in the Merino Skin

DURING research on fleece density in the merino, I was impressed with the urgent need for some form of direct observation of the skin structure in studying the follicle and fibre population. Consequently I have in the main adopted histological techniques. However, the suggestion made by Duerden¹ regarding the possible value of observations on the 'grain' surface of leather appealed to me as an even more rapid and direct approach. Through the courtesy of the Wool Industries Research Association, I was able to secure the tanned skin of a South African Cape merino which Duerden had used in his comparative zoological studies of fibre and follicle arrangement in the Ovidæ.

Fig. 1

After preliminary studies to establish the optimum unit area for counting, the order of accuracy of sample counts and a system of sampling, the whole skin was examined at 584 points. From this data the accompanying chart (Fig. 1) was prepared. The intensity of the colour tone is directly proportional to the follicle population density. Regional variations are defined by grouping values per unit area into four arbitrary class intervals (A, B, C and D). The chart is an accurate reduction of the original skin shape and represents rather more than 90 per cent of the fleece area in the living animal. The photomicrographs (Fig. 2) correspond numerically to the points indicated on the chart, the magnification ($\times$ about 6) being uniform. It will be noted that not only is there a progressive reduction in follicle population per unit area in a dorso-ventral direction but also that, corresponding with this reduction, changes

occur in the arrangement of follicles. The dense and more or less uniformly distributed population of the dorsal regions assumes an increasingly distinct linear arrangement ventrally (Sites 1-6). Passing across the margins of the well-defined inguinal and axillary regions (Sites 7-9) these rows become dispersed into isolated groups and single follicles. It is in such regions that the most obvious trace of the primitive trio grouping can be observed. With reduction in density an increase in mean follicle size occurs. It would seem that the values for density of follicle population are arranged with marked bilateral symmetry about the dorsal longitudinal median line. The main gradient appears to be dorso-ventral, though a fairly well-defined antero-posterior gradient may usually be observed. The inguinal and axillary regions constitute minor gradient fields within the

Fig. 2

main system but do not belong to the fleece area of economic interest. The gradient systems noted here are confirmed in histological studies.

These observations support those of Wildman³ and, considered in relation to embryological and histological studies, may have considerable significance in the development of reliable methods of fleece analysis, especially in regard to the problem of sampling. Further studies on this class of material are suggested in view of the encouraging results so far obtained.

This work was done during my tenure of the Walter and Eliza Hall fellowship in veterinary science at this University.

'Frequency Discrimination' in Insects: a New Theory

It has long been known that some at any rate of those insects which possess tympanic organs are able to discriminate between sounds which differ by a factor other than intensity. Regen¹, for example, showed that a long-horn grasshopper, *Thamnocris apterus*, could distinguish the stridulation of its owl from that of related species, and either from various artificial noises. No insect has any peripheral mechanism which would permit harmonic analysis after the manner of the mammalian cochlea. The only alternative basis for discrimination is that different sound qualities shall be represented in their auditory nerves by different temporal patterns of afferent nervous impulses. But here a limit is imposed by the refractory period of the nerve fibres, and frequency discrimination on this basis would only be expected to be possible for frequencies up to a few hundred cycles per second.

It has been shown^{2,3} that the tympanic organs of insects do not respond at all to such low frequencies, nor is it to be expected that they would, except at enormous intensities, for the area of the tympanic membrane is very small. Maximum sensitivity is found to occur for frequencies of 5000-20,000 c.p.s., and at any frequency the nervous response to a pure tone (if it can be obtained at all) is asynchronous, that is, the nervous activity in the auditory nerve is random and no temporal pattern can be detected. There is here an apparent paradox that the neural mechanism of discrimination seems to be suited to sound frequencies which the insect, by reason of its small size, can neither radiate nor detect.

Our experiments indicate that the way out of this impasse which has been adopted by these insects is closely analogous to the device

which has rendered wireless telephony possible. The high frequencies emitted by a stridulating insect act as a carrier for a low-frequency modulation, and it is the latter which probably characterizes the sound to an insect auditor.

We connected a surviving preparation of the tympanic organ and auditory nerve of a locust to an amplifier and oscillograph so that the nature of the nervous response could be observed. The preparation was exposed to a sound source which would yield pure tones of any desired frequency up to 10,000 c.p.s. These pure tones could be modulated sinusoidally in amplitude at a second chosen frequency. Modulation from 0 per cent to more than 90 per cent could be obtained without serious deformation of the modulation envelope, using a device which has been described in detail elsewhere⁴. As was to be expected⁵ the preparation was completely insensitive to pure tones at low frequencies (50-300 c.p.s.), and, though very sensitive to a pure tone of 8000 c.p.s., the latter elicited a completely random response. But in

response to an 8000 c.p.s. tone modulated at any frequency up to 300 p.s. the nervous discharge consisted of bursts of activity at the modulation frequency. The very characteristic pattern of impulses was found to be quite unaltered by large changes in the carrier frequency, and it is reasonable, therefore, to conclude that such high frequencies have in themselves no significance for the insect. Their function is only to carry the modulation precisely as audio-frequency modulation is carried in wireless telephony by high-frequency electromagnetic waves. In both cases, the radiation and reception of low audio frequencies is impracticable and for analogous reasons.

It is of interest to note the sharp contrast with human hearing. The human ear is about as sensitive as that of this insect at 8000 c.p.s., and deep modulation of such a tone may impart to it a perceptibly rill-like character. A human observer, however, though he readily perceives small changes in the carrier frequency, is quite insensitive to large variations in the modulation frequency provided that the latter is not so low that discrete beats are perceived.

On the hypothesis outlined above, the process of discrimination of the quality of a given sound by an insect with a tympanic organ is quite different in principle from frequency discrimination in the strict sense of human physiology. It is therefore possible to explain a number of puzzling observations which have been recorded. For example, Regen¹ showed that a virgin female cricket will regularly approach a telephone which is transmitting the chirruping of a male, even when the distortion is so gross that the sound is unrecognizable to the human ear. It is evident that distortion of the kind which would be introduced by a telephone, such as partial rectification, frequency discrimination and the introduction of odd harmonics will not alter the modulation frequency. Provided, therefore, that enough high-frequency carrier gets through the telephone to excite the female's tympanic organ at all, the pattern of nerve impulses corresponding to the modulation frequency will appear in her auditory nerve. Conversely, the ability of some insects to distinguish between sounds which are identical to human ears is also explicable if it can be shown that such sounds are differently modulated though the carrier frequency is the same.

A full account of the experiments will be published at a later date.

Sponge Mortality in the Bahamas

A HEAVY mortality broke out among the commercial species of sponge (Wool, Velvet, Grass, Reef, Yellow and Hardhead) on the natural banks in the waters of the Bahama Islands early in December 1938. The mortality was recorded earliest among the

eastern islands of the Colony and spread rapidly westwards, until by the end of February 1939 there remained no sponge-bearing bank unaffected in the Colony. It is reported to have spread to the north coast of Cuba in February and Key West, Florida, in March. The mortality rate in most of the areas affected in the Bahamas is high (70-95 per cent).

The investigations, conducted jointly in the Bahamas by the United States Bureau of Fisheries and the Bahamas Sponge Fishery Investigations Department, were carried out along the following lines.

(1) Chemical and hydrographical observations carried out by Dr. C. Lealie Smith show on the sponge beds themselves (down to 8 metres) a wide salinity range (36.4-43.6 per mille), pH (8.15-8.35), phosphate (undetectable to about 5 mgm. P_2O_5 /m.³), silicate (undetectable to 220 mgm. SiO_2 /m.³), oxygen (90-110 per cent saturation), excess base (2.10-2.90 milli-equiv./litre), calcium (440-550 mgm. Ca/litre, and as much as 400 per cent saturation) and a temperature range of 22° - 28° C. These figures are consistent with results obtained regularly in this area over the last two years, and the main features (temperature-salinity correlation curve, thermocline and oxygen-poor layer) of a deep ocean channel between the islands remained unchanged down to 1,250 metres. As much as 60 mgm./m.³ ammonia nitrogen was observed as compared with the normal level of 20 mgm./m.³; but this is attributed to the large numbers of rotting sponges on the beds nearby. Dr. Galtsoff finds a relatively high copper content especially in inshore areas (between 2 and 8 mgm./m.³), but neither this nor any other observed hydrographical factor is regarded as responsible for the mortality.

(2) Examination of plankton collected by means of No. 20 silk net in the inshore areas of Andros Island and on the Little Bahama Bank disclosed the general paucity of microscopic life in the sea, typical for these waters, and is consistent with the observations over two years in the Bahamas of Dr. Walton Smith. This is correlated with the deficiency of the principal nutrient salts. Microplankton samples obtained by centrifuging small volumes of water also failed to reveal the presence of any minute forms, which might have been responsible for the destruction of sponges. With the exception of the inshore waters in close proximity to sponge kraals, the microplankton was extremely poor, comprising primarily bacteria, shown by Drew to be particularly abundant in this area¹.

(3) The records of a number of observers indicate that the sequence of infection was from east to west following the trend of water movements within the Colony.

At the same time the spread of the disease was recorded more closely from the research vessel, on the largest single sponge-bearing bank in the Bahamas. This bank lies to the west of Andros Island, and the sponge-bearing part of it measures 120 nautical miles from north to south, and between 45 and 70 miles east to west. Seven successive surveys show that the infection spread on this bank in an ever-widening area, from the north-west extremity of Andros. The infection followed the general trend of known wind-influenced water movements. The intensity of the infection on its advancing front suffered no diminution, such as might be expected from the dilution or dispersal of a chemical or physical factor. The spread was consistent with the possibility of transmission over the area of a water-borne biological agent.

(4) Biological investigations have been carried out by Dr. Paul S. Galtsoff and Dr. F. G. Walton Smith. Fungus-like filaments, first observed early in March by Dr. Galtsoff, have been found constantly in all diseased sponge tissues examined. The filaments have not been found in healthy sponge tissues, nor in the remains of sponges which have been long dead. They are particularly abundant in the marginal zone between the newly dead and living tissues of diseased sponges. The infection spreads gradually through the tissues, starting often from an origin inside. The symptoms contrast with those observed when death has ensued from other known factors observed during the previous two and a half years. The infection of the micro-organism and the mortality are confined only to a few species of sponge (including unfortunately all the six commercial species), and have not been observed to affect any other form of marine life.

It has been possible to infect Reef and Wool sponge with the filaments, by contact with fragments of infected sponges of the same species.

Attempts are being made to have the organism isolated and identified. A full account of this and further projected work will be published elsewhere.

Growth of *Borrelia duttoni* in the Developing Chicken Embryo

THE value of the developing egg in the study of many viruses is now well established, and the chicken embryo method of passage has proved of great use in propagating these viruses, which, as a rule, can only be grown in tissue culture, and not in the ordinary bacteriological culture media. Many members of the spirochetal class of organism can only be grown, with great difficulty, in special media, and it was therefore decided to attempt the growth of a spirochete in the developing chicken embryo.

The organism chosen was that responsible for African relapsing fever, *Borrelia duttoni*, for this cannot readily be grown in culture, but is usually maintained by passage from mouse to mouse.

The method was simply the inoculation of a fertile hen's egg, which had been incubated for a certain period, usually eight to twelve days, at the temperature customary for such incubation, namely, 38.5° C. After this preliminary period, which was necessary to ensure that the embryo inside was at a suitable stage of development, the egg was inoculated with a small amount of mouse blood, the mouse having been infected a few days previously with the spirochete of relapsing fever. Having introduced the inoculum into the egg, the site of inoculation was sealed off with sterile paraffin, and the egg now incubated for a further interval of three to four days, at the ordinary bacteriological temperature, that is, 37.0° C. At the end of this time, the egg was opened and the contents examined by microscopical and other methods.

When such an egg was opened and the fluid inside inspected by the dark-ground illumination technique it was found that many actively motile, living spirochetes were present. These findings were easily confirmed by inoculation of the material into mice for on examining the mice forty-eight hours later, it was found that their blood contained large number of the organism.

A second batch of eggs, after preliminary incubation, was then inoculated with the material from the first eggs, and again, after three days further incubation, these were found to contain living spirochetes both by visual examination and by mouse inoculation.

The process of egg passage was then continued and a third sample of developing eggs, this time only seven days old, was infected with a small drop of the fluid from the second passage ones, and these on being inspected by the dark-field method, showed a very large number of spirochetes to be present particularly in the blood of the embryo, with a very much smaller number in the rest of the egg contents. Animal inoculation again proved that these spirochetes had not lost their pathogenicity towards mice.

A fourth passage experiment gave precisely similar results.

Further work is in progress, with the view of determining the effect of continued egg passage on the characters of the spirochete concerned.

It is interesting to note here the effect of the spirochete on the embryo. If viruses are grown in eggs, the usual action is either to kill the embryo or, alternatively, to produce local lesions on the chorio-allantoic membrane, with little or no effect on the embryo. *Borrelia duttoni*, however, has a different action, for in the four passages described above no naked-eye change could be observed in the membrane nor was the embryo killed. Examination of the constituent parts of several eggs appeared to show that the lesion produced took the form of a blood invasion. This finding is similar to the result produced in man and susceptible animals, for in them there is a definite infection of the blood stream, easily demonstrated, as a rule, by blood films.

Since writing the above, my attention has been directed to the work of Morrow and his colleagues¹, who have cultivated *Leptospira icterohæmorrhagiae* on the chorio-allantoic membrane.

Genetic and Cytological Interference

PAIRED meiotic chromosomes may have their four chromatids or strands involved in a variety of ways in two adjacent chiasmata. In most studies of chiasmata the materials have not been favourable enough to permit the tracing of all four strands through two or more chiasmata. We have recently been able to do this in forty-eight complete pollen mother cells of *Trillium erectum*, and have observed therein eight types of chiasma pairs. These are shown diagrammatically in Fig. 1 together with their frequencies and interstitial lengths (alternative one-plane representations of these three-dimensional configurations are here neglected).

Clear separation of chromatids and reduction of coiling at metaphase may be obtained in *Trillium*

y various treatments. An extreme example is shown in Fig. 2 (one of five photomicrographs taken at different optical levels in a single cell), in which the five pairs of chromosomes may each be seen to have four very widely separated chromatids. These can be traced throughout their length in the serial optical sections. The material from which the data in Fig. 1 were obtained was less drastically treated.

Fig. 1.

DIAGRAMMATIC REPRESENTATION OF THE EIGHT CYTOLOGICALLY DISTINGUISHABLE TYPES OF CHIASMATA PAIRS OBSERVED IN *Trillium erectum*.

Hearne and Huskins¹ found in *Melanophus femur-rubrum* 71 compensating pairs of chiasmata (those in which the paired strands separated by one chiasma were reunited by the second) and 35 non-compensating pairs. Sax² classified their figures into four types of chiasma pairs and showed that these did not occur in the proportions primarily expected on existing theories of crossing-over. A modification of the Wilson-Morgan theory which he proposed gave a better fit for these and other data than did Belling's or Darlington's theories of their simple interpretation.

Melanophus chiasmata are terminalized during the meiotic prophase and their position at metaphase

therefore gives little indication of their place of formation. *Trillium erectum*, having little or no terminalization, provides data on both chromatid relationships ('chromatid interference') and on the distances between chiasmata ('chiasma interference'). Fig. 1 shows that the least frequently occurring types of chiasma pairs are those having the greatest number of chromatid twists and the greatest interstitial length. Analysis of the more frequently occurring types in relation to theories of crossing-over involves assumptions which are the result of calculations too extensive to be entered into here. In brief, they also suggest an association between frequency, interstitial length, and complexity of chromatid relationships.

Our analyses of Lindgren and Lindgren's³ *Neurospora* data, and Beadle and Emerson's⁴ and Bonnier and Nordenskiöld's⁵ data from attached-X chromosomes in *Drosophila*, together with the observations of chiasmata in *Melanophus* and *Trillium*, seem to permit the following generalization: A chromatid is most likely to be involved in two adjacent cross-overs or chiasmata if the distance between these is short. In other words, chromatid interference occurs as well as chiasma interference, and it varies with distance. Further study has therefore confirmed and extended earlier conclusions from this laboratory^{1,6}. Details will be published shortly; they indicate certain new essentials for any hypothesis concerning crossing-over and suggest possible mechanisms, though it appears doubtful if sufficiently comprehensive data (particularly biophysical) yet exist for the inductive formulation of a general theory.

Influence of Colchicine on the Sexually Induced Colour Change of *Rhodospirillum rubrum*

In previous communications, I have given an account of some experimental evidence pointing to the intervention of hormonal influences in the action of colchicine in plants^{1,2,3}. I have also suggested⁴ that a similar mechanism of action may be, among others, responsible for the mitotic impetus described by A. P. Dustin and his school⁵ in the germinative zones of animals treated with this alkaloid. This view seemed to be further supported by the extraordinary number of mitoses observed by Allen, Smith and Gardner⁶, Bastenie and Zylberzack⁷, and many others, in the sexual organs of animals treated with sex hormones combined with colchicine. It seemed therefore worth investigating whether colchicine, hitherto regarded merely as a revealer of

these hormonally induced mitotic processes, can also exercise, either independently or synergetically with endocrine products, a hormonal action in animals.

Rhodeus amarus males are known to produce in the breeding season a characteristic colour change (*Hochzeitskleid*). This effect can also be obtained before or after the breeding period by the administration of sexual hormones¹. About ten-months old *Rhodeus* males weighing between 2 and 3 gm. were used about six weeks before their normal breeding period in Hungary. The fishes were divided into five groups and treated as follows:

The first group was placed in a large beaker containing a 0.075 per cent aqueous solution of colchicine. The second group was given intraperitoneal injections of 7.5 mgm. of testis hormone ('Oreutic' Choay) dissolved in 0.075 ml. of physiological serum, and was then placed in a beaker filled with tap water. The third group, similarly injected, was placed in a solution of colchicine of the above concentration. The fourth group received by intraperitoneal injections 0.075 ml. of tap water and was placed in tap water. The fifth group, untreated, served as control, and was placed in tap water, as above. Eighty-five minutes after the beginning of the treatments the animals were transferred into aquariums provided with running water.

Ten minutes after the beginning of the treatment, the animals of the first and second group showed already the first symptoms, consisting in a ruby red coloration of the iris. The animals of the third group manifested the effects of the combined treatment moreover by a carmine red coloration of the anal fin and continued to display, throughout the treatment, the successive stages of the colour change at a more accelerated rate than those of the first and second group. The full *Hochzeitskleid* of great intensity was produced by these animals within *ninety-five minutes*, calculated from the beginning of the treatment, whereas the fishes treated with either colchicine or the hormone alone did not display this full effect until about *twenty hours later*. It was also observed that the intermediary stages of the colour change were attained faster by the animals injected with the testis hormone alone than by those treated with colchicine alone. (This was to be expected as the pharmacological effects of colchicine are also produced after a prolonged period of incubation.) The full *Hochzeitskleid* of all the treated *Rhodeus* was maintained during about forty-eight hours and faded thereafter gradually, until it had practically disappeared about seven days after the beginning of the experiment. No colour change was observed throughout the experiment in any of the untreated or of the water-injected control animals.

These results demonstrated in consequence clearly that: (1) although displaying its effects somewhat more tardily than the hormone, colchicine produces effects of the same intensity; (2) colchicine acts in a high degree synergetically with the hormone.

A supplementary proof of the above gradation of the effects was furnished by an exactly corresponding gradation of the oxygen consumption of the treated and control animals, as measured by H. Mann².

It remained to test whether the above effects were not rather the manifestations of a direct response of the pigment cells, due to purely nervous stimulation, without necessarily involving the intermediary of a hormonal mechanism of action. For this purpose, other fishes (*Leuciscus rutilus* and *Perca fluviatilis*)

known to have lipochrome pigments similar to those of *Rhodeus*—but displaying no sexually induced colour change (*Hochzeitskleid*)—were treated with colchicine and sex hormones as above. No colour change was, however, observed in any of the treated animals. Although indirect, the value of this test was made even more plausible by the fact that the respiratory metabolism of these animals has shown according to the treatment given, an exactly analogous gradation to that previously observed in *Rhodeus*³.

Alimentary Exudative Diathesis, a Consequence of E-avitaminosis

In a previous communication¹, we described a symptom which could be produced in chicks by feeding them an artificial diet in which the protein had been thoroughly extracted by alcohol. The symptom consists in large accumulations of blood plasma under the skin, originating from inflamed and hyperaemic capillaries in the connective tissue, notably the fat tissue. This condition was termed 'alimentary exudative diathesis', and it was shown to be a deficiency disease which could be prevented by alfalfa, and petrol-ether or alcohol extracts from alfalfa.

We have now studied the occurrence and nature of the anti-exudative factor. A relation with nutritional factors known to influence capillary permeability could be excluded with absolute certainty, and the same holds true for the possible relation to vitamin K. Wheat germ and dried hips were found to give protection against the disease when given in the proportion of 5 per cent of the diet and to be better sources than dried alfalfa. 0.15 per cent of the epiphasic fraction of an alcoholic extract of hips was found to afford a better protection than 2 per cent of wheat-germ oil.

A direct test of *d*, *L*- α -tocopherol uncombined or in the form of the acetate (supplied by F. Hoffmann, La Roche and Co., Basel) revealed the fact that vitamin E protects against the disease.

The production of alimentary exudative diathesis in other animals than chicks as well as the possible existence of related conditions in man is under investigation.

It is possible to estimate vitamin E by its anti-exudative activity. Exudative diathesis is inhibited by smaller quantities of vitamin E than encephalomalacia in chicks receiving a fat-rich diet, a disease which may also be used for the biological assay of vitamin E².

By the new method we have found that the lipid of hips is much richer in vitamin E than wheat-germ oil.

Experiments are being carried out in order to settle the question whether vitamin E is also identical with the light white casein factor of Coward *et al.*,³ a possibility which might be supported by the fact that an exhaustive treatment with alcohol is necessary for the complete removal of vitamin E from casein used in artificial diets.

Role of Manganese in the Biological Synthesis of Ascorbic Acid

Guha and Ghosh¹ found that rat liver incubated with mannose produced ascorbic acid, and followed it up by showing that parenteral administration of mannose also produced ascorbic acid in the rat tissue and notably in the liver. Euler *et al.*² were unable to confirm the *in vitro* results, which was explained as due to the absence of molecular oxygen.³ Euler's experiment was made in an atmosphere of nitrogen. However, Hawthorne and Harrison⁴ and Clodt⁵ also could not confirm Guha's results *in vitro* or *in vivo*.

It has now been found that manganese is a determining factor in the synthesis of ascorbic acid by rat tissue. The experiments of Hawthorne and Harrison (*loc. cit.*) were repeated with this modification, that the Ringer-Locke solution in which the

liver was incubated with mannose contained 0.02–0.001 per cent manganese as manganese chloride. The concentration of manganese in the incubated mixture thus ranged from 0.01 to 0.0005 per cent. In my series of experiments 0.001–0.0005 per cent of manganese in the incubated mixture has been found to be most favourable for the synthesis of ascorbic acid *in vitro*. It has also been found that galactose, like mannose and glucose to a less extent, may also act as precursors. In *in vivo* experiments, the mannose solution given intravenously contained 0.001 per cent manganese as the chloride. Typical results are given in the accompanying table.

<i>In vitro</i>			<i>In vivo</i>	
% Mn in R-L	Sugar	Mgm. ascorbic acid per gm. liver	Mgm. ascorbic acid per gm. liver	
			Control (N.B.)	Mannose + Mn
0.002	Mannose	0.22	0.25	0.32
0.002	Galactose	0.21	0.21	0.29
0.002	Glucose	0.19		
Nil	Mannose	0.16		
Nil	Nil	0.16		

Details are being published elsewhere.

Points from Foregoing Letters

F. Adler and H. von Halban, jun., discuss the energy liberation of a nuclear reaction chain, consisting of successive fissions of the uranium nucleus by slow neutrons, and maintaining itself by the neutrons liberated in the fissions. The addition of a small quantity of cadmium to the system provides the possibility of controlling the energy liberation. The system will become stable at a temperature which is characteristic for the chemical composition and the dimensions of the system.

T. Bjerger, K. J. Broström and J. Koch have measured the decay curves of the fission products of uranium bombarded with fast and slow neutrons, and have carried out similar measurements on the fission of thorium. The decay curves with either fast or slow neutrons had the same shape, showing that the fission processes give rise to great numbers of different nuclei, the individual characters of which are smoothed out in the decay curves.

Tracks, on photographic plates with a thick coat of emulsion, of recoil nuclei produced by the action of neutrons from uranium have been recorded by L. Myssowsky and A. Jdanoff. Their range is very close to that of α -particles of uranium. The number of tracks of recoil nuclei having ranges greater than 1.5 cm. in air is equal to about one hundred nuclei per square centimetre per minute, in fair agreement with the results of Frisch.

The emission of short-range groups of α -particles from oxygen, nitrogen and fluorine under proton

bombardment has been discovered by W. E. Burcham and C. L. Smith. The group from fluorine follows a resonance excitation curve similar to that obtained for the γ -rays also produced by bombarding fluorine with protons. The groups from oxygen and nitrogen are interpreted as due to disintegrations of rare isotopes of these elements.

R. C. Majumdar and D. S. Kothari state that if the initial energy of a meson exceeds two thousand million electron volts (2Mc.) it could be transformed into two heavy particles, a proton and a neutron. It is possible that the protons and neutrons found in cosmic rays may arise in this manner.

A group of investigators from Osaka Imperial University have redetermined the isotopic masses of carbon and nitrogen by comparison of the doublets $\text{CH}_4\text{—O}$ and $\text{CH}_4\text{—N}$ and find the values 12.00384 and 14.00761 respectively.

F. W. Aston discusses the difference between his own value for the isotopic weight of ^{13}C and those obtained by other workers using double focusing mass-spectrographs. He points out that while the accuracy claimed is much greater than his own, there are results which suggest the possibility of systematic error. The discrepancy remaining is, however, very small.

Spectra of the 4046 radiation of mercury, scattered by benzene, acetic acid, salol and glycerine, are submitted by Sir C. V. Raman and C. S. Venkateswaran, showing that glycerine behaves in this respect like an

amorphous solid. These observations, and also the behaviour of ultra-sonic waves in viscous liquids, suggest that, for mechanical disturbances of sufficiently high frequencies, a liquid behaves essentially as a solid.

S. Shalyt states that nickel, cobalt, ferrous and chromium chlorides, the magnetic susceptibility of which at the temperature of liquid hydrogen depends on the intensity of the field, also show jumps in the specific heat and that these phenomena are related. They may be explained by the quenching of the orbits of metallic ions in the electric field of the crystal.

A. H. Cooke and R. A. Hull describe new experiments on pumping liquid helium to low temperatures. Using a pierced membrane to restrict the creeping of the helium II film, they reach by simple means temperatures previously only attainable with elaborate apparatus.

S. B. Hendricks states that aluminium silicate layers in the biotite-like micas are stacked in a variety of ways preserving twelve-fold co-ordination of interlayer potassium ions. Incomplete-filling of octahedral co-ordination positions within a layer of muscovite results in a distorted structure with a unique requirement on layer stacking. Diffuse scattering of X-rays by some biotites is a result of random combination of types of stacking. Variation in optic axial angles of micas is largely due to differences in structures.

C. H. Douglas Clark has deduced some simple relations between the heat of dissociation D , the internuclear distance r_e and the bond order α of carbon-carbon linkages. The relation between D and r_e was independently investigated by Fox and Martin by a different method, with the same conclusion. Satisfactory agreement with experiment is obtained.

Excellent optical interference figures of angular aperture up to 120° are obtained by H. E. Buckley by replacing the whole lens-system of the ordinary projector, between crystal and screen, by a single 'Polaroid' filter, of $1\frac{1}{2}$ in. to 2 in. diameter, close up to the crystal.

By observations on the clouds rising from active areas on Mt. Tongariro and White Island, N.Z., S. H. Wilson estimates the amounts of water vapour emitted to the atmosphere from fumaroles at these two localities.

It is suggested by C. C. Caldwell and R. J. W. Le Fèvre that the stable configuration of benzil (Ph.CO.CO.Ph) is one in which the two Ph.CO. units lie in planes, which are approximately at right angles to one another.

E. H. Neville submits that there is no basis in mathematics alone for certain comments made by D. P. Riley and I. Fankuchen on their recently constructed vector map of a cyclol skeleton.

In an experiment on binocular vision through a veiling glare comparable with illuminated fog, B. Babington Smith and R. W. Pickford found that the effect of differential veiling glare on the apparent relative distances or sizes of objects seen through it is very variable from subject to subject. It is much affected by conditions such as the rightward or leftward and near or far initial positions of the variable object, and by the presence of greater glare over the variable or standard—conditions which might be thought irrelevant.

R. S. Barclay and W. O. Kermack point out the contrary to certain opinions, the average maternity in various European countries for which figures are available has decreased while the birth-rate has been falling. The evidence indicates that a similar fall has occurred also in Scotland and in England and Wales during recent decades.

H. B. Carter reports a detailed study of regional variations in the density and arrangement of the follicle population observed on the 'grain' surface of the tanned merino skin. The results indicate the existence of an antero-posterior gradient in population density for which evidence had previously been presented by Dr. A. B. Wildman, but it is shown that in the present case this is subsidiary to the dorso-ventral gradient. This is illustrated by a chart and photomicrographs.

R. J. Pumphrey and A. F. Rawdon-Smith present evidence that the ability of certain insects to discriminate between different sounds is due to the rectifying action of the tympanic organ, which permits the activity in the auditory nerve to be synchronous with the amplitude modulation imposed on a carrier frequency lying within the insect's auditory spectrum. This difference from the mammalian method of frequency discrimination provides a satisfactory explanation of previously irreconcilable experimental observations.

The incidence and spread of a mortality among sponges in the waters of the Bahama Islands, reported by Paul S. Galtsoff, H. H. Brown, C. Leslie Smith and F. G. Walton Smith. Evidence is adduced which suggests that a fungus-like organism may be responsible for the mortality.

The spirochaete of African relapsing fever, *Borrelia duttoni*, has been successfully propagated by R. Knight Oag in the developing chicken embryo for four serial transfers, and a profuse growth of the organisms obtained. The spirochaetes do not kill the embryo or produce visible lesions in the chorio-allantoic membrane, but invade the blood-stream of the embryo. Throughout the series of egg passage the virulence of the organisms for mice has remained unaltered.

Eight types of chiasma pairs have been observed by C. L. Huskins and H. B. Newcombe in the pollen mother cells of *Trillium erectum*. They indicate that a chromatid is most likely to be involved in two adjacent cross-overs or chiasmata if the distance between these is short.

L. Havas reports that treatment with colchicine effects the sexually induced colour change (*Hochzeitskleid*) in *Rhododendron amarum* males, and this, in the same time (20 hours) as treatment with the testis hormone. A combined treatment with colchicine and testis hormone produces, however, the full *Hochzeitskleid* in ninety-five minutes. The oxygen consumption of the animals showed the same gradation of effects.

H. Dam and J. Glavind point out that the alimentary exudative diathesis in chicks can be prevented by synthetic *d*, *l*- α -tocopherol, and by natural sources of vitamin E.

M. N. Rudra has found that incubation of rat liver with mannose, galactose or glucose in Ringer-Locke solution and phosphate buffer containing manganese as chloride produced ascorbic acid in the liver. Intravenous injection of mannose in manganese solution also produced ascorbic acid in the liver.

News and Views

Prof. H. H. Dixon, F.R.S.

ON May 19, Prof. H. H. Dixon reaches his seventieth birthday, an occasion upon which all his friends would like to offer him their best wishes. In collaboration with his lifelong friend, the late Prof. J. Joly, Dixon developed the cohesion theory of the ascent of sap. This classical work, published in 1894, was the precursor of many physiological and morphological papers, which led to his election to the Royal Society in 1908, and to the award of the Boyle Medal of the Royal Dublin Society in 1917. In 1904, he was appointed to the University professorship of botany in Trinity College, Dublin, a position which he, happily, still continues to adorn. During his tenure of the chair, the new School of Botany (1907) and the new Herbarium (1912) were erected, both largely due to Prof. Dixon's enterprise and the late Lord Iveagh's generosity. His early morphological and cytological work enriched his laboratory with many beautiful slides of nuclear division, and, during the Great War, he published an exhaustive examination of the varieties of mahogany, many of which were used in aeroplane propellers. In 1937, he delivered the Croonian Lecture before the Royal Society in which he reviewed the theory of the ascent of sap. This lecture was illustrated with his distinctive experimental ingenuity. In recent years, among other subjects, he has investigated the alterations in the permeability of plant cells due to electrical stimuli and shown how closely they may be paralleled by the changes in resistance of certain emulsions. His pupils, including many medical men, scattered widely over the Empire, will long remember with affection the tutelary genii of the Botany Lab. T.C.D., "Botany Dick" and his "Mate" Mr. Joe Murray.

Dr. D. A. E. Garrod

THE appointment of Dr. Dorothy Annie Elizabeth Garrod as Disney professor of archaeology in the University of Cambridge in succession to Prof. E. H. Minns, who will retire on October 1 next, will be welcomed by all archaeologists as no more than the due recognition of a remarkable career of archaeological research and discovery. It is also the first appointment of a woman to a professorial chair at Cambridge. Miss Garrod, who is the daughter of the late Sir Archibald Garrod, Regius professor of medicine in the University of Oxford, was born in May 1892, and she is now director of studies in archaeology and anthropology (Section A) of Newnham College. In her prehistoric studies, Miss Garrod has been a faithful disciple of the Abbé Breuil, but her discipleship has in no way cramped her in the development of a strong and independent line of thought in archaeological theory, of which the germ is to be seen in her first important publication "The

Upper Palaeolithic Age in Britain" (1926), and came to full fruition in her remarkable analysis of palaeolithic culture in a reorientation, which formed the subject of her striking presidential address to the Prehistoric Society in 1937. To a wider public Miss Garrod is known as the director of a succession of successful archaeological excavations at Gibraltar (1925-26), in Southern Kurdistan (1928), in the caves of Mount Carmel, Palestine (1929-34), and Bulgaria (1938), which have produced among other results the discovery at Gibraltar of a second Neanderthal skull, and in Palestine have traced early man through successive phases of prehistoric culture back to Acheulean times, as well as added a new culture and race to the peoples of that region at the close of the palaeolithic period. Miss Garrod's success as an excavator is equalled by the skill and lucidity with which she has described her discoveries. In 1927 she was a member of the International Commission which reported adversely on the Glozel antiquities; and in 1936 she occupied the presidential chair of the Anthropological Section of the British Association.

Sir Clement Hindley, K.C.I.E.

SIR CLEMENT HINDLEY has been elected president of the Institution of Civil Engineers for 1939-40 and will take up his duties on November 7. Sir Clement joined the Engineering Department of the East Indian Railway in 1897 and his career as a railway engineer in India culminated in his appointment in 1922 as the first Chief Commissioner of Railways for India. On retirement from India in 1928, Sir Clement was appointed as the first chairman of the Racecourse Betting Control Board, and he has recently been lent temporarily by the Board to the Home Office to act as chairman of the Professional Advisory Committee (Shelters) in connexion with air raid precautions. The organization of scientific research is a matter in which Sir Clement has taken a great interest and he was a member of the Advisory Council for Scientific and Industrial Research during 1932-37. He has been chairman, since its inauguration in 1935, of the Institution of Civil Engineers Research Committee, which has been responsible for carrying out many important engineering researches in connexion with soil corrosion of metals and cement products, pile-driving, velocity formulae, special cements for large dams, fish-passes, steel structures, repeated stresses in structural elements, earthing to metal water pipes and mains, breathing apparatus for use in sewers, etc. His election as president of the Institution of Civil Engineers is both a fitting acknowledgment of his eminence as an engineer and a mark of recognition of the importance of research in engineering.

Conference on Air-raid Shelters

THE Government has now announced its decision on the subject of providing heavily protected shelters against air attack for large numbers of the civil population, and it has come to the conclusion that such a policy is impossible as well as undesirable. There is little doubt that the demand for deep tunnels and 'focal' shelters of the type advocated by the Finsbury Borough Council arose in consequence of statements made by superficial observers in Spain that such shelters were available for many of the inhabitants of Barcelona and other large cities, and that their provision was mainly responsible for the small number of casualties that had resulted from the more recent air raids in Spain. This, too, in spite of the fact that the statements were contradicted in January last by the person in the best position to know, namely, the chief air raid officer in Barcelona. That official was reported in *The Times* to have said that only about thirty thousand persons out of a total of nearly two millions in Barcelona had such shelters available, and that only about half the population had shelters of any sort, which consisted chiefly of cellars in private houses, and covered trenches. They had learnt from experience the necessity of evacuating the areas that were made special objects of attack, such as the docks, and of clearing the streets and of getting under cover of some sort.

THE public was, however, misinformed; and the demand for deep shelters became so insistent that, although the Lord Privy Seal has scarcely concealed his disbelief in the necessity for them, he convened a conference under the chairmanship of Lord Hailey to consider the whole matter. In its report (H.M. Stationery Office, 6d.) the Conference has examined the chief proposals put forward and has rejected all of them, giving half a dozen reasons for the conclusion reached, each one of which would have been sufficient to justify the verdict. The report concludes with a warning against a too ready acceptance of some of the estimates of cost put forward, and by expressing the belief that most British citizens would prefer to count upon less effective protection at their own homes, even if this made no pretence of warding off direct hits or near hits of bombs.

Emergency Preparations in the Event of War

THE Minister of Health has forwarded to all local authorities concerned in the Government's Evacuation Scheme in England and Wales a communication asking them to work out in detail their plans for the evacuation of school children and others who are to receive priority under the scheme (Ministry of Health Circular 1800. H.M. Stationery Office, 1d.). Enclosed with this communication is a memorandum (Memo. Evacuation No. 4, 3d.) indicating the general lines of the procedure that would be necessary in an emergency and the problems likely to arise, and discussing transport arrangements, arrangements at detaining stations and details of reception, and giving practical advice for householders and others. Authorities are

recommended to make full use of all voluntary agencies that might be useful, and it is stated that the Government does not intend that the operation of the scheme should result in any additional burden on the local rates. Another circular has been issued by the Ministry detailing the progress in organization and recruitment of first-aid posts in London. These schemes provide for 181 fixed aid posts, five cleansing stations and thirty-four mobile units. The estimated total of fixed posts required for the County of London is approximately two hundred.

Social Relations of Science

THE British Association announces a meeting of the new Division for the Social and International Relations of Science to be held at the Royal Institution at 4.30 on Thursday, May 25, by permission of the managers of the Institution. This will be the first public meeting of the Division to be held in London. Prof. Ernest Barker, professor of political science in the University of Cambridge, and Sir Daniel Hall, former chief scientific adviser to the Ministry of Agriculture, are to be the principal speakers, with Sir Richard Gregory, chairman of the Division, in the chair. The object of the meeting is to show how science and society are 'out of gear', and the nature of the task which the Division has undertaken in trying to assist in bringing about an adjustment. Prof. Barker is to speak on "The Impacts of Science on Society", showing the repercussions of scientific discovery and invention upon the social structure. Sir Daniel Hall is to deal with the failure to apply science properly by showing how the application of science to agriculture has been impeded. Sir Richard Gregory will deal with the work of the Division. Primarily, the meeting is intended for workers in every branch of science with the view of securing their interest and co-operation in the work of the Division. It will, however, be open to members of the public and to representatives of organizations interested in the work of the Division. Tickets may be had on application to the Secretary of the British Association, Burlington House, Piccadilly, London, W.1. Another important meeting of the Division is to be held at Manchester in June, when the effects of science upon certain industries will be discussed. Work of the Division at present in hand includes questions of nutrition, population, social psychology, the organization of science and the international relations of science. A committee has also been appointed to report on the world sources of raw materials.

Indirect Rule and the Anthropologist

As a principle of administration, indirect rule is essentially a system of local government, in theory functioning through local native tribal institutions. Admirable as this principle may be in intention—its object is at once to conduce to fairness and justice in the maintenance of law and order, while educating the native in a sense of civic and political responsibility, and at the same time affording him an opportunity of gradually adapting his institutions to

the conduct of public affairs on modern lines—yet when the searchlight of anthropological investigation is turned on to indirect rule as a working system, difficulties in giving it full effect and shortcomings in its practice begin to appear. In the earlier days of British administration in Africa, it was assumed, perhaps too readily and without intensive anthropological inquiry, that each local unit must be subordinated to a headman or chief, and ruled by him with or without a council of elders. In either event, it was assumed to be a system susceptible of individual representation. In default of a more penetrating examination, it was not realized that local sovereignty, to use an expressive, if not a fully applicable, term, was bound up with religious ritual, belief and organization, upon which the native was not only reticent, but also incapable of expounding the ramifications except in response to the patient inquiry of an experienced and trained observer. Hence the system of native courts composed of members, who have come to be called 'warrant chiefs', was by no means invariably in accord with native institutions, while the legitimate representative of native authority, according to tradition, was often relegated to the background, either through native reticence or the influence of a more forceful personality.

THE relation of the warrant chiefs to the real seat of native authority has been carefully analysed by Prof. O. Daryll Forde, who, as a Rockefeller Research Fellow of the International Institute of African Languages and Cultures, has made a special study from this point of view of the tribal customs of the large village centre of Umor in the Obubra Division of Southern Nigeria, with a population of more than 10,000 (*Africa*, 12, 2; 1939). Not only does he show how intricate an affair is native traditional machinery for the preservation of order and for local administration, but he also goes on to show how native custom and principles in local administration have been controverted by the appointments made, in the praiseworthy desire to secure the representation of native knowledge and opinion. At the time of Prof. Forde's investigation in 1935, reform of the composition of the native court was under consideration, and the moral of his report is clearly that any change should be made only after intensive inquiry into the details and essential character of native institutions. He himself has certain constructive suggestions to make; but at the same time he points out that it is now difficult to make that use of native institutions which at one time was open to the Government. The interest of the natives has been diverted from their own institutions to the form which has been imposed upon them by the white man, and among them discussion has tended to centre on the methods of appointing warrant chiefs rather than on any radical reform, which would allow for the incorporation of the traditional system in the administrative machinery, or its development in that direction. Further, the young men have formed a group now actively in opposition to traditional authority in

village affairs. It is evident that if native institutions are to be used and developed as a means to native education and civic training, some compromise will have to be effected. Otherwise native institutions and the stabilizing influence of tradition will go by the board.

International Standard for Chorionic Gonadotrophin

At the third International Conference on the Standardisation of Hormones, held at Geneva on August 11-13, 1938, it was decided that international standards should be established for certain hormones of the anterior lobe of the pituitary gland and analogous substances found in urine and serum, and that international units should be defined in terms of a weight of each standard. The final preparation of these standards, their dispensing in a form suitable and convenient for the use of the laboratory worker, their storage, preservation and subsequent distribution, was to be undertaken by the National Institute for Medical Research, Hampstead, London. The preparation of the international standard for the gonadotrophic substance of human urine of pregnancy (chorionic gonadotrophin) has now been completed. It has been prepared from substantial amounts of material generously provided by six firms in different countries. The individual samples having been approved by the Conference, a mixture was made and the standard has been finally dispensed in the form of 10 mgm. tablets. The international unit has been defined as the specific gonadotrophic activity of 0.1 mgm. of the standard preparation, an amount of activity similar to that required, under the conditions used by many workers, to cause cornification of the vaginal epithelium of the immature rat. Each tablet contains approximately 100 international units. As in the case of the international standards for other hormones, drugs and vitamins, the new international standard is held, on behalf of the Health Organisation of the League of Nations, at the National Institute for Medical Research, Hampstead, London, from which it can be obtained by national control centres established in other countries; workers in Great Britain should apply to the Department of Biological Standards, National Institute for Medical Research, Hampstead, London, N.W.3.

Preservation of the English Countryside

It may be remembered that at the Cambridge meeting of the British Association, Dr. Vaughan Cornish described his efforts to preserve the natural scenic beauty of the cliff regions near Sidmouth by ensuring that considerable tracts of land in his possession should be restricted entirely to agricultural purposes. *The Times* of April 26 announces that Dr. Cornish has decided to extend these restrictions to cover (during his lifetime) the lands of Thorn Farm, near Salcombe Regis. This is a place of considerable historic interest as well as of natural beauty, which takes its name from an old "Holy Thorn" tree used as a landmark from Saxon times, and replaced with

suitable ceremonial by another whenever it died. This decision has, also, its scientific aspect, on account of the proximity of the Norman Lockyer Observatory to Thorn Farm, where (but for the action of Dr. Cornish) it would have been possible to erect some six hundred houses under the local town planning scheme. It is well known that the work of Greenwich Observatory is badly hampered by smoke and glare from the surrounding district. The erection of six hundred houses in the vicinity of the Norman Lockyer Observatory might have been the first step towards a similar interference with the work of this observatory, and it is a matter of satisfaction that this annoyance has been at least postponed during the lifetime of Dr. Cornish.

Earliest Man

MR. J. REID MOIR, with an admirable sense of propriety, took as the text of his Huxley Memorial Lecture for 1939 before the Imperial College of Science and Technology on May 4 certain questions posed by T. H. Huxley in his famous book "Man's Place in Nature". There Huxley asked: "Where, then, must we look for primeval man? Was the oldest *Homo sapiens* Pliocene or Miocene, or yet more ancient?" Readers of Mr. Reid Moir's lecture in its published form ("The Earliest Men". By J. Reid Moir. London: Macmillan and Co., Ltd. Pp. 32. 1s. net) will appreciate the choice as lecturer on this occasion of an investigator of man's origins, who through his association with Edwin Ray Lankester is directly linked with Huxley, and also by his own researches has contributed so much of the material which must be taken into account by everyone who ponders the problems thus formulated by Huxley so long ago. The evidence of man's skeletal remains, as well as of his artefacts, which has been laboriously collected, pieced together and interpreted by numerous investigators since Huxley's day, ably summarized and surveyed by Mr. Reid Moir, may seem formidable enough in its detailed mass, but it is still far from offering a final solution of man's origins. Nevertheless it makes it possible to adumbrate a generalized formula, from which it may be that a concrete answer eventually will emerge. If in the meantime Mr. Reid Moir's technological and aesthetic arguments may seem a little overweighted in the period and degree of man's development they demand, and his credence in Miocene man a thought too readily conceded, none can deny that in his life work he has abundantly shown faith in that of which his powers of observation and reason have convinced him—the belief in the power of truth ultimately to prevail, which Huxley urged upon the youth of his time.

Verulamium Museum

THE new Verulamium Museum at St. Albans, which has been erected by the Corporation at a cost of £8,000, was declared open by the Earl of Harewood on May 8. The purpose of the Museum is to house the finds from the excavation by Dr. R. E. Mortimer Wheeler and the late Mrs. Wheeler between 1930 and 1934 of the Roman city of Verulamium and the pre-

Roman Belgic city in Prae Wood. A tablet in the entrance hall commemorates Mrs. Wheeler's part in the excavation. The museum building, of which Mr. F. Newton is the architect, and Mr. Philip Corden will act as curator, contains in addition to offices and laboratories, a museum hall 75 ft. long, in which are displayed a selection of the finest and most typical specimens from the two sites, grouped in an arrangement which will most readily convey their significance to the visitor. The large mass of material still under examination at the Institute of Archaeology in London will eventually be stored in the Verulamium Museum, and though not displayed, will be available for students' reference. Three of the finest of the mosaic pavements discovered at Verulamium, including the square pavement displaying the remarkable head of a sea god, and the striking semi-circular scallop-pattern pavement of about A.D. 180–190, are shown on the end-wall, facing the visitor on entering. On the left of the entrance are the wall-cases containing the Belgic pottery, both imported and home-made, from the pre-Roman site of Prae Wood, ranging in date from about A.D. 10–40. The remaining cases are given up to exhibits from Verulamium. The material culture of the inhabitants of the Roman site is exhibited in the long series of burial groups, among which not the least interesting relic is a denarius of Augustus, which was converted into a Mithraic token some two centuries after its issue. A large model of the important south-eastern, or London, gate is also shown.

Preservation of Fauna and Flora

IN an address entitled "The Dawn of a Geological Period" delivered at the London School of Hygiene and Tropical Medicine on May 4 for the University of London, under an arrangement for an exchange of lectures with the Universities of Belgium, Prof. V. van Straelen, director of the Royal Natural History Museum of Brussels, discussed the inroads made on the fauna of the world by the activities of man and especially by the exploitation of Central Africa. He pointed out the fact, which is usually entirely neglected if not always unrealized, that not only are the larger mammals threatened with extinction by the advance of settled areas in tropical Colonies, but also that the felling of rain forests, by exposing the soil to the direct attack of sunlight, renders it impossible to reforest such lands, and by completely altering all the micro climatic conditions, necessarily causes the destruction of all smaller plants and animals, whether they live above, upon or in the soil. In the light of his own great experience of such conditions, and of others the ultimate effects of which are similar, Prof. van Straelen showed that the changes of fauna and flora which are now occurring are in magnitude analogous to those which characterize the geological periods, and thus justified his title.

Cosmic Rays

PROF. P. M. S. BLACKBURN took "Cosmic Rays" as the subject of the thirtieth Kelvin Lecture which he delivered before the Institution of Electrical En-

engineers on Thursday, April 27. He gave a *résumé* of what had been done to discover the nature of these mysterious rays, from their properties. As a rule, engineers consider natural phenomena first of all to find out some possible utility for them. In addition, Prof. Blackett stimulated the imagination of his audience to consider all manner of possible consequences which might arise from the bombardment of the earth from outer space by some twenty particles per minute at astronomical values of electron volts. The effects of cosmic rays can be obtained, shown by experiment and recorded photographically without much difficulty and with quite simple apparatus, but calculation of these effects depends upon equations which, although easily written down, can only be approximately solved with great labour. The labour can be lightened by the use of calculating machines invented by engineers, but it is a lengthy operation. There is little exact knowledge about these rays and it is assumed that they are due to radiation from the extra-solar universe. Interesting accounts were given of the attempts that had been made on these rays by researches in the upper atmosphere, by investigations on the surface of the earth and by experiments below its crust. He said that, in the last case, the necessary apparatus had been installed in one of the underground platforms of the Holborn station of the London Passenger Transport Board, but it was found that the symmetry of the readings was effected by the presence overhead of the tunnel which carries the electric trams below Kingsway.

Photography in Science and Industry

DR. OLAF BLOCH, chief chemist of Messrs. Ilford Limited, delivered the twenty-ninth annual May Lecture before the Institute of Metals on May 10. Dr. Bloch pointed out that the photographic emulsion consists of a finely divided suspension of one or more of the halides of silver in gelatin. There are two broad theories of development, one of which suggests that the process consists in the deposition of silver upon the latent image from the developer which has first become supersaturated, whilst the second postulates increased adsorption at the points constituting the latent image with consequent increase of developer activity in these regions. As to the latent image, we are still without definite proof of its nature. Silver bromide crystals become much more sensitive by the inclusion in them of a small amount of iodide, but the great advance which has been made in emulsion-making technique is largely due to the employment of dye-sensitizers. The second part of the lecture dealt with the applications of photography to industry. By means of the photographic emulsion our powers of observation extend far beyond the limits originally set by the senses, and, further, the grains of the emulsion are rendered developable by the passage of the fast moving particles ejected from disintegrating atoms. Investigations into the nature of cosmic rays are also being actively carried on by the aid of the photographic emulsion. For this work special emulsions have to be prepared, but all are members of a large

emulsion family who serve mankind in the making of illustrations for books, in survey work, in photomicrography and photo-telegraphy, for ordinary picture making and record work, and in nearly every field of research.

Sound Transmission from London Television Station

It is well known that the use of ultra-short wavelengths for broadcasting purposes facilitates the attainment of a very high quality in the sound transmission on account of the extensive range of side-band frequencies which may be employed. At a meeting of the Wireless Section of the Institution of Electrical Engineers on May 3, Messrs. I. L. Turnbull and H. A. M. Clark read a paper on "The Marconi-E.M.I. Audio-Frequency Equipment at the London Television Station". This paper outlines the requirements of a high-quality sound equipment and describes the design and constructional features of the Alexandra Palace installation. The final section of the paper gives information on the overall performance of the apparatus and includes data on the frequency and harmonic distortion of the amplifier equipment. The overall frequency response from the microphones to the modulated radio frequency output to the transmitter is practically uniform from 40 cycles per second to more than 10,000 cycles per second; the second harmonic content varies up to a maximum of 0.5 per cent for full (that is, 100 per cent) modulation, while at the same modulation level the third harmonic content is about 0.1 per cent. The authors express the opinion that it is this low odd-harmonic distortion, quite as much as the extended frequency range, that is responsible for the satisfying and pleasing quality of the sound transmitted. The equipment has been in operation for a period of two years with complete satisfaction. It may be remarked in conclusion that, for some time past, it has been the practice of the British Broadcasting Corporation to transmit part of the ordinary National or Regional programme through the Alexandra Palace 'sound' transmitter, so that listeners having a television or other suitable ultra-short wave receiver may take advantage of this high-quality broadcasting station.

Maternal Mortality and Industrial Welfare

In the course of an address delivered to the Industrial Welfare Society on April 28, the Minister of Health, Mr. Walter Elliot, stated that the provisional maternal mortality figures for 1938 have just been received and that they show a further reduction from 3.13 per 1,000 births in 1937 to 2.97 in 1938, the lowest figure ever recorded in Great Britain. Although abnormally large sums have now to be found for defence, there has been no reduction in our social services. The Government's contribution to these services and to the cost of police, roads, etc., has grown by £186,000,000 since 1925, an expenditure that is proving an excellent investment. In addition to the new low record in maternal mortality, during the period 1927-37 the infantile mortality rate has fallen from 70 to 58, and the tuberculosis death

rate from 97 to 69. The toll of sickness upon industry remains, however, very great, for expenditure on benefits under National Health Insurance amounted in 1937 to £28,000,000, but hundreds of firms to-day are safeguarding the health of their staffs.

Earthquakes Registered at European Observatories

FOUR earthquakes of considerable severity have been registered by seismographs in Europe recently. The first, on April 28, was registered at De Bilt (Holland) at 0h. 38m. 15s. G.C.T. and may have been distant a little more than 24° . The second caused the needle on a seismograph in London to swing about $3/5$ in. It was recorded at De Bilt on April 30 at 3h. 12m. 0s. G.C.T., and at Uccle at 3h. 12m. 12s. Since the epicentral distance was greater than 100° , observations are awaited from more distant observatories before further computations are made. The third was on May 1, and this is discussed below, being the most important of the four. The fourth was recorded at Kew on May 2 at 13h. 27m. 12s. and may have been an aftershock of the one on the previous day, though a slightly nearer epicentre may be indicated.

Japanese Earthquake of May 1

RECORDS of this earthquake have been reported by the following observatories:

De Bilt	at 0h. 10m. 42s. G.C.T.
Strasbourg	at 0h. 10m. 47s. G.C.T.
Uccle	at 0h. 10m. 47s. G.C.T.
Kew	at 0h. 10m. 52s. G.C.T.
with an aftershock	at 0h. 12m. 32s. G.C.T.

The epicentre distance from all these stations was between 80° and 83° and the evidence points to an epicentre in the neighbourhood of the Oga Peninsula north-west of Akita, a town on the north-west coast of the main island of Japan. Possible epicentral co-ordinates are lat. 39.8° N., long. 139.9° E. The shock occurred at 2.59 p.m. local time and lasted 27 seconds. It caused strong vertical movement locally and there was a considerable amount of surface faulting. In the Oga Peninsula the faulting caused land to slide into the sea, and wrecked many houses. In Akita itself plate glass windows were shattered and shop fronts fell out. The reservoir at Funakawa is reported to have burst its banks and drowned three people. Altogether twenty-six people were killed and thirty-eight injured and many slept out in the open that night. Fortunately, the resulting fires were quickly extinguished by the fire brigades, though railway and telegraph communications were disturbed. Aftershocks were frequent locally for some time and some of these were of considerable severity as the Kew records indicate.

The Colonial Service: Recent Appointments

THE following appointments and promotions in the Colonial Service have recently been made: R. H. A. Marlen, veterinary officer, Gold Coast; E. Burt, junior entomologist, Sleeping Sickness Research Station, Tanganyika Territory; A. E. Pound, inspector of plants and produce, Gold Coast; G. H. Swynnerton, game ranger, Tanganyika Territory; R. B. Warner, inspector of produce, Nigeria; G. J. L.

Burton (senior plant breeder and experimentalist) chief research officer, Agricultural Department Kenya; G. Griffith (assistant agricultural chemist Uganda), chemist (soils), Malaya; G. R. Spurrell (inspector of plants and produce), agriculture superintendent, Gold Coast; Dr. G. J. William (assistant geologist, Tanganyika Territory), geologist Gold Coast; R. G. Newberry (schoolmaster), agricultural education officer, Agricultural Department Nigeria; W. H. Reeve (late assistant field geologist Tanganyika Territory), geologist, Nyasaland.

Announcements

SIR CHARLES VERNON BOYS has been awarded the Elliot Cresson Gold Medal of the Franklin Institute in recognition of his scientific achievements, "which have furnished scientists with new and remarkably precise methods for making measurements in gravitation, in sound, in heat, in radiation, in current and static electricity, so refined as to render possible the weighing of the earth, the determination of the radiant energy coming to us from the stars, the photography of the speeding bullet and the immobilization, even, of the lightning flash itself". The medal will be presented on May 17.

THE Chalmers Gold Medal of the Royal Society of Tropical Medicine and Hygiene has been awarded to Dr. Max Theiler of the International Health Division of the Rockefeller Foundation, New York. The medal has been awarded to Dr. Theiler in recognition of research of outstanding merit in tropical medicine or tropical hygiene particularly in reference to yellow fever, and the possibility of producing the vaccine by the use of attenuated virus.

THE twenty-fifth French Congress of Social Hygiene will be held at the Bordeaux Faculty of Medicine under the presidency of Dr. George Rislar on May 19-21. Further information can be obtained from L'Alliance d'Hygiène Sociale, 5 rue Las Cases, Paris.

AN International Meeting on Physics is being arranged during September 4-16 by the Federal Institute of Technology and the Physical Society of Zurich in connexion with the Swiss National Exhibition which was opened by the President of the Swiss Confederation on May 6. The meeting will be divided into five sections, dealing with nuclear physics, physics of the solid body, technical physics, television and high-frequency studies, respectively. Leading scientific workers in these subjects from all parts of the world are taking part. Further particulars can be obtained from the Secretary, International Meeting on Physics, 41 Gloriastrasse, Zurich 7.

THE English Universities Press, Ltd., Little Paul's House, Warwick Square, London, E.C.4, is organizing a competition for schools in the form of question papers on three of its recently published books: "Man against Microbe", "Physical Science in Modern Life" and "Ascaris: the Biologist's Story of Life". The age limit is nineteen years and the competition closes on July 31. Particulars can be obtained from the English Universities Press, Ltd.

Research Items

Petroglyphs of North Central New Mexico

IN the eleventh report of the Archaeological Survey Series of the University of Denver, Colorado ("Petroglyphs of North Central New Mexico", Anthropological Department, University of Denver. Pp. 58 with plates), Prof. E. B. Renaud gives the results of exploratory investigation of the rock carvings, engravings and paintings to be found in the region centring on Santa Fé, which was initiated in 1932, carried on in succeeding seasons, and finally reviewed in an expedition of 1938. The region to the north and south of Santa Fé, here under survey, is divided into three areas, north, west and south-eastern, mainly on geographical grounds. The petroglyphs found in these divisions do not differ materially in character. The whole region is bisected from north-east to south-west by the great Rio Grande valley. Certain general conclusions are drawn from the detailed descriptions of the sites. All sites, with a single exception, have anthropomorphic representations, whether realistic or schematic, isolated or in groups. Among occupations noted are dancers, flute-players, hunters, and warriors. Several dancers wear headdresses—horns or feathers. There were a few instances of men on horseback. The presence of phallic figures, frequently ithyphallic, is unusually marked. Simple or stylized human figures are present on all sites. Hands are seen at fairly numerous sites, though never many together. Zoomorphic figures are abundant, though not to be identified with certainty, excepting deer. Eight sites display birds, one type being the spread-eagle or 'thunder-bird'. The serpent is omnipresent. Phylomorphs are rare, and skeuomorphs not numerous. There is a vast class of geometric figures, signs, and symbols. Though no chronology is attempted, the majority of the figures belong to the prehistoric period of the south-west, which in Mexico ends about A.D. 1540, when the horse first became known to the Indians.

Iron Age Settlement in Wiltshire

THE excavations of the smaller of two prehistoric sites at Woodbury, near Salisbury, Wiltshire, now being carried on by Dr. Gerhard Bersu on behalf of the Prehistoric Society in pursuance of its recently instituted policy of systematic research in the field, have thrown considerable light on social conditions in the Early Iron Age in Britain. The report on the first season's excavation (*Proc. Prehist. Soc.*, N.S., 4; 1939) states that in the period from June 12 to September 18 about one fifth of the total area of the settlement of about 15,000 sq. metres, was uncovered down to the chalk. The settlement belongs exclusively to Early Iron Age A, and was of long duration. A ditch planned during the existence of the settlement was never completed; but it is evident from analogous sites in the area that some threat, at present of unknown character, forced the inhabitants to defend their open settlements by banks and ditches. This was at a time when hill-forts also were being planned. At one period, a simple palisade surrounded the site; but whether before or later than the construction of the ditch awaits elucidation. The main features of the site are the provision by pits and over-

ground structures for the storage of grain after partial roasting, hollows in which it is suggested the harvested grain was prepared for roasting and storage, and two circular structures for habitation—the first of their kind to be found in Early Iron Age A in Britain—of which the larger with the longer structural history, and situated in the middle of the enclosure, is clearly the principal building and the residence of the proprietor of the settlement. This settlement was neither a cattle kraal, as had been suggested, nor a village, but a farm in the nature of the subsequent Roman villa.

Revival After Electric Shock

W. T. McNIFF has reported (*J. Elec. Workers and Operators*, 36, 145; 1937) that he is able to revive small animals, which have been apparently killed by electric shock, by the application of a 'counter-shock' of 60 cycle A.C. As Wiggers has shown, the heart in fibrillation can be made to beat normally by the passage of an electric current through it, and this, apparently, is the mode of action of the 'counter-shock'. If the lethal shock is applied through electrodes on the head and tail, revival is not possible, since the central nervous system is destroyed. It follows, therefore, that this method cannot be employed to revive those subjected to legal electrocution. For the method to be effective, the lethal shock must not pass through the head, and the counter-shock must be applied through electrodes on chest and back within four minutes of the patient having received the apparently lethal shock.

Action of Quinine on Skeletal Muscle

A. M. HARVEY (*J. Physiol.*, 95, 45; 1939) has studied the actions of quinine on skeletal muscle, on the motor end-plate, and on the responses of the muscle to various other drugs in frogs, domestic fowls and cats with the following results. Quinine caused an increase in the tension response to a single maximal stimulus in normal, curarized and denervated muscle. This mechanical potentiation was accompanied by an increase in the amplitude and duration of the muscle action potential. The ability of the muscle to respond to a tetanus was diminished owing to an increase in the refractory period of the muscle fibres. The excitability at the motor end-plate was lowered by quinine, and the ability of a tetanus to facilitate conduction at the end-plate was weakened or abolished. Eserine and veratrine were no longer able to evoke repetitive response to a single stimulus in a muscle treated with quinine. The response of the normal mammalian muscle to injected acetylcholine was abolished by quinine. This phenomenon was largely due to the curariform action of the drug, the otherwise similar response to injection of a potassium salt being little affected.

Optical Isomerism and Growth

J. R. TOTTER and C. P. BERG (*J. Biol. Chem.*, 127, 375; 1939) have prepared the optical isomers of natural tryptophane, histidine and lysine, and given them to mice in diets deficient only in the corresponding natural form and under conditions analogous to

those previously employed in similar studies on rats. The growth promoted by the unnatural isomers of tryptophane and histidine was found to be slower than that induced by the modifications which occurred naturally in proteins. The response was quantitatively but not qualitatively at variance with that observed in rats. Unnatural lysine in the mouse as in the rat failed to promote growth when added to diet deficient in natural lysine.

Mammals of Tennessee

A USEFUL account of the mammals of this State has been based upon the special survey made by the U.S. National Museum in 1937, supplemented by all the relevant material in the collections of the Museum and of the Biological Survey (Remington Kellogg, *Proc. U.S. Nat. Mus.*, 86, 245; 1939). The author does not draw any conclusions from his list, but it is apparent that this is a fair sample of the mammals of the eastern States, its notable feature being perhaps the degree to which man has changed the aspect of the original fauna by his interference. The tale is largely one of reduced numbers and extermination. There is scarcely a creature, valued even in small degree for its pelt, which is not reported to be decreasing; even the opossum and raccoon are fewer, mink and skunk are becoming rare, fisher and otter and perhaps beaver are extinct. So with the larger beasts of prey, the grey wolf, black bear and others having been exterminated in many sections. Bison and elk disappeared in the early years of the nineteenth century; even the Virginian deer seems to be on its last legs, though in 1789 where troops were stationed good venison was accepted in lieu of taxes at a value of 9d. a pound. On the other hand, there have been additions to the fauna: fifteen wild swine from northern Germany were enclosed in 1912 and multiplied; about 100 broke through the fence in 1920 and now their progeny ranges over an area of 50 square miles. Coyotes have also been introduced recently, "for the purpose of training hounds" it is said; and of course those invariable camp followers of civilisation, the house-mouse, black rat, Alexandrine rat and brown rat have long been successfully established.

Distribution of Crop Productivity

It has been found that an area which produces high yields of one crop, for example, wheat, will as a rule also produce yields above the average of other crops, for example, barley, hay or potatoes. A statistical analysis of the geographical distribution of crop productivity in England (*J. Roy. Statistical Soc.*, 102, 21; 1939) has been made by M. G. Kendall, head of the Statistical Branch of the Ministry of Agriculture. The economic importance of the results is obvious, but from a wider point of view perhaps the most interesting aspect of the analysis is the application to agricultural economics of methods devised for psychological tests of intelligence. The prevalence of positive correlations between yields of different crops is a phenomenon similar to the prevalence of positive correlations of the results of mental tests. It is natural to ask if there is a coefficient of general productivity analogous to Spearman's ρ , the much-disputed general factor in intelligence. Mr. Kendall offers no fewer than four such coefficients. The first two, the 'productivity' and 'ranking' coefficients, are based on psychological methods.

These two coefficients give nearly the same results; the first is preferable theoretically, but the second is much easier to calculate. The third and fourth, the 'money-value' and 'energy' indexes, are spatial index numbers, agreeing fairly well with each other, but not so well with the previous pair. Finally, an attempt is made to estimate the validity of the conclusions reached by psychologists by seeing how far the same arguments hold when applied to crop productivity.

Potato Metabolism and the Blight Fungus

AN interesting paper upon the rates of growth of potato foliage and tubers in relation to attack by the blight fungus, *Phytophthora infestans*, by the late P. A. Murphy, has recently been published (*Sci. Proc. Roy. Dub. Soc.*, 22, N.S. No. 7, 69-82, February 1939). It has proved relatively easy to eliminate blight, but more difficult to avoid injury to the foliage. The first effect of spraying is usually to check the production of foliage and tubers, and benefits of the fungicidal wash only become apparent later, when the parasite is eradicated. Complete control of the disease without appreciable injury to the plant was effected by weekly applications of dilute solutions of cuprous oxide, with about half the quantity of copper usually given per acre with Burgundy mixture. Maximum production of tubers reached 1½ tons per week during the month of July, after which it fell off, until in September it was not much above ½ a ton per week. The period of maximum tuber production corresponded with that of maximum foliage. Benefits of spraying depend upon the interval between the arrest of production caused by the blight fungus, and the time of normal cessation of growth in September.

Sexual Isolation

ALTHOUGH it has been known for some considerable time that preference in mating was a powerful means of isolating one species or race from another there has been little experimental evidence available. T. Dobzhansky and P. C. Koller (*Biol. Zentralb.*, 58, 589; 1938) have analysed preferential mating between *Drosophila miranda* and *D. pseudo-obscura* and between *D. aestiva* and *D. athabasca*. It was found that in mixed cultures of these species homogametic mating was greatly preferred. Degrees of preference were, however, exhibited when different races of *D. pseudo-obscura* and *D. miranda* were used. Within *D. miranda* two races (Olympio and Whitney) exhibited a small degree of preferential homogametic mating. Although these species have approximately similar distributions in the wild they remain isolated from one another. There are indications that mating preference is genetical in origin and dependent on genes on the autosomes.

Earthquakes of the Pacific Coast of U.S.A. (1769-1928)

THE whole of vol. 29, No. 1 (Jan. 1929), of the *Bulletin of the Seismological Society of America* is taken up with this descriptive catalogue compiled by Sidney D. Townley and the late Maxwell W. Allen. It occupies 297 pages, earthquakes in California taking 232 pages whilst those of Oregon, Washington, Idaho, Nevada, Utah and Arizona take 44 pages in all, the remainder of the volume being concerned with the introductory remarks. The material used in the catalogue has been largely taken from the Holden

(1769-1897) and McAdie (1897-1906) catalogues, and since 1906 from notes by U.S. Weather Bureau observers, newspapers, magazines and the records of individuals and societies interested, all of which are acknowledged by the authors, and all of which have been carefully checked. The catalogue stops at 1928, since after that date the records have been kept and published by the U.S. Coast and Geodetic Survey annually. There are no figures or maps, and indeed it would be difficult to put all the matter accurately on a map unless it were drawn to an abnormally large scale, but it is hoped that in the near future Mr. Townley will arrange that this valuable information be arranged in geographical latitude and longitude order somewhat after the manner of Miss Bellamy's Catalogue, with cross references to the present work, as this would make it much more valuable from both the statistical and the ready reference points of view.

Detection of Nitrous Fumes

THE detection of nitrous fumes, which are encountered in many industrial operations and are dangerous poisons, is described in Leaflet No. 5, "Methods for the Detection of Toxic Gases in Industry, Nitrous Fumes" (H.M. Stationery Office. 3d. net) issued by the Department of Scientific and Industrial Research. The test depends on the Griess-Isolvy reaction. The atmosphere under test is drawn by a hand pump through a tube containing the reagent until a rose-pink colour of standard depth is reached, and from the number of strokes of the pump the concentration may be found from a table given in the leaflet.

Distribution of Carbon Isotopes

A SYSTEMATIC study of the relative abundance of the carbon isotopes ^{12}C and ^{13}C in various groups of materials has been made by A. O. Nier and E. A. Gulbransen (*J. Amer. Chem. Soc.*, 61, 697; 1939) with a mass spectrometer of high sensitivity and high resolving power. The compounds studied were arranged in four groups: (1) igneous carbon (graphite, meteorite and diamond); (2) limestones; (3) plant sources; (4) various (dry ice, air, flesh, coal, etc.). The $^{13}\text{C}/^{12}\text{C}$ ratio found appears to depend upon the classification of the material. In general, the heavy isotope seems more abundant in limestones and the light isotope in plant forms. The maximum variation in the ratio was about 5 per cent. More data would probably provide a method of determining the origin of carbon compounds in Nature. If the $^{13}\text{C}/^{12}\text{C}$ ratio in air is assumed to be 90 ± 2 , the atomic weight 12.012 is calculated for carbon, with the isotopic weights 12.0041 and 13.0079, and a conversion factor of 1.000275 in going from the physical to the chemical scale.

Structure of Triborine Triamine

TRIBORINE triamine, $\text{B}_3\text{N}_3\text{H}_6$, is iso-electronic with benzene. Fuller implications of this are brought out very elegantly by B. L. Crawford and J. T. Edsall (*J. Chem. Physics*, 7, 223; 1939) from a study of the long-wave spectroscopy of $\text{B}_3\text{N}_3\text{H}_6$. They have examined the Raman spectrum of liquid $\text{B}_3\text{N}_3\text{H}_6$, and the infra-red spectrum of gaseous $\text{B}_3\text{N}_3\text{H}_6$. The symmetry of the molecule is D_{3h} , and it should therefore have twenty distinct internal vibrations. Of these, seven should appear in the Raman spectrum only (four should be polarized), three should appear

in the infra-red spectrum only, seven should be common to both spectra, and three should be inactive in both spectra. These theoretical predictions have been substantially verified by the ascertained spectra, but the number of coincident frequencies is less than the predicted seven. However, by means of a normal co-ordinate treatment of the molecule, it has been possible not only to calculate the force constants of the various bonds but also to calculate all the fundamental frequencies, both active and inactive. This permits the assigning of all observed frequencies. One instance of an isotopic effect, due to molecules containing the isotope of boron of mass 10 has been noted and thermodynamic properties of $\text{B}_3\text{N}_3\text{H}_6$ have been calculated. The interesting comparison of the spectra and force constants of $\text{B}_3\text{N}_3\text{H}_6$ and C_6H_6 , which is made leads the authors to favour the assignment of the benzene frequencies made by Lord and Andrews in preference to the assignment of Angus, Bailey, Ingold, and co-workers.

American Meter-testing Methods

IN Mr. Shotter's recent paper to the Institution of Electrical Engineers on April 14, several useful and novel methods of testing electric meters are described which deserve to be better known in Great Britain. He was struck by the fact that Americans have to a large extent eliminated the use of stop-watches in their electrical laboratories, the timing being effected by impulses from a standard clock. This is achieved by the aid of a photo-electric cell. The method consists of keeping a constant load on the rotating substandard electric meters, which are kept under test for a definite time period with the potential circuit of these instruments controlled from the standard clock. A method which appears to be becoming popular is the use of a rotating standard fitted with a stroboscopic attachment, one meter at a time being tested. With the types of meter the Westinghouse Co. is producing the method appears to be very satisfactory. Mr. Shotter saw also a chemical method for cleaning badly corroded and tarnished clockworks and other types of mechanism. The method employed consists in the use of a rotating cleaner containing one or more solutions in which the clockwork is immersed for a short time. Similar apparatus for cleaning watches and clocks has been on the market in the United States for some years. The method appears to have considerable possibilities. Microscopic examination of pivots and jewels was employed in all the servicing laboratories which the author saw.

Measuring Focal Lengths of Zones of a Mirror

W. H. NEWMAN's paper entitled "A Method of Measuring the Focal Lengths of Zones of a Mirror for a Reflecting Telescope" (*J. Brit. Astro. Assoc.*, 49, 5; March 1939) will prove interesting to all makers of specula. Instead of using a complete Ronchi grating, two fine slits were employed, or, to be more correct, two lines were ruled with a needle on smoked glass, their distance apart being 0.02 in. The glass was smeared with paraffin first as this facilitates the ruling of straight lines, whereas smoking the glass without this paraffin coating may lead to ragged edges. This modification of the Hartmann method of testing was discussed by experts at the meeting of the Association, and some of them were a little dubious of its utility.

Pleistocene Stratigraphy of the Breckland

By T. T. Paterson, University Museum of Archaeology and Ethnology, Cambridge

AT the British Association meeting last year, during an excursion by the Geological Section to the Breckland, a sequence of the Pleistocene deposits there was demonstrated. Many requests for information have indicated that a short review of the stratigraphy and prehistory, prior to publication of a full memoir on that region, would be useful to geologists and prehistorians interested in the Pleistocene in England.

Moreover, they are coloured brownish by reason of loam and clay derived from an earlier interglacial deposit. The Middle and Upper have previously been confused and named the Upper Chalky Boulder Clay.

The Lower Boulder Clay (*B*) is only found on the slopes of shallow ancient valley forms and on higher ground, having been removed principally by a long period of erosion (*O*) which succeeded the ice advance and was related to a period of uplift. This must be

There are three boulder clays, called here the Lower, Middle and Upper. The Lower, hitherto called the Great Chalky Boulder Clay, is distinguished by its erratics from Scotland, Yorkshire and Scandinavia, as well as Jurassic and Kimmeridgian material; whereas the Middle and Upper are very much alike, carrying a great quantity of English, especially Triassic, erratics and none from very far parts.

been quite extensive since valleys several hundred feet deep were then cut out, and it is the period when the major features of the present landscape were decided. A great period of aggradation filled these valleys with gravels (*D*) up to about the level of our present river system. A warm fauna roamed the land surface so established. A period of increased rain deposition led to some slight erosion (*E*) and

subsequent formation of a loam (F). Another period of slight aggradation with a temperate fauna (G) was followed by advance of an English glacier (H), when the land was depressed some 150 feet.

The sequence of the first interglacial was repeated, but during a shorter second interglacial. Uplift was followed by erosion (I), valleys being excavated, generally along previously established drainage lines though some deflections occurred. Aggradation (J) was continued into a temperate period. A colder oscillation (K) was followed by temperate conditions, and deposition of a loam (L). A period of slight erosion (M) cut into the loam, and the Upper Boulder Clay was then deposited as a skin over the greater part of the Breckland, though not in the hills to the south.

This boulder clay and its associated gravels form an Upper Terrace dissected by an erosion phase (O) which cut out the present radial drainage of the Breckland. A Middle terrace was formed of well bedded gravels (P). Towards the upper part a cold fauna is succeeded by a bed (Q) showing the effects of sludging under severe cold conditions. A period of erosion and aggradation forms a late Low Terrace (R).

Because of its general lithological character and physiographic configuration the Lower Boulder Clay (the Great Chalky Boulder Clay of West Norfolk and Suffolk) is equated with the Norwich Brickearth. The Middle Boulder Clay is equated with the Great Chalky Boulder Clay (the Great Eastern Drift) of East Norfolk and Suffolk. The Upper Boulder Clay is equated with the 'Upper Chalky Boulder Clay and Little Eastern Drift'. A more widespread correlation is not possible here, but will appear in the full memoir, which, it is hoped, will be published later this year.

At several horizons palaeolithic industries have been discovered. The Acheulean is divisible into Lower *a* and *b*, Middle *a* and *b*, Upper *a* and *b*, and Final. The Clactonian can similarly be subdivided, into Lower *a* and *b*, Middle *a* and *b*, and Upper *a* and *b*. In general, it may be said that:

The Lower Acheul occurs during the early part of the Lower-Middle Interglacial prior to phase (E) and is characterized by free flaking, no controlled secondary work, no fine retouch, thickness, cortex remains, irregular outline and dominant pyriform shapes.

The Middle Acheul occurs during the later part of the Lower-Middle Interglacial and is characterized

by the presence of much controlled secondary working, some retouch (more in Middle *b*), and lingulate and ovate forms dominant. (In southern England the pseudo-Micoquian is dominant in Middle *b*.)

The Upper Acheul appears in the Middle-Upper Interglacial and is characterized by much controlled secondary working, fine retouch including controlled step retouch, thinness, no cortex, very fine and regular outlines (twisted forms common), small foliates, pointed ovates and straight-sided pyriform types dominant.

The Final Acheul appears in the post-Upper Boulder Clay aggradation gravels with the same general characters as the Upper Acheul, somewhat finer if anything, but the 'proto-celt' and the triangular forms appear.

The Lower Clacton occurs in the same period as Lower Acheul; with massive flakes, generally much cortex remaining, no controlled secondary retouch, no specifically prepared forms, and the cores coarsely biconvex and serrate, with no flat-bottomed forms.

The Middle Clacton occurs in the same period as the Middle Acheul and has thinner flakes, cortex wholly removed, controlled secondary working, some retouch, specifically prepared forms, points and such-like, proto-Levallois and Levallois cores, biconvex, serrate and flat-bottomed.

The Upper Clacton occurs in the same period as the Upper Acheul. Apparently the Upper Acheul has absorbed some northern Upper Clacton* elements and the only dominantly Clacton industry is of southern facies†, direct descendant of a Middle Clacton *b* of the Thames. The flakes are equally side- and end-types from biconvex and flat-bottomed cores, and of specific shapes. There are no pseudo- or proto-Levallois flakes or cores. The flakes are strong with median ridges instead of flake scars. There is no secondary working, but finely developed scaling retouch. Outlines are regular.

Faceted, possibly Levallois, flakes are occasionally found but no industry has so far been unearthed.

On broad palaeontological and stratigraphical grounds, the Pleistocene is divided into Lower, Middle and Upper. This division corresponds to three cycles of deposition, the first being less marked than the others. Both Middle and Upper begin with extensive land movement. The Lower is so named because of the Villafranchian and late Villafranchian character of the fauna.

* "Tayacian" stem of the Clacton.

† "Moustorian" stem of the Clacton.

British Empire Telegraph Communications

DURING the last ten years very rapid progress has been made in both telegraph and radio communication throughout the British Empire. In a paper by K. L. Wood recently read to the Institution of Electrical Engineers, the engineering aspect of the whole of this world-wide communication is considered. A short history of progress in cable telegraphy is given, but full explanations are given of novel technical methods. Methods of operating radio are also described, and reference is made to the effects of varying cosmic conditions on radio signals.

September 29, 1929, was a notable date in world communication, as on that date all the telegraph communications of the British Empire were, by Act of Parliament, placed in the hands of a single operating company. At the same time an Imperial Communications Advisory Committee was set up, the members of which were nominated by the British and Dominion Governments. A long list is given of the main companies taken over by the operating company. In addition, the ship and aircraft services were taken over as well as various small radio

circuits. In many parts of the world, the cable systems have been reorganized. The terminals of certain radio circuits in South Africa, India, Canada, Egypt and Australia are operated by local companies.

The Post Office also maintains a broadcast telegraph service on long and short wave-lengths. Radiotelephony in the United Kingdom is controlled and operated by the G.P.O., but the overseas terminals in the Dominions are controlled by the local companies or by the operating company. The operating company also handles abroad the shore end of various ship services, some of which are fitted with direction-finding apparatus. At Nairobi, Bermuda and Bahrain, Adcock direction-finding stations for air services are in operation. There are radio-phototelegraph services with New York, Buenos Aires, Melbourne and Tokio; also land telephony in Cyprus and Peru, and broadcasting in Kenya. The present telegraph system comprises 155,090 nautical miles of submarine cable, 125 wireless circuits, and 161 overseas branches. The tables given show that nearly all the Empire routes from the United Kingdom are served both by cable and by wireless. London stands out clearly as the focal point of the whole system.

During certain periods of the day, much of the traffic between distant parts of the Empire passes through London. For example, South Africa-India traffic may travel via the Cape Town-London beam and the London-Bombay, or via the cable chains over the same route. Many alternative routes to Australia are given. The choice as between wireless and cable is primarily dependent on the senders' instructions; but the particular route is regulated in part by the out-payments that have to be made on the various routes. These depend very largely on the time of traffic flow, and this, again, is largely dependent upon the business times in various parts of the world. During the night on a route which is served both by wireless and by cable, the cable circuit may carry the bulk of the traffic, since the majority of the cable chain stations may have to be kept

fully manual to serve other routes; methods have now been devised which largely overcome the effects of 'fading' and 'atmospherics'. Vardan working, while largely eliminating fades and atmospherics, fails when both these factors are present at the same time. Considerable experimental work is still being carried out, but only with limited success.

The author also considers the effect of cosmic conditions on wireless telegraph circuits, and explains how in practice large use is made of the effects of the solar cycle when predicting future conditions. The optimum wave-lengths of transmission for any given route are dependent upon the season and the time of the day and—this is an important factor—the degree of solar activity, which is found to follow approximately an 11½ years' cycle. The last sunspot maximum period was during 1928-29, and the minimum period during 1933-34. The years following the latter period have been accompanied by a marked increase in activity, which on a half-yearly basis exhibited a well-defined peak for January-June 1937. Records for the past hundred years reveal that, whilst the average length of cycle is 11.4 years, the change from minimum to maximum activity occurred over an average period of only 4.5 years; a study of wireless data for the year 1938 indicates that it is not improbable that the year 1937 may prove to have been the maximum peak of the present cycle. Unlike long-wave transmission, it is found that increased solar activity, with its increase in ionization, enhances the utility of the shorter wave-lengths.

At certain times and seasons, the attenuation of wireless signals is so low over both the major and minor arcs of the great circle embracing the two terminals that signals may arrive both by the forward and the backward route, and even encircle the globe some two or three times. Diagrams are given showing the reception at the P.O. station at Bridgewater of two consecutive dots transmitted from Cape Town together with a sequence of three 'echoes' of the main transmission, as the result of the rays encircling the globe three times.

The Gorge Dam, Hong Kong

THE problem of providing adequate water storage to meet the needs of the population of Hong Kong is a peculiarly difficult one by reason of the relatively large population living in a small mountainous area in which the rainfall is confined to the monsoon period of about six months. Although provided with twelve reservoirs with a gross capacity of 3,000 million gallons, there were only seven years since 1921 during which an unrestricted supply of water could be given. Faced with the necessity of obtaining further supplies, the director of public works, Mr. R. M. Henderson, came to the conclusion that the best solution lay in constructing a reservoir which should impound the waters of the Shing Mun—a river situated in an area on the mainland leased from the Chinese Government in 1898 for a period of ninety-nine years and known as the 'leased territory'.

The scheme, as finally developed, provided for the construction of a reservoir having a capacity equal to the combined capacities of the existing reservoirs,

thus doubling the provision for the Colony. To give effect to this plan it was necessary to build several dams and, of these, the largest—the Gorge Dam—presents both in its design and in its construction several features of especial interest. These were described in a paper read before the Institution of Civil Engineers by W. J. E. Binnie and H. J. F. Gourley on January 24.

The design selected as most suitable for the purpose and place was based on two principal considerations—economy in construction and the elimination of cracks such as would allow of the penetration of water and might arise from earth tremors or from volumetric changes due to the thermal phenomena exhibited in large masses of setting concrete.

The dam has a height of 275 ft. above the stream-bed and its length at the top is 690 ft. Its main structure, the 'thrust block', is not the actual dam but, in conjunction with the 'rock-fill' and the 'sand wedge', acts as a support for the 'diaphragm' or screen which forms the barrier to the water.

This thrust block transmits the water pressure to the rock-fill and presents to the diaphragm a row of buttresses faced with pre-cast concrete blocks. Against these blocks leans the diaphragm, which forms the main water face and is an articulated structure composed of vertical panels 25 ft. in width. Each panel was made in 'lifts' of 20 ft. at one operation and is reinforced with a 'grille' of steel rods $\frac{1}{4}$ in. in diameter.

Every precaution was taken to ensure water tightness, and when the reservoir was filled to top water-level there was no leakage whatever. The spaces between the buttresses, the centres of which are $2\frac{1}{2}$ ft. apart, and the function of which is to

support the diaphragm, constitute inspection pits whereby the diaphragm can be examined. Access is obtained to these pits by branch galleries connected with the main galleries, which are reached by steps from both ends of the dam. These pits would also, in emergency, act as interceptors of any water leaking from the reservoir and so prevent it entering and disturbing the sand wedge. It will be apparent that the design adopted has produced a structure possessing considerable flexibility so that disturbances might take place without giving rise to more than minor and controllable cracking. The details by which this result is obtained are described and illustrated in the paper.

River Physics in India

ONE of the major problems of India is that of the rivers, and it was with the object of inviting the attention of the central and provincial Governments to the urgency of making investigations on scientific lines that a symposium was organized by the National Institute of Sciences of India a little more than a year ago. The several papers presented have now been published (*Proc. Nat. Inst. Sci. India*, 4, No. 4) and show the profound interest that is being taken in the subject by a number of well-qualified workers. The presidential address by Prof. M. N. Saha pointed out the importance of the rivers to the agricultural life and as a means of the industrialization of India, and dealt with their influence on the level of cities on their banks, instancing the destruction of many ancient cities and the increasing difficulty now being experienced in the drainage of Calcutta by reason of this action (see also *NATURE*, 141, 797; 1938).

"The Post-Tertiary Hydrography of Northern India and the Changes in the Courses of the Rivers during the last Geological Epoch" were dealt with in a paper by D. M. Wadia, in which he traced the tectonic movements which have caused widespread and radical alterations in the whole system of drainage lines. The number, volume and direction of the units of this system bear evidence of changes which in some instances have amounted to the complete reversal of the flow of such a principal river as the Ganges. In a paper on the "Changes in the Drainage of India as evidenced by the Distribution of Fresh-water Fishes", Dr. S. L. Hora adduced evidence from various sources to show that there was a reversal of the drainage in the post-trappean period. From the nature of the valleys of the rivers and from certain other features of the physiography of the peninsula, it is concluded that the present-day lower portions of the rivers are of great antiquity, whereas the upper reaches are comparatively recent.

Coming more closely into touch with the nature of the problem of the present day, one of the difficulties facing the engineer is the construction of works in an alluvial boulder river bed, and the problems in respect of river training thereby presented have yet to be solved. Associated with these is the need for constructing irrigation canals transporting alluvium from the river on such lines as should ensure a condition of working stability and tend neither to silt

nor to scour. This aspect is dealt with in a paper, "Flow of Water in Alluvial Channels", by G. Leacey, in which he directs attention to those elementary principles which help to clarify issues and restrict generalization in river physics. He submits the view that despite the complexity of the problem presented by the great Indian rivers, the basic equations are of a simple nature and that it is on the foundation of the 'normal' or 'regime' channel flowing with constant discharge and silt charge that our ultimate knowledge of river physics must be based.

In his address on "The Use of Models for Elucidating Flow Problems based on Experience gained in carrying out Model Experiments at the Hydrodynamic Research Station, Poona", C. C. Inglis described several types of models and explained why some present little difficulty and yield results suitable for immediate application. Other types, especially those relating to alluvial rivers, present great practical difficulties, and in these cases, the data available are usually too meagre. In so many instances the problems presented are too urgent, requiring immediate steps to arrest the damage that is taking place. The magnitude of this class of problem is shown by the statement that during two years the cost of repairs to the Hardinge Bridge over the Ganges amounted to nearly a million pounds. Such questions require an intimate knowledge of the engineering side of the matter combined with a flair for diagnosis and a capacity to visualize a remedy.

It is the silt carried down by the floods which is at the root of much of the trouble. It has created the land, and made it habitable; it has also fertilized it and made it prosperous. But, as is shown in S. C. Majumdar's paper, "River Problems in Bengal", it has also, by damaging the river channels, caused their diversion through lower areas, leaving the other to become derelict. By raising the beds and consequently the flood level, the silt has created another set of problems, and it is the silt which has destroyed many of the tidal rivers in Central Bengal and is threatening also the cross channels so valuable to navigation. The concluding paper by Dr. N. K. Bose, entitled "River Physics Laboratories of Europe and America", deals briefly with what is being done on these lines elsewhere, but ultimately it must prove that the solution of the problems of India must be found by long and concentrated study of local conditions.

Science News a Century Ago

Exploration in North America and Abyssinia

AMONG the papers read at the meeting of the Royal Geographical Society on May 13 was an account of the recent arctic discoveries of Messrs. Dease and Simpson. This was communicated by the Governor and Committee of the Hudson Bay Company, and when thanking the Company the president announced that two gold medals had been awarded to the explorers. A map was displayed showing the discoveries of Franklin, Ross, Dease and Simpson in 1837-38 and from this it was shown that 150 miles had yet to be explored to connect the recent discoveries with those of James Ross in 1832 and Captain George Buck in 1834.

At the same meeting, Antoine Thompson d'Abbadie (1810-97) gave an account of his recent travels in Abyssinia with his brother Michel Arnaud d'Abbadie (1815-93). They started from Jeddah and visited Massawah, Adowah and also Gondar, from which place Michel endeavoured to penetrate to Enérea.

The Royal Society

At a meeting of the Royal Society on May 16, 1839, a paper entitled "On the Visibility of Certain Rays beyond the Ordinary Red Rays of the Solar Spectrum" was read by J. S. Cooper, who had sent it to Faraday. The author stated that he had observed an extension of the red portion of the solar spectrum, obtained in the ordinary way, beyond the space it occupies when seen by the naked eye, by viewing it through a piece of deep blue cobalt glass. He had found that the part of the spectrum thus rendered perceptible to the right was crossed by two or more very broad lines or bands; and he observed that the space occupied by the most powerful calorific rays coincided with the situation of the red rays thus rendered visible by transmission through a blue medium.

Ductile Thread from Rock Salt

In a communication printed in the *Athenaeum* of May 18, 1839, a foreign correspondent said: "M. Gaudin, one of the employés of the Observatory of Paris, has just submitted to the Academy of Sciences a process for converting Rock Salt into ductile thread. You must not shake your head at this, M. Gaudin is no quack. The Academy, at any rate, received his memoir with marked favour. Everybody knows that glass when in a state of fusion, may be drawn out into very slender threads; and M. Gaudin having succeeded in melting down rock salt, discovered that it was susceptible of the same modifications as vitreous substances—that it could be wound round a bobbin, or converted into a solid tissue at will. But of what use, you may say, is this discovery. According to M. Arago there are various ways of turning it to good account. The torsion balance (la balance de torsion) which in the hands of Coulomb has proved so useful is rendered *uncertain* by the variable elasticity of the wires which support the electric or magnetic needle. To remedy this defect, there can be no surer way than to substitute rock salt threads for the metallic wires now employed". There are other applications equally interesting.

Marc Antoine Augustin Gaudin was born April 5, 1804, and for a long time was a calculator for the Bureau des Longitudes. He devoted much time to researches in optics and in photography.

Societies and Academies

Paris*

Academy of Sciences (*C.R.*, 208, 953-1080, March 27, 1939).

R. FAIVRE and A. MICHEL: Chemical composition and crystalline structure of the product of slow oxidation of magnesium in a moist medium. The black compound formed seems to be brucite (a magnesium hydroxide) with additional magnesium atom inserted in the lattice.

O. BARON: Use of light metals in the composition of explosives with an ammonium nitrate base. Addition of powdered aluminium increases the power of the explosive by 10-12 per cent.

P. JACQUET and P. ROQUENT: Application of electrolytic polishing to the micrographic examination of iron and steels.

G. COSTANTU and P. RENAUD: Action of water on sodium, copper and mercury.

H. GUÉRIN: Arenates of calcium; study of the system $As_2O_3 - OCa - OH_2$ at 17°.

J.-M. DUNOYER: Reduction by hydrogen of allotropic varieties of manganese dioxide.

MILÉ, B. TOHOUBAR and O. SACKUB: Alkaline dehalogenation of chloro-1 cyclohexylmethyl-ketone and of chloro-1 cyclohexylphenyl-ketone; transposition in α -substituted cyclohexylformic acids.

D. BOUBOUX: Preparation of true acetylenic hydrocarbons.

L. DENTIVILLE: Butane diol-2, 3 and its esters.

M. TUOT: Carbonation of organo-magnesium compounds and the secondary reactions which accompany it in the aliphatic series.

R. PAUL: Reactivity of the two dianic systems of furyl ethylene.

A. MICHEL-LÉVY and J. WYART: Synthesis of anorthite by pneumatolysis with the help of an explosive (hexogene).

R. ABRARD and E. A. DE LA RÛN: Marine quaternary formations in the neighbourhood of Obock (French Somaliland).

G. DELAPINE: Extension and characteristics of the marine fauna of the oil basins of Djerada (Morocco) and Kenadza (Southern Oran).

H. BRUILL, L. AUFRÈRE and MME. A. BOWLER-KENLY: The *Hipphas meridionalis* alluvial deposits of the Carpentier quarry near Abbeville.

E. PHILIBIN: A water-sampling bottle. A metal tube of capacity about 2½ litres is used; the limit of depth is about 250 metres.

MILÉ, J. SALMON: Formation and structure of the sieve tubes in the hypocotyledonary axis of *Cucurbita pepo*.

A. BRUNEL and R. ROCHVIN: Assimilation of allantoin by the higher plants.

E. POZZI-ESCOOT: A case of xenia in the vine.

G. NICOLAS and MILÉ, B. AGGÉRY: Effects of the simultaneous presence of three parasitic fungi in *Senecio vulgaris* L.

MME. S. LALLERMAND: Action of colchicine on the chick embryo at different stages of development. The strophosomic reaction is only produced in embryos of 40-68 hours.

A. VANDER: Mode of distribution of the sexes of the terrestrial isopod, *Armadillidium vulgare* (Latr.). Proportions of the sexes are extraordinarily variable.

M. LECAMP: Regeneration of buccal pieces in phasmids.

(Continued from p. 774.)

N. FRETKE: Action of the salts of normal saturated fatty acids on phagocytosis *in vitro*.

J. LAVOILLAY and Mme. F. LABOREY: The lacto-avine produced by *Aspergillus niger* V. Tgh. is characteristic of culture media partially deprived of magnesium.

J. CUILLE and P.-L. CHELLI: Experimental transmission of 'trembling' in the goat. Virus from a sheep suffering from this disease produced 'trembling' in goats after a period of 25-26 months.

Cracow

Polish Academy of Sciences (March 6, 1939).

J. WYSSSENHOFF: Variations of the integrals of hypersurfaces under an invariant form.

A. BIELICKI, M. MATHISSON and J. WYSSSENHOFF: A theorem concerning a transformation of quadruple integrals into curvilinear integrals in Riemann space.

F. LOWWINSON-LESSING: Some queries on classification and nomenclature of igneous rocks (2).

N. B. VASSONVICH: New data on the stratigraphy of Upper Jurassic and Neocomian of north-eastern Azerbaidjan.

N. T. KACHIDEN: Chromomere structure of wheat chromosomes.

A. S. AFANASSIEVA: Effect of comallarine upon seeds of summer wheat.

W. J. BUT: A quantitative dredge for investigating benthic population of plant communities in water.

C.R., 21, No. 4; 1938.

W. K. TURKIN: Normal divisors in the groups of odd order.

P. E. DUBUQU: Fundamental theorem of Frobenius.

W. K. TURKIN and P. E. DUBUQU: A criterion for non-simple groups.

N. D. MORGULIS and B. I. DIATLOVITSKAJA: Ionization of sodium atoms on the surface of thoriated tungsten.

G. FRANK-KAMENETSKIJ: Secondary radiation produced by the penetrating component of cosmic rays.

I. I. KORNILOV: Conversion velocity of super-saturated solid solutions of magnesium-aluminium.

O. E. ZVIAGINCHV and I. A. PAULSEN: Action of minerals on gold solutions.

B. N. SCHWANWITZ: Stereo-effect of cryptic colour patterns in Lepidoptera.

N. A. MAXIMOV: Increase of permeability of protoplasm in wilting plants.

N. A. MAXIMOV, M. M. GOCHOLASHVILI and V. I. TEKHOIDEH: Root-formation induced by heteroauxin in cuttings of subtropical plants difficult with regard to rooting.

A. P. SCHERBAKOV: Physiological role of elements indispensable for plants in minute amounts.

SHIGIUS LVOFF and E. L. LIMBERG: Effect of inorganic phosphates on the formation of citric, gluconic and oxalic acids in *Aspergillus niger*.

V. S. MURATOVA: Ecological and geographical classification and evolution of beans (*Viola Faba* L.).

A. A. WORTKOWITSCH: The influence of thyroidectomy on the development of ducklings.

S. YUDITSKAJA: Growth and differentiation of embryonic muscles in the extremities of a chicken.

L. F. BEREZKINA: Interrelation between the fibres existing in the tissue during explantation and those formed anew *in vitro*.

K. MARTINSON: Fossil sponge fauna of Tertiary deposits around Lake Baikal.

S. N. SEMIOHATOVA: Some results of investigation of the internal structure of Carboniferous brachiopods.

Tokyo

Imperial Academy (Proc., 15, No. 2, February 1939).

YASIO MUTO: Generalized circles in the conformally connected manifold.

KINJIRO KUNUGUI: On a theorem of Seidel and Reurling.

TATSUO KAWATA: Boundedness of the spectrum of a distribution function.

MISHIO ISHIMOTO: Characteristic of a seismic fault and its course.

JURO HORIBE and MASATUGU IKUSIMA: Mechanism of the hydrogen electrode process on platinum (2).

SIN'ITI KAWAI, TAKAO NAKAMURA and NOBORU SUGIYAMA: Researches upon ergonol (continued). A new general synthetic method for 2-phenyl-cumarone and its derivatives and the synthesis of ergonol.

SHIGEHICO SUGAWA and NOBIO SUGIMOTO: Oxidation of some β -phenylethylpyridinium- and -quinolinium salts.

SHIGEHICO SUGAWA and KITEIRO KAKEMI: Studies on the synthesis of dibenzopyridocoline derivatives. (2) Synthesis of 4', 5'-dimethoxy-4', 5'-methylenediomy-3, 4, 5, 6-tetrahydro-(1', 2': 1, 2; 1'': 2'', 8-dibenzopyridocholine) and the corresponding tetramethoxy derivative.

JUN SUZUKI: Age of the Sambagawa system.

NOBUHIKO OHARA: Studies on the nature of the sea-water and the bottom materials of Heda Bay, Izu Peninsula, Shizuoka Prefecture.

Forthcoming Events

[Meetings marked with an asterisk are open to the public.]

Monday, May 15

ROYAL GEOGRAPHICAL SOCIETY, at 5.—Dr. E. B. Worthington: "Echo-Sounding of British Lakes".

Tuesday, May 16

ST. MARY'S HOSPITAL, LONDON, W.2, at 5.—Dr. A. S. Parkes, F.R.S.: "The Hormones of the Anterior Pituitary Body".

EUGENIUM SOCIETY (at Royal Society, Burlington House, W.1), at 5.15.—Prof. A. M. Carr-Saunders: "Some Problems of Population".*

CHADWICK PUBLIC LECTURE (at the Royal Institute of British Architects, 68, Portland Place, W.1), at 5.30.—G. H. Henderson: "Comparative Study of the Housing of the Working Classes, with Special Reference to Scotland".*

Wednesday, May 17

ROYAL MICROSCOPICAL SOCIETY (at B.M.A. House), at 5.30.—F. C. Bawden: "Some Properties of Plant Viruses".

Thursday, May 18

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society), at 5.—Prof. J. E. Lennard-Jones, F.R.S.: "Order and Disorder in Nature".

CHEMICAL SOCIETY (at the Institution of Mechanical Engineers), at 6.—Prof. C. N. Hinshelwood, F.R.S.: "Some Considerations on the Nature of Catalysis" (Laveridge Lecture).*

Friday, May 19

GEOGRAPHICAL DISCUSSION (at the Royal Astronomical Society), at 4.30.—"The Night Sky and Aurora" to be opened by Prof. S. Chapman, F.R.S.

ROYAL INSTITUTION, at 9.—Prof. J. D. Cockcroft, F.R.S.: "New Phenomena in Liquid Helium".

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

ASSISTANT (grade I) for the Research and Technical Publications Section of the Air Ministry.—The Under-Secretary of State, Air Ministry, Berkeley Square, London, W.1 (Ref. B 196. May 19).

CHIEF DESIGNER, ASSISTANT CHIEF DESIGNER AND ASSISTANT (grade II—chemical problems) at the Royal Aircraft Establishment, South Farnborough.—The Chief Superintendent (May 19).

SENIOR LECTURER IN PHYSICS in the Bradford Technical College.—The Principal (May 20).

ASSISTANT LECTURER AND DEMONSTRATOR IN GEOLOGY in University College, Cork.—The Registrar (May 27).

CHEMIST in the Admiralty Chemical Pool.—The Secretary of the Admiralty (O.B. Branch) (Ref. O.B. 5022/29. May 27).

ASSISTANT LECTURER IN ORGANIC CHEMISTRY in King's College, London.—The Secretary (May 30).

LECTURER IN PHYSIOLOGY in King's College, London.—The Secretary (May 30).

DEMONSTRATOR IN CHEMISTRY in King's College, London.—The Secretary (June 1).

ASSISTANT LECTURER (OR LECTURER) IN PHYSICS in University College, Southampton.—The Registrar (June 1).

ADVISER IN AGRICULTURAL CHEMISTRY AND HEAD OF THE DEPARTMENT OF AGRICULTURAL CHEMISTRY in University College, Aberystwyth.—The Principal (June 5).

PROFESSOR OF CHEMISTRY in Natal University College, Pietermaritzburg.—The Universities Bureau of the British Empire, 88A, Gower Street, London, W.C.1 (June 12).

SCIENTIFIC SUPERINTENDENT OF RESEARCH IN FOOT-AND-MOUTH DISEASE at the Experimental Research Station, Pirbright, Woking, Surrey.—The Secretary, Foot-and-Mouth Disease Research Committee, Ministry of Agriculture and Fisheries, 10 Whitehall Place, London, S.W.1 (June 23).

ASSISTANT STATISTICIAN at Rothamsted Experimental Station, Harpenden.—The Secretary.

Ideals in Africa*

ON March 9, 1938, H.M. the King appointed a Commission "to inquire and report whether any, and if so what, form of closer co-operation or association between Southern Rhodesia, Northern Rhodesia and Nyasaland is desirable and feasible". The Commissioners were five in number, of whom Viscount Bledisloe acted as chairman. After preliminary inquiry and the hearing of evidence in England, the Commission proceeded to Africa, arriving at Bulawayo on May 16. When evidence had been taken in Southern Rhodesia, the Commission visited Portuguese East Africa, passed on to Nyasaland and returned through Northern Rhodesia to Salisbury.

Taken together, the three territories which came under the purview of the Commission include an area of approximately 500,000 miles, with a total population estimated at roughly 3,300,000. Of these, approximately 68,000 are European, 8,000 are Asiatics and 'coloured' in the sense in which that term is used in southern Africa, namely, the offspring of union between non-native and native, and 4,230,000 are natives. The proportion of Europeans to natives in the combined territories is 1 to 62; but the ratio is more significant when the territories are distinguished: in Southern Rhodesia it is 1 to 22, in Northern Rhodesia 1 to 129 and in Nyasaland to 881. While both European and native populations have increased between 1926 and 1936, the rise among Europeans has been relatively more rapid owing to the development of the copper mines. It shows a decrease in the later return owing to the interruption of development work in the mines; but with the renewal of activity it is again increasing slowly.

* Rhodesia-Nyasaland Royal Commission. Report. (Cmd. 5949.) p. x+288. (London: H.M. Stationery Office, 1939.) 7s. 6d. net.

It is especially important to bear these figures and their inter-relations in mind, in view of the conditions which were imposed on the inquiry of the Commission and its findings. In the Royal Warrant, it was specifically laid down that in reporting on the desirability and feasibility of co-operation or association between the territories, due regard was to be had to "the interests of all the inhabitants, irrespective of race . . . and to the special responsibility of Our government in the United Kingdom of Great Britain and Northern Ireland for the interests of the native inhabitants". As will appear, the members of the Commission, collectively and individually, have given full weight to this instruction. The manner in which they have discharged their obligation raises issues in native policy of the gravest importance, not only as affecting the territories immediately concerned, but also as touching the interests of all natives throughout British colonial possessions in Africa. Indeed it may not be without repercussion elsewhere, in territories other than British, should certain suggestions which arise out of the report be given practical effect.

Broadly speaking, the recommendations of the Commission do not favour the proposal of an amalgamation of the three territories, at any rate in the near future. While there is a suggestion that they may look forward ultimately to becoming one great united territory, which might well aspire to dominion status, the time for such a development is far from being yet. Certain suggestions are put forward as practicable, with the view of securing greater uniformity in administration, especially in finance and education, as well as affecting labour, while certain measures in what may be termed the machinery of government are

adumbrated as likely to secure an even greater measure of association in organization and policy. On the whole, however, unless and until conditions change, the Commission is adverse from the close union, if not amalgamation, which for some time has been the subject of consideration and much discussion.

The report, in regard to its recommendations, is a document of singular interest. The main recommendation is, of course, unanimous; but in certain respects the report is exceptional. We are accustomed to reports of commissions in which the main recommendations are accompanied by a minority report; but a report in which each member of the commission, including the chairman with one other, makes what is virtually a minority report, is surely unusual. In fairness to the members, however, it must be stated that some of them add their individual statements with reluctance, and as a measure of self-protection lest silence should be misconstrued as complete acceptance.

The explanation of this remarkable position is that the circumstances with which the members of the Commission had to deal are of singular difficulty, even among matters of native policy in Africa. The crux of the situation is that of outlook in native policy. The difference between Southern Rhodesia and the two remaining territories of Northern Rhodesia and Nyasaland, which in this matter for practical purposes are at one, is so great, so fundamental, as to form an obstacle to amalgamation which in present circumstances is felt to be insuperable. In this the members of the Commission are agreed. Their differences lie in the degree to which they regard a measure of co-operation as immediately possible, and ultimate closer union as both practicable and desirable. At the same time, however, it is pointed out that native policy and the methods of native administration in all three territories are to a great extent still experimental; and it is by no means impossible that, as experience grows, modifications may be effected which will bring an outlook, at present diverse, into greater harmony.

In order to understand a situation which is regarded as of such gravity as to block a proposal which has much to recommend it in the many advantages, administrative, economic and financial, which would immediately accrue, especially to the less prosperous of the territories, it is perhaps necessary to recall that it is only within the last few years that certain important changes have

been made in the principles and methods of native government in all three territories. While, however, in Northern Rhodesia and Nyasaland the principle of indirect rule has been applied with all that involves in regard to the respect paid to native law and custom in matters affecting the natives—that is while, in the words of the White Paper which stands as a charter of the principles of British Colonial government, the interests of the natives are paramount—in Southern Rhodesia where the lead of policy in the Union of South Africa has been followed, the principle of segregation has been applied, and in the enthusiasm for reform, it must be admitted with some rigour. Not only is segregation physical—not only are native lands inaccessible to Europeans, but also native ownership or occupation of European land is forbidden—and the opportunities open to Europeans in the higher branches of education in certain occupations, and so forth are debarred to all natives. In short, a 'colour bar' no less strong and no less rigid than that which exists under the Union has been instituted in Southern Rhodesia. The problem raised by this difference in outlook to some extent is aggravated in Northern Rhodesia by the difficulties which arise from the poverty of the people and overcrowding, in itself a consequence of the poverty, alleged to be irremediable, of large parts of their lands, as well as the special problem, which has already arisen through the development of industry, of the urbanized native—a problem which will require but has still to receive, adequate special treatment.

A factor in the situation which should not be overlooked or underrated is the attitude of the natives themselves in both Rhodesia and Nyasaland. Their opposition is "unmistakable, pronounced and strikingly unanimous".

The position of Southern Rhodesia in following the lead of the Union, is, of course, one that is readily comprehensible, and to a great extent arises out of its history. Like the Union, its policy is based upon the ideal of a white civilization in a country that has been regarded as eminently suitable for remunerative and permanent white settlement with a white civilization as predominant while its main preoccupation in domestic economy has been the provision of an adequate and readily available supply of labour. With such an outlook Southern Rhodesia, being, as she would, the predominant partner in any amalgamation, manifest features in the present situation, which are not in the best interests of the natives of the other

two territories, might be rendered permanent, if not intensified. For example, much attention has been devoted to the question of the supply of labour, and the danger is stressed whereby it is feared that the native populations of these territories might become permanently no more than feeders of the labour supply.

The inquiries of the Commission have covered a wide field and the members have made full use of the labours of the numerous commissions and inquiries which have preceded them. They have taken a wide view of the departments of native life which they feel would be affected by the proposed changes in administration. They have, therefore, not hesitated to direct attention to matters affecting the development of the native in which they feel a progressive policy should now be applied, and in which rapid progress might be made by the measure of co-operation between the Rhodesias and Nyasaland which they recommend. Education, instruction in agriculture and technical training, instruction in the care of the soil and in hygiene and the principles of

nutrition, the fostering of the development of the peasant farmer class, are some only of the fields to which they point as urgently requiring development.

Fundamentally, however, the importance of this report lies in the stress laid, unostentatiously but nevertheless with unmistakable strength, on the difference in outlook of what may be termed the two schools of native policy, segregation and indirect rule, taking the latter in a broad sense. This antinomy prompts inquiry whether the white peoples in exercising their rule over Africa, and accepting their responsibilities for the welfare of the African as they profess to do, have any clear idea of the end to which they are directing him in assuming that responsibility for his development. Is indirect rule, which rests upon native custom, unless we do it no more than lip service, likely to lead either to stagnation, or a masked tribal disintegration, or is segregation, which sets the bounds of native development and that not beyond his presumed powers, the choice of the better part?

Prehistoric Crete

The Archaeology of Crete

An Introduction. By J. D. S. Pendlebury. (Methuen's Handbooks of Archaeology.) Pp. xxxii + 400 + 43 plates. (London: Methuen and Co., Ltd., 1939.) 30s. net.

IT was in 1894 that Sir Arthur Evans made his first journey in Crete, and in 1899 that his excavation of Knossos commenced. His own account of "The Palace of Minos" began to appear in 1921 and was completed in 1936. From time to time others have tried to summarize both the progress of discovery in Crete and the general bearings of it on the prehistoric archaeology of the Mediterranean. But Mr. Pendlebury's book is the first thorough and satisfactory account of the work of many travellers and excavators; his numerous maps show how vast an accumulation there has been of observations and finds, and the lists of sites appended to them how much he has himself contributed by persistent exploration, covering now every district of the island. As curator formerly of Knossos, where the Palace and its surroundings have been made over by Sir Arthur Evans to the British School of Archaeology at Athens, he has not only written an invaluable

"Handbook to the Palace", but has also himself examined and catalogued the stores of classified objects from every room and corridor, and from every stratum from the neolithic tell on which the Minoan settlements stand, to the sparse relics of classical antiquity, when the site had become a 'no-man's-land' in the outskirts of the Greek and Roman city. After directing excavations at Tell-el-Amarna, the Egyptian site most closely connected with Aegean peoples in the fourteenth century B.C., just after the fall of the 'Palace' regime, he has devoted himself to a series of small but most significant excavations in the Lasithi district of Crete itself, on sites ranging from the earliest human occupation to the turbulent age which intervenes between the latest Minoan and the earliest Hellenic periods. Here are, therefore, all the qualifications for an "Introduction", as the author modestly describes it, to the archaeology of Crete.

The greater part of the book is inevitably concerned with archaeological detail, most carefully selected, and clearly described; but it begins with a convenient retrospect of Cretan discoveries, and a presentation of the physical characteristics of Crete, and of the topography and routes,

ancient and modern, which show Mr. Pendlebury to be a worthy successor of Paahley, Spratt, and Raulin. Future travellers will value his personal estimates of distances, and of the practical utility of the more difficult tracks, especially in the western districts, which have been curiously neglected by travellers; though it has been left to Mr. Pendlebury to make it probable, by his closer examination, that there is not very much to find there; the reason, he thinks, being that, west of Mount Ida, the island was not only less well provided with cultivable lowlands, but also very densely forested.

Of the early inhabitants, it is here repeatedly insisted (pp. 61, 267) that they remained physically uniform throughout the Minoan age. This is, however, not in accord with the measurements of Duckworth, Hawes, and von Luschan, summarized by Sir Arthur Evans in the passage quoted by Mr. Pendlebury to support his contrary view; nor with his own derivation of early elements both of culture and of population from Anatolia (p. 53).

On more controversial points, Mr. Pendlebury presents fairly the evidence and arguments, and gives his own views cautiously; but where it is a matter of personal observation and long experience, he knows his own mind. On the disputed date of the 'Médallion Pithoi', he thinks they may have remained in vogue for long; and he emphasizes also on several occasions that objects that were durable as well as valuable, such as stone vessels, may well have endured for ages. On the relations between Crete and the Mainland, as to the building of cupola-tombs, he gives the Mainland priority; and his book was finished just too soon to note the newly discovered cupola-tomb of

earlier date at Knossos, which negatives that hypothesis.

Most accounts of Cretan archaeology stop short with the fall of Knossos about 1400 B.C., or treat what follows as an epilogue. Here, however, we have full and intimate description of the difficult and not very attractive sequel, when the natural resources of Crete attracted adventurers and eventually settlers from elsewhere, and therewith new elements of culture—iron, brooches, cremation—and a new æsthetic outlook, diverse expressions of which are the Idæan bronze-reliefs, and the fine geometrically painted pottery of Hellenic Knossos. Examples of both would have been welcome additions to the plates.

The general survey of Cretan prehistory, which follows the detailed account of successive periods, inevitably repeats many points; but it is very acceptable as a reasoned estimate of what was going on, in the arts and industries, and also in economic and social life. Mr. Pendlebury knows the Cretan countryside so well, that his reconstructions are often vivid and convincing: among revolutions in the superstructure, the fundamentals of Cretan life remaining essentially unaltered.

The fifty plates, from the author's own photographs, are extraordinarily good, and full of interest; and a word must be said in praise also of Mr. Pinion's distribution maps and the specimens of decorative design drawn by Miss Money Coutts. In a second edition—which there will surely be—would it be possible to include an orographic sketch map, with which to compare the distributions of sites and routes?

JOHN L. MYERS.

Cultivated Poplars

The Black Poplars and their Hybrids Cultivated in Britain

By G. S. Canadale and Members of the Staff of the Imperial Forestry Institute. Pp. 52+1 plate. (Oxford: Imperial Forestry Institute, 1938.) 3s. 6d.

IN common with many other groups of cultivated plants, the poplars include a number of hybrid forms, intergrading to such an extent in their morphological characters as to create considerable difficulties in the recognition of the different sorts. These difficulties are enhanced by the variation of the foliage borne on the several kinds of shoot normally found on a tree. Neverthe-

less, the necessity for careful selection of material intended for identification has often been overlooked. The author of the work under review wisely limits his attention to the vigorous long shoots and to the short shoots that carry the bulk of the foliage. The leaf and stem characters are studied, and those of critical value selected for use in the preparation of a key to the species and hybrids cultivated in Britain. With a genus such as *Populus*, flowering before the leaves appear, it is advantageous for a key to be based on vegetative characters only, providing ease and accuracy of identification are not impaired. In a few cases, the relative times of foliation and sex are introduced to distinguish closely related hybrids; but on the

whole the key is particularly clear and easy to use, and will be appreciated by all who have to deal with this critical group.

The short critical descriptions of the species and hybrids are excellent, and together with notes on various points of interest, they occupy about a third of the book. The same praise cannot be extended to the treatment of the nomenclature. Although much of the existing confusion has been cleared up, it is most unfortunate that the author has misinterpreted the International Rules of Botanical Nomenclature with respect to hybrids;

each segregate from the hybrid *Populus nigra* L. $\times$ *P. deltoides* Marshall is given a different binomial name. To comply with the rules, segregates of one hybrid should be given the status of varieties or forms under the oldest valid binomial applicable to the group. It is obvious that failure to observe this rule must result in the publication of numbers of invalid and unwanted combinations.

The book also contains a historical review of the literature on the black poplars, and a bibliography of the more important works on the genus.

R. MALVILLE.

Progress in Physics

Reports on Progress in Physics

Vol. 5. General Editor: Allan Ferguson. Pp. v+445. (London: Physical Society, 1939.) 20s. net.

THIS, the latest annual volume of progress reports sponsored by the Physical Society, is larger than any of its predecessors, and the editors' notes have been spread even more widely than heretofore. There are nineteen separate chapters, and of these general physics is divided into four sections (R. C. Brown on surface tension and Brownian motion, Cox on elasticity, and Good-ve on the viscosity of non-Newtonian fluids), and optics and spectroscopy have five sections each, specially edited by L. C. Martin and W. Jevons respectively. Atomic physics is represented by two sections, single scattering of elementary particles (Champion) and cosmic rays (Heitler). Skinner contributes a long article on the soft X-ray spectroscopy of the solid state, which might also be classified as atomic physics.

The longest individual report in this volume is that of Hartshorn on absolute electrical measurements. This, and the articles on sound (E. G. Richardson), heat (Powell) and quantum mechanics (Flint), are in the well-established tradition of these reports. Astbury's article on electric wave filters and Nunn May's on the mechanism of the Geiger counter are also in the tradition, though they reflect a little more strongly the tendency towards a somewhat increased degree of specialization. In view of the very wide scope of some of the earlier reports, this tendency is entirely natural and in no way undesirable.

Breaking entirely new ground, and reflecting the interests of many members of the Physical Society, are long reports on meteorology (Brunt) and astronomy (Crommelin), while Malville's

article on plastic is the first in this series to deal specifically with industrial physics. Further, this volume appreciably widens the appeal of the series to the physical chemist. McBain and Mills contribute an article on the Gibbs adsorption theorem, and, as has already been noted, one of the sections of general physics is from the hand of a physical chemist. Again, Mott and Gurney's report on recent theories of the liquid state is of almost equal interest to pure physicists and physical chemists.

Again on new ground, Dr. Phyllis Tookey Kerridge contributes an interesting chapter on instrumental aids for defective hearing, in which stress is laid on the medical aspects of the problem, while Dr. Mayneord's article on the use of X-rays and γ -rays in medicine is largely concerned with the difficult and purely physical problem of the accurate and unambiguous specification and measurement of dosage.

Finally, Barton's report on the teaching of physics in schools will interest a very numerous class of readers. It has been evident for some time, in the pages of the *School Science Review* and elsewhere, that there is in Great Britain an able, as well as an enthusiastic, body of science teachers. In particular, the Science Masters' Association and the Association of Women Science Teachers are doing much to raise the standard of instruction in physics in the secondary and public schools. The subject is obviously of importance to university as well as to school teachers; and as the Physical Society includes many teachers of both these types, it was a particularly happy idea to requisition a report of this kind from a practising schoolmaster with strong views.

The short list of contents given above may serve two purposes. In the first place, it may give new readers some idea of the type of fare provided;

it may be taken as axiomatic that most readers who have already used the reports will automatically subscribe to the new volume. Secondly, the *embarras de richesses* so revealed may indicate clearly enough the impracticability of setting down, in any reasonably modest space, an adequate analysis of individual contributions to the volume. In brief, we have, as an assurance of the authoritative nature of the reports, the fact that every writer is an active worker in the field that he describes. Thus, in the chapter on optics, Prof. Martin himself deals with optical instruments; Hampton and Wheat, of Messrs. Chance, with optical glass manufacture; Selwyn, of the Kodak Research Laboratories, with the theory of photography; and W. D. Wright with television optics. The spectroscopy team is drawn from an even wider area—Shenstone (Princeton), Crawford (Toronto), Foster (McGill), Hunter (Greenwich) and Pearce (Imperial College), dealing respectively with atomic spectra, hyperfine structure, Stark effect and related phenomena, astronomical spectroscopy, and the spectra of the alkali-metal hydrides.

The fact that the articles are written by specialists is not, of course, one which calls for comment; it would in these days be much more surprising if the

matter were ordered otherwise. What is rather to be noticed here is the extraordinarily high standard of readability of the articles. It has already been pointed out that the chapters differ appreciably in degree of specialization; but everywhere the specialist writers have succeeded admirably in writing for, and not ostentatiously down to, the general reader so that he, as well as the more directly interested researcher, may profit from these most valuable summaries. The general impression left by the reports is that, on the whole, the authors have rather enjoyed writing them. One guesses that each writer has been given very free hand to deal with the subject in his own way; something of this has indeed been implied in the prefaces to volumes 4 and 5, and the reports have benefited largely from the application of this sound editorial precept, at the cost, possibly, of a relatively trivial loss of homogeneity.

Prof. A. Ferguson, who has, with apparently undiminishing zest, seen the first five volumes through the press, now passes the editorial work to another hand. He has given the series a magnificent start, and there is every reason to expect that it will continue to prosper under the direction of his successor, Mr. J. H. Awbery.

The Ganges Delta

The Changing Face of Bengal

A Study in Riverine Economy. By Prof. Radhakamal Mukerjee. (Calcutta University Readership Lectures). Pp. viii + 293 + 23 plates. (Calcutta: The University, 1938.)

THE problems of the Ganges delta are immeasurably more complicated than those of the Nile and Mississippi in that there are two mighty rivers, fed by heavy rains and melting snow, which carry maximal quantities of silt from the greatest of mountains into the head of a deep bay, not on to an open coast. Rivers in gorges, cut through the foothills, have by their silt formed broad alluvial plains. South, the Ganges and Brahmaputra now meet and, to a considerable degree, are at war with each other for right of way, their battles influenced by strong tidal flows. Modern changes in their deltas, which have become conjoined, are illustrated by a dozen maps dating from the sixteenth century, but the lack of a map showing existing conditions and settlements often embarrasses the reader. Even in this late historical period the population has more than doubled, 125 millions

to-day, with a concentration which, in parts, equals that of the lower Yangtze. This has always been the richest agricultural area in India, and, as the author shows, the aim of invaders and the centre of a succession of empires. He indicates fluctuations in the sites of these, and ascribes them to the variation of the courses along which the rivers deposited their silt, particularly the gradual eastward movement of the delta. He foretells, in the not distant future, the necessary decay and abandonment of Calcutta, its water courses silted up, and its drainage impossible. It can only be saved by the further development of roads and railways; the embankments that such necessitate, have often been most damaging in hindering natural water movements, and hence producing miasmatic swamps.

An immense amount of work and a high standard of learning have been conjoined in these lectures; the facts are culled from many sources. Footnotes are useful, but great help will be given to the scientific reader by the considered bibliography. He may well desire to think more deeply of all the varied actions implied in delta formation, the

ilding of higher banks enclosing lower lands, the
 ■ting up of main water channels and in conse-
 -ence their divergences, and finally the effects of
 -ese on agriculture and population. Rich and
 -tile rice marshes—often jute to-day—may dry
 -, and perhaps the silt underlying basins may
 -ink downwards, turning them into impossible
 -amps or jungle in which the tiger finds its home.
 -story affords instances of the loss of many even
 -eat cities in such; their estuaries are to-day
 -rely swamp flats. While there is always growth
 -d reclamation seaward, the decay behind
 -lances, and no settlement has proved permanent.
 -arge areas have become malarious and have
 -ulted in great migrations of a population made
 - of many ethnographic features, and, of course,
 -th rival religions, for there was here a Moham-
 -edan conquest. In the Yangtze region, which
 -et compares, there is no such change, and
 -ability is ensured by infanticide, which the
 -ychology of the Ganges peoples does not
 -ourage.

The footnotes provided by the author suggest that the Government is fully alive to all the difficulties which confront it, and which must remain with every Government. Prof. Mukerjee refers to agricultural deterioration and rural decay in large tracts of land, but he does not attempt to balance loss and gain—and we require more information on the economic results of irrigation along the upper courses of the rivers. He gives the impression of never having personally investigated the conditions of the delta, and he is not constructive in his suggestions. We are not convinced that his proposed "Ganges River Commission" will or can do more than is being already done, presumably by a corps of specialist officers. The conclusion forced on us by a study of this work is that any "co-ordinated policy of forest, soil and water management" depends on the complete harnessing and control of the Ganges and Brahmaputra, and that this, if attempted, is as likely to destroy as much as it conserves.

The Phase Rule

) The Phase Rule and Phase Reactions :
 heoretical and Practical
 y Dr. Sydney T. Bowden. Pp. xviii+303.
 ondon: Macmillan and Co., Ltd., 1938.) 10s. net.

u) The Phase Rule and its Applications
 y Prof. Alexander Findlay. Revised with the
 -istance of Prof. A. N. Campbell. (Textbooks
 n Physical Chemistry). Eighth edition. Pp.
 v+327. (London, New York and Toronto :
 ongmans, Green and Co., Ltd., 1938.) 12s. 6d.
 et.

1) **D**R. BOWDEN'S book is an elementary introduction to the subject and is suitable for general B.Sc. students, many parts being adapted to teaching of intermediate standard. It contains numerous good laboratory experiments and there are collections of questions and examples, many taken from examination papers.

Special mention should be made of the illustrations, which are very clear and in many cases have been simplified so as to make them more intelligible to students beginning the subject. A notably good feature is the grouping of diagrams in the summaries; many students feel difficulty in co-ordinating the various parts of the subject, and this plan will be a very useful help. Another good feature is the inclusion of descriptions of structure as determined by X-ray and other

methods, for example in the cases of the allotropy of sulphur, tin and iron. The contents include a good introduction to three-component systems, where the diagrams are very well chosen.

Although the book is intended to be elementary, the clearness of treatment will make it useful to more advanced students. The close relation to practical work tends to remove the rather abstract impression which most students get from a study of the phase rule. The book may be warmly recommended, and it is certain to be very popular both with teachers and students.

(2) Prof. Findlay's book is too well known to need description. It has established itself as the standard work on the subject and still remains the best introduction to the phase rule and its applications. The first part gives a very clear account of the fundamental principles, which is intelligible to students beginning the subject, and the general standard of the book is suitable for honours students.

The first edition of the book was published in 1904 and subsequent editions have left its main structure unchanged. It might be suggested that some sections could now be rewritten, and as examples those on the hydrogen-palladium system, liquid crystals and the iron-carbon system may be quoted. The book is assured of a continued and well-deserved popularity.

J. R. P.

(1) *Alpine Flowers*

36 Colour Plates from Watercolours specially prepared by Paul A. Robert. With Introductory Text by Prof. Dr. Carl Schroeter. (Art and Nature in Colour Series.) Pp. 12+36 plates. (London: B. T. Bataford, Ltd., 1938.) 10s. net.

(2) *A Gallery of Gum Trees*

By A. W. D'Ombraim. Pp. 54+21 plates. (London: H. K. Lewis and Co., Ltd., 1938.) 14s. 6d. net.

HERE are two beautiful examples of book production.

(1) The multi-coloured alpine flora of Switzerland lends itself easily to the painter in water-colours, and the many books printed and published in Switzerland containing reproductions of paintings of Swiss flowering plants are well known. Here we have thirty-six exquisite colour studies by Paul Robert reproduced by the world-famous 10-colour Iris Press of the Polygraphische Gesellschaft Laupen, Berne. These have been collected together and an introductory text has been written by none other than one of the greatest authorities on the Swiss alpine flora, Prof. Karl Schröter, who has recently died (*NATURE*, 143, 365; 1939). Messrs. Bataford, the publishers of the English edition, are deserving of special commendation for offering this splendid collection at such a very modest price. The book is to be strongly recommended to botanists interested in alpine plants, artists, those interested in colour reproduction, and anyone keen on acquiring good books for his library.

(2) This descriptive collection of Australian gum trees is equally worthy of praise for its twenty-one beautiful coloured plates and good all-round production. It was set up and printed by the Australasian Medical Publishing Co., Ltd., which is to be congratulated on another real work of art. All the plates are reproductions of original paintings in water-colour executed by Miss Tydfyl Evans. Those living in Australia should have no difficulty in identifying any eucalypt if they have this book handy, and other botanists will get a very satisfactory idea of these peculiar trees from the text and illustrations. Any lover of a well-produced book, too, would consider himself fortunate in possessing a copy of this one.

A Monograph of the British Neuroptera

By Frederick James Killington. Vol. 2. (Ray Society Volume 123 for the Year 1936.) Pp. xii+306+plates 16-30. (London: Bernard Quaritch, Ltd., 1937.) 25s.

THIS volume completes the author's account of the British Neuroptera. It is in every way up to the standard of volume 1, which was published in 1936 and has already been noticed in these columns. In volume 2 the subject-matter is concerned with the remainder of the family Hemerobiidae together with the Chrysopidae. Of the Hemerobiidae it is noticed that the genus *Hemerobius*, as now understood, comprises eleven British species. Of the other genera of the family, *Boriomyia* with five British species, has undergone change of name. In the appendix to this volume the new genus *Kimmeria*

is erected by the author to take its place. Of rarer forms, *Megalomus* and *Drepanopteryx*, each with a single British species, are still comparatively little known. Some account of the metamorphosis of the first named is given, but as regards *Drepanopteryx* progress has been made in our knowledge of biology since a brief note by Standfuss published in 1910. Of the Chrysopidae, fourteen British species are dealt with and these belong to the genera *Chrysopa* and *Nathanica*.

The volume is illustrated by fifteen plates (colour and plain) and forty-seven text-figures. These are well executed and reflect credit upon all concerned their production. We congratulate Mr. Killington on the completion of a really excellent treatise.

A. D. I

Plant Physiology

With Reference to the Green Plant. By Prof. Edw. C. Miller. (McGraw-Hill Publications in the Botanical Sciences.) Second edition. Pp. xxxi+1201. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 45s.

THE first edition of this very comprehensive textbook was favourably reviewed in *NATURE* December 5, 1931, p. 952. In the second edition about three hundred pages have been added and the price increased by ten shillings. This makes the price of the book rather excessive for the type of student for whom it is intended. All students reading for university degree would find the book very useful and research workers and other advanced students are offered an extensive bibliography at the end of each chapter. Subdivision of the text into large and small type will aid the student reading for a general degree. The questions inserted at the end of each chapter of the first edition have been omitted in this edition.

The whole text has been thoroughly revised and brought up to date, and much new material has been included.

Inorganic Colloid Chemistry

By Prof. Harry Boyer Weiser. Vol. 3: The Colloid Salts. Pp. viii+473. (New York: John Wiley & Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 30s. net.

THIS volume completes Prof. Weiser's treatise on inorganic colloid chemistry, and it is in every way a very satisfactory account of the subject with which it deals. The five parts treat of the colloids: sulphates, halides, sulphides, ferro- and ferricyanides, and silicates. The treatment is essentially experimental, although the theories concerned receive adequate treatment. Full literature references are supplied. Among other general topics which come under review are the stability of sols and the mechanism of electrolyte coagulation, adsorption on ion lattices, adsorption indicators, the permeability of membranes, and the phenomena of thixotropy and rheopexy. Technical aspects receive careful attention.

The amount of information contained in the book is very large, yet the author has been able to produce a very readable text.

The Drift of the *Sedov**

By Prof. N. N. Zubov

THE scientific importance of the drift of the *Sedov* is comparable to that of the *Fram* or the Papanin North-Polar Expedition on the drifting icefloes of 1937-38. Certain circumstances make the drift of the icebreaker specially interesting; from a theoretical and practical point of view. First, the *Sedov*, together with the icebreakers *Iko* and *Malygin*, began to drift in the Laptev Sea at lat. $75^{\circ} 91'$ N. and long. $132^{\circ} 25'$ E. on October 23, 1937, that is, while the Papanin expedition was still working.

Thus we have had the movement of the ice in the Arctic sea under continuous observation since May 21, 1937, the date when the Papanin expedition began its drift.

Secondly, a convoy of icebreakers, escorted by the icebreaker *Lenin*, was carried away by the ice from Khatanga Bay at the beginning of November, 1937, that is, soon after the commencement

of the drift of the *Sadko*, *Malygin* and *Sedov*. These vessels drifted in the south-western part of the Laptev Sea until August 7, 1938, when they were freed by the icebreaker *Krassin*, which outlasted the passage through the ice.

Two groups of vessels were thus drifting with the ice simultaneously at some distance from each other for the space of nine months, one group in the south-western part of the Laptev Sea and the other in the north-eastern part of the same sea, north of the New Siberian Islands.

As is seen from the accompanying map, the drifts of the *Sedov* and the *Lenin* groups, although differing in detail, are remarkably similar. The *Sedov* is being carried approximately through the same region as Fridtjof Nansen's expedition of 1893-96 on the *Fram*.

A comparison of the drifts of the *Sedov* and the *Lenin* on one hand, and of those of the *Sedov* and

the Papanin Expedition on the other, and finally a comparison of the drifts of the *Sedov* and the *Fram*, are of great scientific and practical value. The comparison of the drifts of the *Sedov* and the *Fram* is of particular interest because, as is known, climatic conditions have changed considerably since Nansen's time. As is evidenced by many facts, the atmosphere and hydrosphere in the Arctic have now become much warmer.

An examination of all the peculiar features of

DRIFT OF THE *Fram*, *Sedov*, *Maud*, *Lenin*, *St. Anna* AND THE PAPANIN NORTH-POLAR EXPEDITION.

the *Sedov's* drift will only be possible after all the data collected have been carefully studied; but from data already available, it is possible even now to draw some important conclusions.

An important achievement of the *Sedov* has been the final destruction of the legend of 'Sannikov Land'. This alleged land derived its name from a Russian hunter named Sannikov who, in 1811, observed high land to the north of Koteln Island but failed to reach it. Toll, a well-known Russian traveller, on the occasion of two visits to the New Siberian Islands made in 1886 and 1894, saw the land and even distinguished on it four high mountains, of which he drew the contours, and his guides, too, assured Toll that they had seen this land on more than one occasion.

Afterwards, several Arctic expeditions endeavoured to find this mysterious land. They were the 1900-3 expedition of the *Zarya* under

* The Soviet ice-breaker *Sedov* became ice-bound on October 23, 1937, in lat. $75^{\circ} 21'$ N., long. $132^{\circ} 15'$ E., near the New Siberian Islands. Attempts to free her last autumn failed, but some of her crew were exchanged with men from the rescue vessel *Krassin*. The *Sedov* provisioned for several years and has fifteen men on board. On January 20, 1939, she was in lat. $86^{\circ} 2'$ N., long. $119^{\circ} 5'$ E., a little more than two hundred and fifty miles from the North Pole.

Toll, the expeditions of 1913 and 1914 on the icebreakers *Taimyr* and *Vaigach*, which discovered Severnaya Zemlya, and the Norwegian expedition on the *Maud* in 1924. 'Sannikov Land' was not sighted during any of these voyages, but this did not necessarily disprove its existence. None of the aforementioned vessels succeeded in going beyond the limits of the shallow waters of the continental shelf, while sailing north of the New Siberian Islands. So long as this shelf had not been adequately explored it was always possible that an island of continental origin might be found.

One of the objectives of the high latitude expedition on the icebreaker *Sadko* in 1937 was to search for 'Sannikov Land'. The *Sadko* on that occasion went northwards along the Kotelný Island meridian, and then eastward a little below the 78th parallel, approximately as far as the Bennett Island meridian. She then sailed to Henrietta Island. No trace of 'Sannikov Land' was found.

Now, during the drift of the *Sedov*, the region to the north of the New Siberian Islands was crossed on two more occasions—once from west to east and then from the south-east to the west. Moreover, the icebreaker has proceeded beyond the limits of the continental shelf.

The air expedition under A. Alexeyev made six flights across that region from Cape Kotelný last spring, when engaged in removing part of the crews from the *Sadko*, *Sedov* and *Malygin*, which were then still drifting together. Visibility was excellent on each occasion, but nothing was seen of the mysterious 'Sannikov Land'. The legend of 'Sannikov Land' has now been finally exploded.

The second important geographical achievement of the *Sedov* is her exploration of the continental shelf and the slope down to the great depths of the Arctic Ocean.

Prior to the Nansen expedition there was no knowledge of the central part of the Arctic Ocean. Soon after he entered the ice north-west of the New Siberian Islands, Nansen found a depth of 1,600 metres, approximately at lat. 78° N. and long. 134° E. A subsequent sounding taken approximately at lat. 80° 50' N. and long. 126° E., showed the depth to be 3,850 metres, which was the deepest sounding taken by Nansen during his expedition.

These soundings established a deep-water basin. Hence, the determination of the boundaries of the continental shelf of the Arctic Ocean became one of the most important objectives of every expedition sent out to the central part of the Arctic.

The boundary of the continental shelf was established by the Papanin Expedition near the

north-east coast of Greenland; by the expedition on the *Sadko* in 1935, near the northern part of the Kara Sea, where a sounding taken at 82° 42' N. and long. 87° 4' E. showed a depth of 2,365 metres; and by the 1937 expedition of *Sadko* in the Laptev Sea, where a sounding taken at lat. 77° 34' N. and long. 118° 28' E., showed a depth of 2,381 metres; and finally, during the drift of the *Sedov*.

The data obtained by the *Sedov* are very characteristic. The continental shelf in the region of New Siberian Islands was shown to stretch farther north than had been supposed. Moreover, the continental slope proved exceedingly gradual; stretches nearly 120 kilometres in a north-easterly direction, and its gradient is only between two and three degrees.

The observations carried out by the *Sedov* during her drift have made it possible once again to verify and to establish the fact that the direction and speed of the drift depend on the direction and velocity of the wind.

Like all previous drifts of icebound vessels, that of the icefloe of the Papanin Expedition, the drift of the *Sedov* did not proceed in a straight line. The icebreaker quite frequently veered to one direction, turned back on her course, and described zigzags or even loops.

These changes in the direction of the drift are due to the changes of the wind, to which the ice fields respond very rapidly. As Nansen had discovered and explained, the direction of the ice drift in the central part of the Arctic Ocean, owing to the action of the deflecting force of the earth's rotation, deviates approximately 40° to the right from the direction of the wind blowing at a given moment over the ice. The speed of the drift is approximately one-fiftieth of the velocity of the wind. The *Sedov's* drift, too, has been subject to this law.

The accompanying diagram shows the remarkable similarity between the course of the wind and the course of the *Sedov*. Where the course of the wind is even, the drift proceeds approximately in the same direction, the only difference being that the drift is turned approximately 40° to the right. Where the wind changes sharply, the *Sedov*, too, begins to describe zigzags and loops. Very characteristic, in this respect, are the figures described by the wind and the *Sedov* between October 2 and October 25 of last year, the zigzags between November 10 and November 30, 1938, and the loops between December 17, 1938, and January 17, 1939.

An examination of available data relating to the Central Polar Basin shows that there is either no constant current in the regions of the *Sedov's* drift, or, if such a current exists, it is so negligible

likely to have any effect on the future movement of the vessel. Wind conditions will play the principal role.

The prevailing winds during the drift of the icebreaker have been south-easterly. From September 1938 to February 1, 1939, a moderate wind blew from the south-east at a velocity of about 10 metres per second. From this it follows that the *Sedov* is on the edge of a polar anti-cyclone, the centre of which is somewhere to the north-east of the vessel.

The *Sedov's* drift during the first half of last December was exceptional. At that time the vessel was under the influence of westerly and north-westerly winds. In other words, she was on the southern edge of cyclones sweeping into the central Arctic between her and the North Pole.

The North Polar Expedition of Papanin was the first to establish that these cyclones break through to the central part of the Arctic. However, they are much more likely to occur there in the first half of the winter than in the second. Hence, it may be presumed that the *Sedov* will not again be affected by such cyclones before the polar summer begins and that she will continue to drift in a north-north-westerly direction during the next two or three months.

Owing to insufficient data, there is as yet no certainty as to the way in which the ice in the central part of the Arctic Ocean moves. Some Arctic explorers are of the opinion that in general the drift of the ice proceeds simply from the seas of the Soviet Arctic, first northward and then eastward, to the strait between Greenland and Spitzbergen, and also from the shores of Alaska in a straight line across the North Pole to the Greenland Sea.

The famous drifts of the *Jeannette* (1879-81), the *Frank* (1893-96), the *Karluk* (1913-14) and the *Aud* (1922-24), which took place near the continental slope in the central Arctic, are confirmation of this view. The way in which the icefloes of the Papanin North Polar Expedition (1937-38) as carried almost in a straight line from the Pole to the north-eastern coast of Greenland also fitted in with this view.

However, from the time of Toll's expedition of 1900-3, a theory has existed that besides the general movement of the ice from east to west, under the influence of a given system of winds there is a circular movement of the ice in a clockwise direction. This movement is supposed to have its centre near the 'pole of inaccessibility', which is situated between lat. 83° and 85° N., approximately on the meridian of Bering Strait.

Should this theory be correct, it is possible, judging from the direction of the wind and the drift, that the *Sedov* will later be drawn into a

vast anti-cyclone and, consequently, into a circular movement around the 'pole of inaccessibility'. If this happens, the vessel will find herself after some time in the region between the North Pole and Bering Strait.

It may be assumed that the icefloes of the Papanin North Polar Expedition during its drift was on the eastern edge of the Greenland area of high atmospheric pressure and on the western boundary of the trough of low pressure created as a result of Atlantic cyclones breaking through into the Arctic. The *Sedov*, it seems, is on the western edge of the North American area of high pressure and on the eastern boundary of the trough of low pressure passing through the Arctic in the vicinity of the North Pole.

DIRECTION OF WIND AND DRIFT OF *Sedov* COMPARED.

The low figure obtained for the speed of the constant current by a study of the *Sedov's* drift does not seem to contradict these suppositions. Occasional but strong winds in one or other direction may draw the Papanin icefloes or into a drift similar to that of the Papanin icefloes or into a drift around the 'pole of inaccessibility'. This view was expressed by the present writer as early as the beginning of last December, and the data so far received from the vessel do not contradict it.

Another circumstance must be taken into account in connexion with these suppositions. The ice around the *Sedov* differs appreciably in its nature and movement from that observed by Soviet airmen at the North Pole. The vessel is surrounded by comparatively young ice (about two

or three years old), small fields with a considerable quantity of hummocky ice prevailing. In the region of the North Pole, old comparatively level fields were the most common. At least a year or more is necessary for the *Sedov* ice to be transformed into fields of this kind.

When flying from Franz Josef Land to the North Pole, the Soviet airmen first saw a belt of comparatively young ice. This was followed near lat. 86° N. by a peculiar belt of hummocky or jagged ice, the origin of which has not been sufficiently studied. Level fields of old ice stretched beyond this belt to the Pole itself.

To judge by the data at our disposal, the *Sea* is in the belt of hummocky ice situated between the main mass of Arctic ice and the ice carried comparatively recently into the central basin from the seas of the Soviet Arctic. This would explain the constant movement and jamming of the ice observed by the *Sedov* expedition.

Finally, it is possible that the belt of hummocky ice stretches along the trough of low pressure created by the inrush of masses of Atlantic ice into the Arctic. This is all the more probable since the passage of this air is usually accompanied by powerful winds.

Medical Research in Great Britain

FOR those who desire to obtain some conception of the progress of medical research in Great Britain, no better means can be suggested than a perusal of the latest annual report of the Medical Research Council*. Subjects to which the Council wishes to direct special attention are reviewed in the introduction; the remainder of the report falls naturally into several sections describing work carried out for different Government Departments, at the National Institute for Medical Research (including the Department of Biological Standards), by members of the Council's external scientific staff, and in clinical research units and in hospitals and other institutions by investigators aided by grants. The Council also awards research fellowships in tropical medicine, Rockefeller medical fellowships and Dorothy Temple Cross research fellowships in tuberculosis. During the year, Prof. A. J. Clark and Sir John Ledingham retired from the Council and Prof. C. R. Harington and Prof. W. W. C. Topley were appointed to succeed them.

The report mentions that a beginning has been made with the work of construction of the new National Institute for Medical Research at Mill Hill, to which reference was made in last year's report. At least two years, however, will be required for completion. The new Institute will provide accommodation for the central laboratory under the national scheme for research in chemotherapy, of which an account was also given last year. At present, research work is being gradually developed by selected investigators at different centres, the Council having assumed responsibility for supporting the chemical as well as the biological investigations: previously the former were supported by the Department of Scientific and Industrial Research. The policy of transferring

the Institute to Mill Hill has involved reconsideration of the proposed memorial to the late Sir Walter Fletcher. The original intention was to apply the balance of the fund, after providing the personal memorial, towards a new laboratory for research on nutrition at Mill Hill. With the transference of the Institute, this laboratory, instead of being the chief building on the site, will occupy only a relatively subordinate position. It has been decided, therefore, with the agreement of the subscribers to the fund, to devote it to the provision of a hall for meetings and lectures as an addition to the new Institute. The Council will meet the whole cost of the nutrition laboratory.

The Council points out that, during the past twenty-five years, since the Medical Research Committee was first set up, there has been a great increase in knowledge of the body in health and disease, greater even than that of the previous twenty-five years. This new knowledge has had two influences which, in their effect on medical practice, are often opposed to each other. In the first place it has resulted in a great improvement in methods of diagnosis and treatment of disease which has involved a vast increase in medical services. Many patients suffering from disease which, twenty-five years ago, were incurable and uncontrollable can now be restored to health and well-being. At the same time new knowledge of curative treatment may in itself also bring about a reduction in incidence of disease; for example the more rapid and effective cure of gonorrhoea by drugs of the sulphanilamide group should result in a reduction in its incidence by reducing the spread of the infection. Recent results also give hope that these drugs may lead to reduction of the number of cases of middle ear disease, which is responsible for a large proportion of the cases of disabling deafness in Great Britain.

* Committee of the Privy Council for Medical Research. Report of the Medical Research Council for the Year 1937-38. (Cmd. 5439.) Pp. 221. (London: H.M. Stationery Office, 1939.) 8s. 6d. net.

On the other hand, medical research has brought other kind of knowledge which, properly used, leads directly to the prevention and elimination of disease. The effect on medical practice is clearly opposed to the first-mentioned effect, since, by minimizing disease, it tends to reduce the needs for curative aids. The report points out that there is often a great delay in bringing about the application of new discoveries to preventive ends. Fresh means of curative treatment, on the other hand, are generally applied within a short period of their discovery. This delay is considered to be due to the fact that there is no means of educating the public in the established advances in preventive medicine. It is responsible for much unnecessary suffering. The report illustrates this point by reference to the prevention of diphtheria and to the value of improved nutrition. Where preventive inoculation with diphtheria toxoid has been generally adopted, diphtheria as a clinical entity has practically disappeared: yet in 1937 there were more than 61,000 cases in England and Wales, with almost 3,000 deaths. The report urges parents to demand this prophylactic inoculation for their children, and considers that there is no doubt that its general adoption would lead to the virtual disappearance of the disease from Great Britain.

The need for improved nutrition has been discussed in previous reports, but the adoption of modern teaching in the subject is still depressingly slow: a much greater consumption of milk and other dairy products, of eggs, vegetables and fruit and of fat fish at the expense of bread, biscuits, sugar and sweets, will improve the physique of the people, reduce the amount of mental decay and greatly raise the standard of health. An increased consumption of the 'protective' foods would also be of great economic value to the country.

The Council is sometimes asked what is its policy in promoting research: whether it favours research on disease itself rather than on more academic problems of physiology and biochemistry. The general answer is that it welcomes both kinds of investigation. Promotion of specific research by the Council is usually done by appointment of individuals to its permanent staff, the choice depending on the subject which seems to require special attention and the merits of the person chosen. Thereafter the individual has wide liberty of action in planning investigation. The Council seldom chooses particular diseases for investigation; generally the choice is of a wider nature, to include study of an etiological factor common to a group of diseases, or a type of treatment of wide application; in fact, such subjects as virus diseases, endocrinology or chemotherapy. For another large

part of the work helped by the Council by means of personal and expenses grants, the initiative in choice of subject and method of investigation lies with the head of the laboratory in respect of some individual worker, or with the worker himself. The Council considers that at the present time there is a relatively great dearth of work in clinical science and in experimental pathology, so that it is offering scholarships and fellowships to attract young investigators into these particular fields of inquiry.

An important duty of the Council is to help Government departments confronted with immediate problems of health and disease in the course of their work. The report describes briefly some of the main investigations now being made. Important research on nutrition in the Colonial Empire has been carried out in association with the Colonial Office. In Nyasaland, the dietetic and nutritional conditions of the people are being accurately assessed and related to other surveys of the agricultural and social conditions. It is hoped thereby to determine methods of producing those agricultural products which will cause a great improvement in the physical condition of the population. It is also hoped that this survey may form a model for many similar studies elsewhere in the Colonial territories. Other investigations made for Government departments relate to the nature and causes of chronic lung disease in coal miners, and to the dangers to health which may follow the use of certain organic substances as solvents in industry. Research has been made into the best methods of ridding houses of the bed-bug; it is hoped by this work to discover new insecticides for the purpose which are rapid in action, safe and cheap; good results have already been reported from fumigation with heavy naphtha.

The report describes results obtained in the treatment of cancer of the mouth, tongue, pharynx and larynx by radium beam therapy; most of the patients have been in an advanced and inoperable stage of cancer, but the results appear to compare favourably with those to be expected from surgery. Of even greater importance than the actual therapeutic results are the new technical methods which have been elaborated as the result of close co-operation between physicists and clinicians: they are already being widely used as models to be followed in researches in radiotherapy at other centres.

For the student of medicine and the specialist, the descriptions of recent researches on the hormones, the vitamins and virus diseases should prove of particular interest. It is pointed out that as a result of intensive chemical researches in the last few years, new synthetic substances having actions closely simulating those of some of the

natural hormones have been produced in the laboratory and made available for the treatment of disease. Thus diethylstilboestrol is a synthetic oestrogen which is active by mouth and is already finding a place in treatment. A lengthy account of the physiological action of different hormones is given in the section of the report devoted to work carried out at the National Institute.

This summary is intended only to give a general

idea of the work and policy of the Medical Research Council: brief reference has also been made to few subjects in which there have been recent advances in knowledge. The interested reader will find in the report full references to all the research carried out under the auspices of the Council which have been published in the scientific journals as well as mention of the many investigations still in progress.

Observation of the Sun's Corona and Prominences without Eclipses

M. BERNARD LYOT, of the Astrophysical Section of the Paris Observatory, delivered the George Darwin Lecture before the Royal Astronomical Society on May 12, the subject being "A Study of the Solar Corona and Prominences without Eclipses". To this research, M. Lyot has made unique and fundamental contributions for which he has been awarded this year the Royal Astronomical Society's Gold Medal. The presentation of the Medal was made prior to the lecture by the president of the Society, Prof. H. C. Plummer, who spoke of the medallist's great achievement in recording for the first time the sun's corona without an eclipse.

M. Lyot began his lecture with a brief review of past attempts made by various investigators from 1878 onwards to record the solar corona without a total eclipse of the sun. Direct photography from high altitude sites, thermo-electric, spectroscopic and polariscopic methods had all been tried but gave negative results. In consequence, the problem was generally regarded as being beyond the range of observational technique. Ten years ago, M. Lyot, encouraged by the advice of the late Prof. H. O. Barnard of the Colombo Observatory, made a fresh attempt to record the corona in full sunlight.

Measurements made during total solar eclipses showed that the brightness of the corona at 2' from the sun's edge was only about one-millionth that of the light from the disk. To obtain any success, it was therefore a primary necessity to reduce to a negligible amount the diffusion of light by the optical train of the telescope. This diffused light in an ordinary telescope is at least two hundred times greater than the inner coronal image. Furthermore, the whitish aureole of diffracted light around the sun produced by dust in the earth's lowest atmosphere and by ice crystals of cirrus cloud is generally in itself more than a hundred times brighter than the corona.

To overcome the first difficulty, M. Lyot constructed with increasing success three special coronagraphs. To avoid the dust, he took his apparatus to the Pic du Midi in the Pyrenees at height of 2,870 metres, where excellent conditions on cloudless days are obtained especially in the late spring.

The general plan on which the coronagraph were constructed is as follows: A single plano-convex lens (*A*)* forms an image of the sun on a blackened disk of brass projecting just beyond the image by 15"-20". A field lens placed behind the disk produces an image of the lens *A* in a diaphragm, the edge of which intercepts the light diffracted by *A*. A small screen placed in the centre of the diaphragm intercepts the light of the solar image produced by reflection from the surfaces of *A*. Behind the diaphragm and the screen, protected from the diffused light, an over-corrected objective forms an achromatic image of the corona on the plate. The whole optical train is contained in a tube, open only during the observations and coated inside with thick oil to trap the particles of dust. The primary lens must be wiped frequently with particular care.

M. Lyot showed a number of slides of the observatory and instruments. Even under the best conditions, the last part of the ascent of the Pic du Midi has to be made on foot. The coronagraphs are made to telescope into sections for manual transport often over deep snow.

THE CORONA: DIRECT PHOTOGRAPHS

Lyot's work on the direct photography of the corona was made in two stages: (1) 1930-34, when the new method by his coronagraphs was being

* The two later objectives were cut from flawless disks of borosilicate crown glass produced by Messrs. Parra-Mantoux. The lens of the second coronagraph was ground in the Institut d'Optique in Paris, while that of the third instrument was figured by M. Couder at the Paris Observatory.

ted; (2) after 1934, when new results were attempted. The first positive result was obtained July 25, 1930, with his coronagraph of 8 cm. aperture (stopped down to 3 cm.) and 2 metres focal length. Using a red colour-filter, prominences were easily seen. The sun's image was surrounded by a slight halo without detail. Interferometer tests showed the light of this halo to be polarized in a radial plane like the corona as observed at total eclipses but less strongly. The measures, in point of fact, indicated that one fifth the light of this halo belonged to the corona, the remainder being due to diffusion. But there was other evidence to prove that Lyot had in reality isolated the sun's inner corona. On July 21 and the following days, an attached spectrograph showed amongst the absorption lines due to diffused solar light, an emission line in the green of the wave-length of which to within one angstrom was the same as that of the well-known coronal line, λ 5303. The red coronal line, λ 6374, was also faintly visible.

A year later, a larger and more perfect coronagraph (13 cm. in aperture and a focal length of 15 metres) had been constructed and transported with accessory apparatus to the Pic du Midi. With this instrument the first direct photograph of the sun's corona was obtained on July 21, 1931. This photograph and others exhibited on the screen showed the distinctive features of the inner corona—photographed at total eclipses—luminous arches, dark spaces, fine jets of coronal matter, etc. Changes of structure were also apparent within a few hours. To this coronagraph was attached a spectroheliograph, isolating a part of the spectrum of λ A. wide containing the green line 5303. Thus the distribution and strength of this coronal line around the sun could be studied.

Slides of the earliest direct photographs of the corona had to be made by successive copying on the same plate, and in exact superposition, of the best of twelve negatives taken in succession on any one day, the coronagraph being turned on its axis through 30° between each exposure. This procedure diminished considerably the effect of spots produced by dust particles deposited on the second lens of the coronagraph. In 1938, a rotatory mechanism was added to the latest of Lyot's coronagraphs (20 cm. in aperture and 4 metres focal length) which annuls the effect of dust particles on the lens. A single negative is sufficient to gain a good picture of the corona (on a scale of 5 mm. to the solar diameter) with an exposure as short as seven seconds.

Among the many slides shown by M. Lyot to illustrate the delicate, complex structure of the inner corona and its changes, were some taken on May 11, 1937, when Mercury passed close to the

sun's disk. At 10h. 10m., when the planet was only $1' 11''$ from the sun's edge, it was seen projected against a prominence. Later, at 11h. 14m., when at a distance of $2' 37''$, it was outlined against the corona itself; the sky then clouded.

THE CORONAL SPECTRUM

New and powerful spectrographs were devised by Lyot to be used with his two latest coronagraphs, and with these the spectrum of the corona has been explored from 3350 Å. (the limit of the transparency of the coronagraphs) to 1200 Å., which represents the limit of the sensitivity of the plates. To compass this range of spectrum, seven different kinds of plates had to be used, with exposures ranging from 10 minutes in the visible spectrum to 4 hours in the infra-red. M. Lyot then proceeded to show examples of the two hundred or so spectra which he has obtained up to the present time. The slit of the spectrograph is in the form of an arc crossing the east and west sides of the corona about $40''$ from the sun's edge between latitudes $\pm 70^\circ$. These spectra, usually on a scale of $5\text{--}7\frac{1}{2}$ Å. per mm., show in addition to a continuous spectrum from the corona (and also the spectra of any prominences present), eleven coronal emission lines of which five are new lines not previously recorded under conditions of total solar eclipse. These emission lines are as follows, the new lines being indicated by an asterisk :

3386 Å.	7000 Å.* †
5116	7892
5303	8024*
5694*	10747*
6374	10796*
6702	

† Found later by Menzel on spectrograms taken at the eclipse of 1936.

The wave-length of the fourth and seventh lines listed are given more exactly as 5694.42 Å. and 7059.62 Å.

A notable feature of all the coronal lines shown is their great width. Allowing for instrumental corrections, their average widths are 0.8 Å. in the green, 0.9–1.0 Å. in the red, and greater than 1 Å. in the infra-red. The distribution of these lines around the sun show differences from one another which are being studied. As an example, M. Lyot cited the curious distribution of λ 5694, which is invisible where λ 5303 is at a maximum. Another anomaly is the absence from the above list of the line λ 5536, of which no trace appeared on spectrograms taken in 1936, 1937 and 1938 under very favourable conditions and high solar activity. Perhaps the line does not extend to $40''$ above the sun's limb like the other lines. Lyot considers

that the eleven lines listed fall into three groups : (a) $\lambda\lambda$ 5303, 3388, 5116, 6702, 7059, 8024, and probably 10747 and 10798 ; (b) 5694 ; (c) 6374 and 7892.

By measuring the differential Doppler effect given by the strong emission line, 5303 Å., at the east and west edges of the sun, it is found that the corona rotates in the same sense as the general body of the sun and at approximately the same rate.

SPECTRA OF PROMINENCES

Some of the Pic du Midi spectrograms are very rich in lines from the spectra of prominences. The hydrogen spectrum was shown represented by the Paschen series (from the 6th term at 10939 Å. to the 31st term, and the Balmer series in the ultra-violet from the 8th also to the 31st term. The lines of the Paschen series are much fainter than those of the Balmer series, but the atmospheric diffusion, greatly reduced in the infra-red, allows spectra of the Paschen series to be obtained easily without an eclipse.

PROMINENCES THROUGH COLOUR FILTERS

The continuous spectrum of prominences has been observed during eclipses, but it was thought that the spectrum was emitted only by some particular parts of the most intense prominences. To test this, three filters were used transmitting (a) continuous spectrum from 6100 Å. to 6400 Å. ; (b) the D_α line of helium ; (c) $H\lambda$ of hydrogen. It was seen that (a) and (b) gave identical pictures both with respect to form and relative intensities. These results, taken in conjunction with polarization measurements, indicate that this continuous spectrum comes from all parts of a prominence, and in the visible range would appear to be due to the diffusion of the sun's light by the electrons that they contain.

MOVEMENTS OF PROMINENCES

Lyot's coronagraph, supplied with a filter isolating the line $H\lambda$, shows the prominences with great brilliancy against a very dark sky, and their faintest details appear. Since 1935, the movements of stable and eruptive prominences have been recorded at the Pic du Midi on cinematograph films, usually at a rate of two per minute and, in projection, speeded up 600 times. The height of the pictures which M. Lyot showed usually represented about 380,000 km., that is the distance of the moon from the earth, or thirty times the

earth's diameter. These gave an extraordinary exhibition of prominence movements, of which few examples may be outlined :

(1) Filaments fading away as they rise and brightening again as they fall back into the sun with a speed of 180 km./sec.

(2) A suspended cloud pours luminous material inwards to the chromosphere.

(3) A fountain-like prominence is suddenly thrown up by an explosion.

(4) A particularly stable prominence ; small internal motions are, however, perceptible. After many hours, part of the cloud becomes very bright. A chromospheric eruption leaves the sun at the speed of 700 km. per sec. and cuts the prominence into two parts. The luminous material, its equilibrium lost, flows into the sun and seems to flow around an invisible obstacle.

(5) A prominence similar to those called "coronal prominences" by Pettit and McMath, originating in invisible clouds, flows downwards on both sides of a loop or arch in the chromosphere.

In conclusion, M. Lyot said that it would be very interesting to compare the observations of the corona by both methods—with and without eclipses. The outer parts of the corona can be obtained only during eclipses ; the new method without an eclipse shows only the inner corona but daily or even hourly variations of the corona can be recorded. With regard to the coronal spectrum ; in the ultra-violet, the violet and the blue, the atmospheric diffusion is very strong and the new method is in consequence very inferior to the old method. In the green, the diffusion is less strong, and its effects can be diminished by increasing the dispersion and making longer exposures. By choosing days on which the corona is intense, the faint coronal lines appear. The numerous spectrograms on a large scale possible with the new method, enable the lines to be distinguished from the agglomerations of grain on the plate, and their wave-lengths are measurable with great precision. In the infra-red the new method is superior.

For studying prominences, the extra-eclipse method alone enables the solar observer to wait for the appearance of very bright objects having the richest and most interesting spectra. Observations made without eclipses can therefore not replace the work of expeditions investigating total eclipse phenomena, but the two methods complement one another in numerous ways and their simultaneous use would increase our knowledge more rapidly of the sun's outer atmosphere.

Obituary Notices

Miss M. F. Rich

BY the death on April 20 at Ruislip, Middlesex, of Mary Florence Rich, botanical science has lost an active and enthusiastic contributor to our knowledge of freshwater algae. Born at Weston-super-Mare in 1865 and educated at Aske's School, Hatcham, Miss Rich studied at Somerville College, Oxford, where she held a Clothworkers' scholarship. Taking up the teaching profession she held for some years a post at Roodean and then established a girls' school (Granville School) at Leicester, which acquired a considerable reputation and which she continued to direct until 1923.

Although not primarily trained as a botanist, Miss Rich had already so far back as 1903 taken up the study of freshwater algae, to which she devoted a considerable amount of her leisure time while she was at Leicester. During this period she published with her husband a series of papers on the periodicity of these forms and also compiled a valuable list of the algae of Leicestershire. After her retirement from scholastic work, she devoted the remaining years of her life to algal work, settling in the Department of Botany, Queen Mary College (then East London College), in which she afterwards held the position of honorary research assistant. As witness to her activity during these last fifteen years of her life, we have a long series of taxonomic papers, largely dealing with the freshwater algae of Africa, including the phytoplankton of the Rift Valley lakes in Kenya and that collected by the Cambridge Expedition to the East African lakes. Many of the research workers in the Department owed much to her kindly help and her keen interest in any work that was in progress. In recognition of her services she was made a fellow of Queen Mary College in December last. She was elected a fellow of the Linnean Society in 1926.

F. E. FRITSON.

Prof. I. M. Gubkin

SOVIET science has sustained a great loss in the death on April 21 of Prof. I. M. Gubkin, the oil geologist, known not only in the U.S.S.R. but also to geologists throughout the world.

Born in 1871 of poor peasant parentage and requiring an education with difficulty, Gubkin, though early interested in geology, was compelled to spend some years in teaching before he managed, at the age of thirty-two years, to enter the Mining Institute, where even as a student he attained distinction for original work.

He had made a study of the oil deposits of Maikop, Kuban and the Taman Peninsula, adjoining the Caucasus, and later of the Apsheron Peninsula, where he determined the stratigraphy and tectonics of the oil layers. In 1917, he was sent on a commission to the United States to study oil

deposits of various ages and methods of their prospecting.

After the revolution, Gubkin organized the Soviet slate industry, became chairman of the council of the oil industry, and later, in the region of the Kursk magnetic anomaly, directed the boring operations which led to the discovery of big deposits of iron ore at a depth of 200-300 metres from the surface.

Gubkin was the first professor of the geology of oil deposits at the Moscow Mining Institute, of which he afterwards became the rector. He founded the Institute of Research in Petroleum, of which he was the head for a long time. He gave courses of lectures on the geology of world and Soviet oil deposits, creating a school of numerous pupils now engaged in studying and prospecting for oil on the territory of the U.S.S.R.

In 1929, Gubkin was elected a member of the Academy of Sciences of the U.S.S.R. In the Academy he founded the Institute of Combustible Minerals, of which he became the head. He was elected vice-president of the Academy in 1936. In 1933, he headed the Soviet delegation to the Geological Congress at Washington, and in 1937 he presided at the International Geological Congress in Moscow, where he read a paper on the oil reserves of the Soviet Union which, largely as the result of his own work in the discovery of new deposits, had been increased by several times during the period of the Soviet regime.

As head of the Geological Department, Prof. Gubkin directed work in the study of geological formations in the Soviet Union and the compilation of geological maps of the country. He was the author of a hundred and fifty scientific works. One completed not long before his death is entitled "Estimated Oil Reserves of the Soviet Union".

PROF. JOSEPH KLOBOUČEK, a distinguished Czech mathematician, died in Prague on April 18 at the age of sixty-four after a long illness which had necessitated his retirement early last year. He studied at the Universities of Turin and Milan but graduated at Prague, and before obtaining a professorship in 1919 had taught mathematics and science in secondary schools. He was a member of many Continental scientific societies and had contributed a number of papers, mainly on analytical geometry, to Czech and other periodicals.

We regret to announce the death of Prof. Edward A. Burt, professor of botany in the Henry Shaw School of Botany in the University of Washington during 1913-25. He was an authority on the morphology and physiology of the Basidiomycetes.

News and Views

Dr. J. D. Cockcroft, F.R.S.

DR. J. D. COCKCROFT, whose election to the Jacksonian professorship of natural philosophy, in the University of Cambridge, has just been announced, is, like his predecessor, the present secretary of the Department of Scientific and Industrial Research, both a member of St. John's College and a northerner. Having gained valuable experience in heavy electrical industry at an early stage in his career, Dr. Cockcroft entered St. John's College from the University of Manchester as Dowman Sizar and Hoare Exhibitioner in mathematics in October 1923. In 1924, he obtained the highest possible honours in Part II of the Mathematical Tripos and was elected scholar of his college. Thereafter he was engaged in research in Cambridge, first of a mathematical nature, concerning the heating of transformer coils (1925) and later, at the Cavendish Laboratory, of an experimental character regarding the deposition of surface films by atomic beams (1928). He took his Ph.D. and was elected fellow of St. John's College in 1928. Although his publications have not been numerous since that date, during the last ten years he has contributed in a remarkable degree to the prosecution of physical research in Cambridge. He was largely responsible, with Kapitza, for the design of much of the equipment used in the production of intense magnetic fields in the early years of this period (and latterly the direction of the Royal Society Mond Laboratory has devolved almost entirely upon his shoulders)—and, with Walton, of the arrangement by which nuclear disintegration was first effected by artificially accelerated particles (1932). More recently, he has been the moving spirit in the construction and development of the Cambridge cyclotron, and he has taken over the major work of supervision of the building operations made possible by Lord Austin's bequest. Then, in college, he has filled the office of junior bursar for the last six years, and in the University has been indispensable on numerous executive bodies. He was elected a fellow of the Royal Society in 1936 and this year was the recipient with Walton of the Hughes Medal of the Society. His many friends will wish him well in his new office, and some measure of relief from his numerous extraneous duties.

The Royal Society: New Foreign Members

At a recent meeting of the Royal Society the following were elected to the foreign membership of the Society: Prof. Walter Bradford Cannon, professor of physiology in Harvard Medical School, Boston, U.S.A., distinguished for (a) his X-ray investigations of the movements of the alimentary canal, (b) his analysis of the mechanism and conditions of excitation of the suprarenal gland, and (c) his work on the chemical transmission of impulses in

peripheral nerves as shown by the sympathetic system; Prof. George von Hevesy, research professor in the Institute of Theoretical Physics, Carlsberg Laboratory, Copenhagen, distinguished for (a) his work in experimental chemical physics, particularly the use, for the solution of biological and chemical problems, of radioactive and isotopic substances as indicators, (b) for his discovery of hafnium, and (c) for his geochemical researches and for his work on isotopes and their separation; Prof. Herbert Freundlich, University of Minnesota, Minneapolis, U.S.A. distinguished for his researches in colloid chemistry and colloid physics.

The Linnean Society: New Foreign Members

THE following five biologists were elected foreign members of the Linnean Society of London at the general meeting on May 11: Prof. Alfred Ernst, director of the Institute of General Botany in the University of Zurich, distinguished for his work on apogamy in plants and related subjects, and for his fundamental investigations on heterostyly in Primulaceae and tropical Rubiaceae. His monograph on the new flora of the volcanic island of Krakatau was translated into English more than thirty years ago. Dr. William King Gregory, of the American Museum of Natural History, New York, distinguished for his researches on the morphology and evolution of the vertebrate skull and locomotor systems, the evolution of mammalian molar teeth, the phylogeny of fish skulls and the origin of man. Dr. William Marinus Docters van Leeuwen, formerly director of the Botanic Gardens, Buitenzorg, distinguished for his work on galls and the various relations between plants and insects, on the regeneration of vegetation on lava and the biology of plants on mountain tops. His recent "Biology of Plants and Animals occurring in the Higher Parts of Mount Pangrango-Gedeh in West Java" and "Krakatau 1883-1933" are outstanding contributions to tropical botany.

DR. ALFRED REHDER, associate professor of dendrology and curator of the Herbarium, Arnold Arboretum, distinguished for his outstanding contributions to the taxonomy of trees and shrubs. His "Manual of Cultivated Trees and Shrubs" is a standard work, as is also "The Cultivated Conifers", which he wrote in collaboration with Prof. L. H. Bailey. His contributions to botanical bibliography include the preparation of the monumental "Bradley Bibliography". He has played a valuable part in suggesting practical additions and emendations to the International Rules of Botanical Nomenclature. Prof. William Albert Setchell, emeritus professor of botany in the University of California, distinguished for his researches on the classification and distribution

of marine algae, particularly kelps, calcareous algae and parasitic red algae. In addition, he is the author of several papers on mosses, fungi and flowering plants. At the same meeting Mr. John Ardagh, clerk in charge of the Library, Department of Botany, British Museum (Natural History), was elected associate of the Society. Mr. Ardagh has an extensive knowledge of botanical literature, and those engaged upon investigations in taxonomy or botanical history greatly appreciate the readiness with which this knowledge is placed at their service.

Dr. E. W. R. Steacie

DR. E. W. R. STEACIE has been appointed director of the Division of Chemistry, National Research Council of Canada, in succession to Dr. G. S. Whitby, who recently resigned to accept the post of director of the Chemical Laboratories of the Department of Scientific and Industrial Research in Great Britain. Dr. Steacie, who will assume his new duties in July, has been a member of the teaching staff of McGill University for the last ten years, being at the present time associate professor of chemistry. During his period most of his time has been spent in the supervision of research by graduate students working on problems in the fields of hydrocarbon chemistry, combustion, chemical kinetics and photochemistry, in which work he is recognized as an authority. Dr. Steacie's studies have been directed largely along lines of fundamental research on problems of industrial importance, such as gaseous combustion, catalysis, pyrolysis of organic compounds, gases in metals, and high-pressure reactions. He has published many scientific papers and treatises, and is an associate editor of the *Journal of Chemical Physics*.

Sir John Eliot, K.C.I.E., F.R.S., 1839-1908

ON May 25, 1839, the distinguished meteorologist Sir John Eliot was born at Lamesley, Durham. Though the son of a schoolmaster, he did not matriculate until he was twenty-six years of age, and he then entered St. John's College, Cambridge. In 1869 he graduated as second wrangler and he was first Smith's prizeman. After graduating he went to India and successively was professor of mathematics at Roorkee Engineering College (1869-72), at Muir College, Allahabad (1872-74), and professor of physical science at the Presidency College, Calcutta (1874-86). This last post he relinquished to succeed Henry Francis Blanford (1834-98) as meteorological reporter to the Indian Government. He had already served as reporter to the Government of Bengal. In 1899 he became director-general of Indian observatories, retiring from this post in 1903, being made K.C.I.E. He wrote largely on meteorological subjects, and his "Handbook of Cyclonic Storms in the Bay of Bengal" proved of great use to commerce and shipping. Elected a fellow of the Royal Society in 1895, after his return to England in 1904 he was president of the sub-section of astronomy and cosmical physics of the British Association. He died suddenly at his estate at Var, in the south of France, on March 18, 1908.

Civil Defence Research Committee

SIR JOHN ANDERSON, the Lord Privy Seal, has appointed a Civil Defence Research Committee, to be constituted as follows: Dr. E. V. Appleton (chairman), formerly Jacksonian professor of natural philosophy at the University of Cambridge, now Secretary of the Department of Scientific and Industrial Research; Prof. J. F. Baker, professor of civil engineering at the University of Bristol; Prof. J. D. Bernal, professor of physics at Birkbeck College, University of London; Dr. C. G. Darwin, director of the National Physical Laboratory; Prof. A. J. S. Pippard, professor of civil engineering in the Imperial College, University of London; Prof. R. V. Southwell, professor of engineering science at the University of Oxford; Prof. G. I. Taylor, Yarrow research professor of the Royal Society at Cambridge; Prof. W. N. Thomas, professor of engineering at University College, Cardiff. The secretary of the committee is Dr. E. N. Fox, Clarendon House, Page Street, S.W.1. The committee will advise the Lord Privy Seal on programmes of research and experiment. The aim is to secure the fullest possible co-ordination over the wide field of work now comprised in civil defence.

Pottery from Mersin, Cilicia

EXAMPLES illustrative of the whole of the remarkable range of pottery discovered by Prof. John Garstang in his archaeological investigations on the prehistoric Cilician site of Mersin in Asia Minor (see NATURE, March 18, p. 484) are to be available for study in Great Britain. Prof. Garstang, in the course of an account of his excavations before the Society of Antiquaries of London on May 11, paid a tribute to the Turkish Government not only for the facilities afforded him for excavation, but also for the generosity with which the authorities had allowed a selection of no fewer than five hundred pieces to be brought to England for exhibition on long-term loan. In making his selection, Prof. Garstang added, his aim had been to secure that the series should be as representative as possible of the whole sequence of development on this very ancient site, and also to demonstrate in the sequence the position of the remarkable early architectural remains, which had been discovered—at present the oldest known. A number of specimens of the pottery were shown by Prof. Garstang to illustrate his lecture, including wares of the Cilician-Hittite periods, as well as of the whole range of the series of the chalcolithic culture, in which several new types are included. Attention was specially directed to the examples of the black ware with white decoration of the late chalcolithic culture of about 3000 B.C., and the trichrome ware from the sixteenth level, showing direct contact with predynastic Mesopotamia and the Tell Halaf culture. Wares from the neolithic level, still incompletely explored, were also shown. Arrangements are being made for the pottery to be allocated to the British Museum and museums at Oxford, Cambridge, Birmingham, Liverpool, Edinburgh, Glasgow and elsewhere. Prof. Garstang also spoke of his discoveries in Cilicia in a Friday evening discourse at the Royal Institution on May 12.

Sir Robert Mond's Bequest to the British Museum

At the meeting of the Trustees of the British Museum on May 13 the receipt was reported under the terms of the will of the late Sir Robert Mond of the biggest and most important collection of Egyptian antiquities of all periods that has reached the Museum for at least fifty years. The bequest includes 260 objects, which fill gaps in the collections in every class of Egyptian art. Among the sculptures are an Eighteenth Dynasty three-quarter size head and shoulders of an official, a number of *ushabtis*, among which is one contained in a nest of model coffins, also belonging to the Eighteenth Dynasty, and a statuette in steatite, which is especially fine, of an official, Sunuri, of the Nineteenth Dynasty. Of the bronzes, one of the most remarkable, as well as one of the best, is an axe-head of the Eighteenth Dynasty, obviously intended for ceremonial or ornamental use. It is in the Syrian style, and has inserted within its margin an extremely beautiful group of a dog bringing down a wild goat. The bequest also contains jewelry, scarabs, pottery, copies of the Book of the Dead, and some examples of the now well-known Roman portraits from the Fayum. Of these, one represents a woman with a gold tiara and necklace, and is most vivid and convincing. Among other accessions to the Egyptian collections reported is an open-work scarab in gold of the Middle Kingdom c. 2700-2300 B.C.), which is of a type new to the Museum. It has been given by Prof. P. E. Newberry. Two fragments of Anglo-Saxon sculpture, the first to be received for some years, have been presented by Mrs. G. W. Haswell and Mr. F. T. Haswell. Both pieces are in red sandstone, and are North Mercian work of the ninth or tenth century A.D. from Chester or its neighbourhood. The finer fragment is ornamented on both faces and on the sides and end with an interlaced pattern of animals and scrolls, the chief figure being a large lion of barbaric design.

Archæology and A.R.P.

A DISCOVERY of considerable interest to archaeologists has been made at Canterbury in the course of excavations for an A.R.P. Control Centre at the rear of the municipal buildings on the Dane John. A Roman pottery kiln has been found in the natural clay at a depth of about seven feet below the present ground level. Associated with the kiln were a number of potsherds, together with some forty to fifty of the tops of jars and other vessels in a variety of shapes and sizes. Among fragments of Belgic and Samian ware is a base which bears the name of the potter, 'Pavlim'. A trench running across the excavation, and extending some four to five feet into the clay, is, it is presumed, the source of the clay from which pots were made. A.R.P. excavation is also responsible for a find, in certain respects of even greater interest, which is reported from Barton-on-Humber, Lincolnshire (*The Times*, May 15). Here human skeletons have been found in association with a number of objects, which are held to be Anglo-Saxon of the fifth or sixth century A.D. They have been examined by Mr. T. Sheppard, of the Hull

Municipal Museum. Among the associated antiquities are a large hanging bowl of bronze, with three escutcheons for attachment, probably originally used in the Saxon church of St. Peter, a cylindrical bronze box, with a lid highly decorated, used by Saxon women for needle and thread and having an attachment for suspension to the waist, and a large decorated gold bead. The find of the bronze bowl is of particular interest, as it belongs, presumably, to a class of antiquity which has been made the subject of study by Mr. T. D. Kendrick of the British Museum and has been shown by him to be of British (Celtic) derivation.

Culture of Pre-Industrial Britain

SIR CYRIL FOX, director of the National Museum of Wales, delivered the annual Im Thurn Memorial Lecture to the Scottish Anthropological and Folklore Society on April 17. Sir Cyril emphasized the urgent need of making an adequate record of the cultures of Britain of the pre-Industrial Revolution era, cultures which survive more or less intact in outlying districts, and the material remains of which are still very widely distributed. He had cast his title "A Field Museum To-morrow: What's to be To-day?", into a colloquial form to emphasize his view that the matter concerned the man-in-the-street in every geographical or political region in Britain. The collection of material for the future national open-air museums should be carried out on rigidly scientific lines, special attention being devoted to things related to life and work on the land. We need the furniture of farmhouse and cottages of every century from the sixteenth; the carts, tools and implements used on the farms; tools used in, and products of, rural industries. Techniques of farm and house building should be recorded and photographed; farm lay-outs should be planned. Only adequately provenanced objects should be collected only so can we hope to map, ultimately, the culture regions of pre-industrial Britain. We want to know whether the boundaries of these regions are political or economic. If political, do they go back to the Heptarchy in southern Britain? Outside a few museums, the fate of British folk-material is a sad one—torn from its environment, it is regarded as 'old world' and ' quaint', collected by those from whom its real interest and importance as a manifestation of a once vigorous culture are hidden. How many collectors trouble to record the exact provenance of their specimens?

Exhibit of Historic Aeroplanes

A SPECIAL exhibit of aeroplanes representing an epoch in the history of aviation has been arranged in No. 1 Gallery at the Science Museum, South Kensington, and will be on view for about six weeks. The machines have been lent by Mr. R. G. J. Nash who has carefully restored them to their original condition and has flown them on various occasions. The exhibit is an interesting supplement to the permanent National Aeronautical Collection which contains such historic machines as the original Wright

planes of 1903 and the Vickers-Vimy trans-Atlantic monoplane of 1919. A Blériot monoplane, type XI (cross-Channel type), was flown by M. Leon Molon from Doncaster in October 1909, where it gained a flight record. It has a speed of about 40 m.p.h. and is similar to the machine in which Louis Blériot made his historic crossing of the Channel from the French coast to Dover on July 25, 1909. Another Blériot (type XXVII) with a speed of 80 m.p.h. is the original Gordon Bennett Cup racing machine which Alfred Leblanc flew at Long Island, U.S.A., in 1911. These machines represent the aeroplane in an early stage of its development as a mode of transport—still experimental and confined mainly to exhibition flying and competitions. No degree of standardization had then been reached, and the aeroplane was not regarded as a really proved instrument; the situation was still one of uncertainty as to the future of flight. The advent of the Great War in 1914 had, however, a profound effect on the aeroplane, and it induced an intensive development which may be estimated from the example of a Sopwith "Camel" of 1917, a famous fighter scout which was the first aeroplane to be fitted with twin synchronized guns and had a performance undreamt of in 1909, namely, speed of 113 m.p.h. at 10,000 ft. and a climb to 10,000 ft. in five minutes. An actual wartime Fokker D.VII fighter, which belonged to Jagdstaffel 71 of the German Air Force, also shows the rapid development of the aeroplane for military uses which resulted from the stimulus of war. Another famous aeroplane of the War period is the Vickers-Vimy bomber, which made the first non-stop flight across the Atlantic on June 14-15, 1919, piloted by the late Sir John Alcock with Sir Arthur Whitten Brown as navigator, now exhibited in Gallery VI.

An Early Wet-Plate Folding Camera

VALUABLE additions to the photography collections at the Science Museum, South Kensington, include a complete outfit for the wet-plate process, of date 1854, presented by His Grace the Duke of Devonshire. The outfit comprises a folding wood camera by Ottewill, a sensitizing bath, and a complete set of chemicals and reagents in its original leather carrying case. These objects are all of considerable interest as showing the types of apparatus and accessories necessary for "photography in the field" in the early days of the "photographic art".

Water Pollution

THE forty-sixth Bedson Lecture was delivered by Sir Robert Robertson on May 8 in King's College, Newcastle-upon-Tyne. Sir Robert confined himself to two recent investigations connected with the subject of water pollution. The first of these concerns the pollution problems of the River Tees. A thorough biological and chemical survey of this river has been carried out. This has shown that, whilst the river is unpolluted until its union with the Skerne, the entry of sewage from Darlington in this tributary causes appreciable pollution of the lower reaches. In the estuary, the condition of the river is

rendered much worse by industrial refuse containing cyanide. As a result of the investigation, the sewage disposal system of Darlington has been improved, and several undertakings upon Teeside have modified their plants, so that cyanide does not enter the river. With regard to the second topic—the disposal of milk factory waste—Sir Robert said that diluted milk, on account of its easily oxidizable nature, is a potent fish poison. As a result of its consistency, the refuse is difficult to treat by ordinary filtration methods, and success was first obtained by a modified activated sludge process. However, better results have been obtained by use of two filters in series. The refuse is passed first to one filter, *A*, and thence to the second, *B*. When *A* shows signs of clogging, usually in about three weeks, the direction of flow is reversed, that is, the liquid passes first to *B* and then to *A*. Filter *A* then recovers, and in due course the direction of flow is again reversed, and so on.

A Utilitarian Classification of Fragmentary Fossils

It is generally understood that the generic and specific names given to fossils cannot often be defined so precisely as those given to existing organisms. It is also recognized that the classification of extinct genera into families and orders is not always satisfactory. At the same time, readily distinguishable fossil fragments with definite characters need names, because they can frequently be used to determine the geological age of the rocks in which they occur. Such names are now proving especially useful in the microscopical study of sponge spicules, holothurian and echinoid spicules, plates of star-fishes and crinoids, conodonts, fish teeth and scales, otoliths, pollen grains, and other fragments which denote special conditions or mark horizons in series of rocks. The names are always in the Linnean form, and the so-called genera and species are grouped into so-called families and orders on the Linnean plan. Prof. Carey Cronquist, in a recent letter to *Science* (89, 314; April 7, 1939), and in an earlier article in the *Journal of Geology* (46, 975-984; Oct.-Nov. 1938), points out that this classification is misleading. For the various grades he proposes adopting the terms used in the old Roman army: for species he would use 'centuria'; for genus, 'manipulus'; for family, 'cohort'; and for order, 'legio'. He would thus distinguish a utilitarian classification from one which has the appearance of being natural.

Prevention of Road Accidents

THE report of the Select Committee of the House of Lords, appointed to consider what steps should be taken to reduce the number of casualties on the road, is discussed in *Roads and Road Construction* of May. It is pointed out that since 1910 the number of vehicles on the roads has increased twenty times, and in addition there has been a marked increase of mileage run per vehicle. During the same period the increase in road production is only about two per cent. The Committee is unable to accept the con-

clusions of the Ministry as to the causes to which these accidents are attributed. First, only one cause has been assigned to each accident, although the blame should be distributed in various proportions between road conditions, the road user, the vehicle and both parties involved in the collision. Secondly, the system of police reports on road accidents is often inadequate. Thirdly, the vehicles are sometimes so damaged that it is impossible to say whether they were defective or not. Fourthly, the Committee does not agree with the general principle on which the Ministry proceeds, that even if the condition of the roads and cars was unimpeachable the total of accidents would not be appreciably affected. The Committee believes that segregation of drivers, cyclists and pedestrians on the main roads must come and that the attainment of this ideal is essential if road safety is to be ensured. The highway code should be revised and it should be given the force of law. Witnesses before the Committee were strongly of opinion that an extensive and persistent campaign of educational propaganda should be undertaken and that it should be aimed at every class of road user. The improvement of main roads and the construction of new roads should be carried on simultaneously. 'Lay-byes' and 'draw-ins' should be made on every few miles of highway. The costly system of erecting kerbs should cease and guard posts should be erected 18 inches outside the edges of roads, at suitable intervals, sloping outwards at an angle of 15° from the vertical and provided with reflectors. Many other useful suggestions are made and we hope that some of them will be adopted.

The National Botanic Gardens of South Africa

In September 1938, the National Botanic Gardens of South Africa, at Kirstenbosch, and the Botanical Society celebrated their silver jubilee, and in the close of the year was produced a special number of the *Journal of the Botanical Society* with some very fine photographs, which show something of the beauty of the Kirstenbosch Botanic Garden with its ideal site on the slopes of Table Mountain. The number contains a brief note by the editor, Prof. R. H. Compton, upon the history of the Gardens, the site of which was selected in 1913 by the late Dr. Pearson, then professor of botany at the South African College. On a motion by Sir Lionel Phillips, the House of Assembly and the Senate passed unanimously in that year a motion that Kirstenbosch, bequeathed to the people of the Cape by Cecil Rhodes as part of his great Groot Schuur Estate, should be granted by the Government as the site of the National Botanic Gardens. The Government consented, making an annual grant towards its support, and at the same time the Botanical Society was formed, with some three hundred subscribers, to enlist public support for the new venture. The early onset of the Great War and the subsequent financial depression has caused delay, but the Director can record many striking indications of progress in the Gardens, and the Botanical Society has now nearly 2,000 members enrolled.

Biology in Education

THE Educational Advisory Board of the British Social Hygiene Council is attempting to give a new orientation to the teaching of biology by bringing more into touch with individual needs and social problems of to-day. With this aim in view, a Summer School has been arranged at Keble College, Oxford, during July 28–August 4. The School is primarily intended for teachers and others who are concerned with the place of biology in education, but membership will be open to anyone who is interested in the biological problems of modern human life. The inaugural address will be given by Prof. J. S. Watson. One section of the School will deal with current problems in social biology and their repercussions on the school-child, and another section will be concerned with problems of personal growth and development. These sections will be contributed by lecturers with considerable experience in the particular fields. The third course will include lectures on subjects of topical interest by prominent workers in biological research, including Mr. C. Elton, Dr. S. Zuckerman, Dr. H. N. Sinclair and Dr. Keith Murray. There will be considerable opportunities for discussion, while excursions to places of academic interest are being arranged. Further particulars can be obtained from Mr. T. H. Hawkin, Education Officer, British Social Hygiene Council, Tavistock House South, Tavistock Square, London, W.C.1.

The League of Nations Union

A LEAFLET issued by the League of Nations Union for the assistance of teachers preparing to address their pupils on Empire Day emphasizes the part played by representatives of the British Empire in drafting the Covenant of the League, which is described as a first attempt to apply on a world scale the ideals of democratic government common to the British Commonwealth of Nations and the United States of America. It suggests the possibility of federation of these and all other democratic States and the sharing of the control of colonial territories and our responsibilities for the development of colonial peoples to full nationhood. The League of Nations Union's arrangements for the summer include (a) for schoolboys and schoolgirls, Nansen Pioneer camps in Devon, Shropshire and Peebleshire and summer school at Geneva, and (b) for educational administrators and teachers, a conference to be held partly at Geneva, where members will attend the lectures and discussions of the Geneva Institute of International Relations, and partly at a mountain chalet.

The International Seismological Summary

THE April, May and June 1933 number of the *International Seismological Summary* has just come into the hands of those recipients who previously stated their wish to have copies straight from the press rather than wait until the annual set could be prepared and bound. This number consists of 14

dealing with 180 epicentres, 77 being new and the remainder repetitions from old epicentres. Five deep-focus shocks are listed, namely, those of April May 6, 24, 27 and 28. These were respectively in the Pacific Ocean north-west of the Ladrone Islands, in the Pacific Ocean south of Panama, in the deep ocean off the east coast of Japan, near the Marianas north-west of India, and in the Pacific Ocean immediately to the south of the main island of Japan. It would be an advantage if all recording stations could send in their readings promptly, so that the interval of six years between the occurrence of earthquakes and the publication of authoritative data on them could be reduced.

Wells and Steel Institute Awards

The following awards have been made by the Wells and Steel Institute: the Andrew Carnegie Gold Medal for 1938 to Dr. James White, of Glasgow, in respect of his paper on "Equilibrium at High Temperatures in Systems Containing Iron Oxides"; the Andrew Carnegie Gold Medal also to Dr. W. Ruff, of Stettin-Lahn, Germany, in respect of his paper on the Running Quality of Liquid Malleable Iron and Steel, published in 1936; the Williams Prize for 1938 for a paper of practical interest to Mr. D. V. Ishna Rao of Bhadravati, India, in respect of his paper on "The New Steel Plant of the Mysore Iron and Steel Works, Bhadravati, India"; the Ablett Prize for 1939, for a paper by a junior engineer, to H. Escher of Wollongong, Australia, for his paper on "Ten Years' Development in Steam Engineering at the Port Kembla Steel Works, N.S.W., Australia". The following Andrew Carnegie research scholarships have been awarded: O. Gessner (Breslau, Germany), £100 in aid of a research on the viscoelasticity of cast-iron alloys, steel, metals and alloys and slags; Ljunggren (Stockholm, Sweden), £100 for a microscopical investigation of grain boundaries; Parker (University, Leeds), £100 in aid of a research on oxidation and scaling of steel.

Institution of Electrical Engineers Awards

The Council of the Institution of Electrical Engineers has made the following award of premiums for papers read or published during the session 1938-39: *Institution Premium*, to Dr. T. E. Allibone, E. Bancroft and G. S. Innes; *Ayrton Premium*, to F. W. Lawton; *Fahie Premium*, to K. L. Wood; *John Hopkinson Premium*, to N. F. T. Saunders; *Oliver Premium*, to Dr. L. Hartshorn and E. Rushton; *Paris Exhibition (1881) Premium*, to R. Nelson; *Webster Premium*, to N. F. S. Hecht; *Overseas Premium*, to H. S. Hvistendahl; *Extra Premiums*, to G. H. Fletcher and A. Tustin; Dr. W. Betteridge and J. A. Laird; F. Brailsford; J. Higham and P. Wolfenden; Dr. K. L. Jensen; *Wireless Section Premiums*, to L. W. Hayes and B. N. McLarty (Duddell Premium); Dr. J. D. McGee and Dr. H. G. Lubczynski; Dr. R. L. Smith-Rose and Dr. H. G. Hopkins; P. R. Coursey and S. N. Ray; *Motor and Instrument Section Premiums*, to Dr. E. G. Ames, G. R. Polgreen and G. W. Warren (Silvanus Thompson Premium); Dr. H. M. Barlow; D. C.

Gall; G. F. Shotton; *Transmission Section Premiums*, to Dr. W. G. Radley and C. E. Richards (Sebastian de Ferranti Premium); Prof. W. J. John and Dr. C. H. W. Clark; E. W. W. Double and W. D. Tuok; T. R. Scott and R. C. Mildner.

Announcements

MR. F. J. DU TOIT, representative of the Union of South Africa on the executive council of the Imperial Agricultural Bureaux, has been appointed chairman of the council, in succession to Lieutenant-Colonel George P. Vanier, who resigned on taking up an official appointment abroad.

A COMMITTEE has been formed to present Prof. Jules Bordet, director of the Brussels Pasteur Institute, with a medal on the occasion of his being made a Commander of the Legion of Honour. Subscriptions should be sent to M. Georges Masson, 120 Boulevard Saint Germain, Paris 6^e.

At the annual general meeting of the Institute of Wireless Technology held on April 28, the following officers were elected for the year 1939-1940: *President*, Mr. Sydney A. Hurren; *Honorary Treasurer*, Mr. George Lea. The assistant secretary is Mr. E. Carter, I.W.T., 4 Vernon Place, Southampton Row, London, W.C.1.

PROF. FREDERICK C. LEONARD, chairman of the Department of Astronomy of the University of California, Los Angeles, will be visiting professor of astronomy in the summer session of the University of British Columbia, Vancouver, Canada, during July 3-August 18, while Prof. Daniel Buchanan, dean of the Faculty of Arts and Science and head of the Department of Mathematics of the University of British Columbia, will be visiting professor of astronomy and mathematics in the summer session of the University of California, Los Angeles, during June 26-August 4.

THE twenty-sixth annual meeting of the Swiss Röntgen Society will be held in Zurich on June 3 and 4, when the subjects for discussion will be cosmic radiation, the biology of cosmic radiation and the radiological appearance of pulmonary tumours. Further information can be obtained from the secretary, Dr. Max Hopf, Effingerstrasse 49, Bern.

VOLUME 35A of the *American Journal of Science* (1938) is dedicated to Dr. Arthur L. Day and contains a series of papers by members of the scientific staff of the Geophysical Laboratory of the Carnegie Institution of Washington, from the directorship of which Dr. Day retired in 1936. In a short foreword it is stated that the publications from the Laboratory number one thousand and contain a body of knowledge which is being successfully employed in the interpretation of geological observations. The volume contains several very interesting papers, among which may be mentioned those on the system water-boron oxide and the system calcium sulphate-water, which elucidate some previously obscure points in these subjects.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 860.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Emission of Neutrons accompanying the Fission of Uranium Nuclei

THE experiments of Halban, Joliot, and Kowarski described in NATURE¹ give an indirect proof of the neutron multiplication accompanying the fission of uranium nuclei after neutron capture. It can be deduced from these experiments that the additional neutrons are, on the average, faster than the photo-neutrons from radium C-beryllium used as active primary radiation. This conclusion is confirmed in a subsequent note² by the same authors in which they find that the neutrons contributed by uranium are able to produce the endo-energetic reaction $S(n,p)P$.

I have made some experiments on the same problem by a different method. Any increase of neutron effects observed when neutrons are allowed to pass through a given medium may be due: (a) to the inelastic scattering of neutrons, (b) to the reaction $(n,2n)$ or, exceptionally $(n,3n)$; (c) to an unknown cause, as in the case of uranium to the fission of its nuclei. In the experiments of Halban, Joliot and Kowarski, effects (a) and (b) are excluded owing to the integrating method adopted and to the low energy of the primary neutrons. But if these effects are present, it is possible to estimate their importance relatively to effect (c) by comparing uranium with substances in which only effect (a) or only (a) and (b) are possible. I have used aluminium and copper as comparison substances of the first and of the second type respectively.

A radon plus beryllium source was placed in the cylindrical axial hole of a cylinder of aluminium, of 2.2 cm. diameter and 5 cm. height, or, alternatively, of a cylindrical double-walled vessel of identical dimensions filled with uranium oxide (U_3O_8) or copper oxide. The mass of aluminium was 40 gm., of uranium oxide 49 gm. and of copper oxide 42 gm., and the thickness of walls could be neglected. The number of absorbing or scattering uranium nuclei was therefore 9.2 times smaller than the corresponding number of aluminium nuclei and 3.3 times smaller than the number of copper nuclei. One would expect, therefore, that the effect (a) due to aluminium, and effects (a) and (b) due to copper would be at least of the same importance and probably larger than the same effects due to uranium. The number and quality of neutrons issuing from these substances were compared by measuring the activation of a silver foil surrounding the cylinders in two cases: first, when no appreciable scattering of neutrons took place outside the cylinders, and secondly, when the neutrons were scattered back by a cylindrical sheet of paraffin wax of 6 mm. thickness. The results are given below, the figures being the total numbers of counts of a Geiger-Müller counter in corresponding series.

It can be inferred from these data that uranium gives off, in fact, more neutrons than aluminium or

copper. The increase is larger relatively to aluminium than to copper, which must be attributed to the reaction $(n,2n)$ occurring in this last element. In both cases, the increase is larger when the neutrons are slowed down by a small quantity of paraffin which shows that the additional neutrons from uranium are, on the average, slower than the bulk primary neutrons emitted by the source. As, from other evidence, they appear to be faster than the radium C-beryllium neutrons, we can estimate that their average energy must be of the order of 1 Mev.

Owing to the small number of uranium nuclei acting as absorbers or scatterers, it seems very unlikely that the apparent excess of neutrons given off by these nuclei should be due to some trivial cause like the inelastic scattering or the reaction $(n,2n)$. It probably represents the 'neutron shower' accompanying the fission of an activated uranium nucleus. Assuming the cross-section for this process produced by the neutrons from radon plus beryllium equal to 5×10^{-28} cm.², I calculate that the number of neutrons emitted in a single fission is equal to 6.

Statistical Calculation of Composite Decay Curves

WHEN uranium or thorium is bombarded with neutrons, a number of radioactive bodies are formed with periods ranging from a few seconds to several days. The decay of this assembly of fission product (not chemically separated) has been studied by Bjerger, Broström and Koch¹ and found to be practically the same for thorium and uranium. They have pointed out that this may be due partly to the fact that some of the fission products are the same for uranium and thorium but that, apart from this, the large number of periods would tend to wipe out any individual features of the decay curve.

This suggests that it would be possible to calculate the decay curve of such an assembly by the use of statistical assumptions on the distribution of periods. I have made such a calculation, based on admittedly crude assumptions, the result of which is indicated by the full line in the accompanying diagram, while the circles represent the measured decay².

In this calculation, the actual (discontinuous) assembly of periods is replaced by a continuous distribution with a suitable density function $f(\lambda)d\lambda$, where λ is the decay constant. We introduce the decay energy E , using Sargent's law $\lambda = k.E^2$, and assume the density function with respect to E to be constant.

(This may be justified by arguing that the decay energy of a radioactive isotope is roughly proportional to the

	Aluminium	Uranium	Increase (%)	Copper	Uranium	Increase (%)
No paraffin	9,089	9,335	2.6	4,810	4,900	1.8
With paraffin	10,195	10,775	4.8	10,049	10,323	2.4

difference, in nuclear charges, from the stable bar and that, after infinitely long irradiation, all values, within relevant limits, for this difference will be about equally represented among the nuclei resulting from the fission and subsequent β -decay.) The decay curve is then obtained by integrating:

$$J_{\infty}(t) = \int_0^{\infty} f(\lambda) e^{-\lambda t} d\lambda = \int_0^{\infty} \text{const.} \cdot e^{-\lambda t} d\lambda = \text{const.} \cdot t^{-1/n},$$

here $J_{\infty}(t)$ is the number of atoms decaying per unit of time, at the time t after the end of an infinitely long irradiation. If the irradiation has the finite duration T , we get

$$J_T(t) = \text{const.} (t^{-1/n} - (t+T)^{-1/n}).$$

This function, for $T = 100$ minutes and $n = 5$, is represented by the full line in the diagram. The close agreement with the experimental points would seem to support the choice of $n = 5$, but actually $n = 7$ (the dotted line) fits almost as well. The small differences are probably real and due to the individual periods. The smallness of these deviations emphasizes to what high degree the influence of the single periods is smoothed out, and indicates that the similarity between the thorium and uranium decay curves can be explained entirely on this basis, without assuming any similarity in the details of the distribution of periods.

Specific Heat of Copper Sulphate below 1° K.

It is well known that caesium titanium alum exhibits no specific heat anomaly due to Stark splitting, but only a large increase at very low temperatures attributed to magnetic interaction between the ions. This is explained by the well-supported hypothesis that the orbital momentum is quenched, leaving the ion effectively in an ^1S state since it possesses only

one electron spin, and Kramers has shown that the ^1S state is remarkably free from splitting due to the lattice field. The cupric ion would be expected to behave similarly, since susceptibility measurements show that the orbital momentum is largely quenched and since there is only one electron spin.

Experiments have therefore been carried out on the specific heats of copper sulphate and copper potassium sulphate below 1° K. Only relative measurements were attempted, so that the ordinates in the two graphs below are arbitrary. A constant influx of heat was maintained by an external γ -ray source, and the susceptibility was measured very precisely with an inductance bridge as the salt warmed up. The temperatures T^* in the curve below were derived on the

assumption that the Curie law holds below 1° K., but it seems unlikely that this is very much wrong in the upper part of the range since the law holds approximately at helium temperatures. No correction has been applied for the demagnetizing coefficient.

The specific heat of copper potassium sulphate is entirely in accord with expectation as it exhibits only a sharp rise due to magnetic interaction at a very low temperature ($0.01^\circ T^*$). It was accordingly possible to reach $0.005^\circ T^*$ by demagnetizing from 35.9 kilogauss and 1.17° K. The salt thus compares favourably with caesium titanium alum as a means of reaching extremely low temperatures, and has the advantage of being cheap and easily obtained.

It would be expected that copper sulphate would behave in much the same way as the double salt since the ionic moment is the same when calculated from the low field susceptibility of either compound

in the helium range¹, so that the quenching of the orbital momentum should apply equally in the two cases. Owing to the closer approach of the ions, the magnetic interaction specific heat is naturally shifted to a higher temperature, but the most remarkable feature is the presence of a very large specific heat throughout the whole region below 1° K. A first survey of the specific heat in the helium range indicated that it only falls to a low value at about 4.5° K. The large extent of the maximum is remarkable and may have important applications in experimental technique. The specimen was an ellipsoid of axis ratio 3.18:1, and consisted of very many small crystals of purity better than 99.9 per cent compressed by about 100 atmospheres into a coherent mass.

An attempt was made to estimate absolute temperatures by demagnetizing from different fields at the same bath temperature, and calculating the entropy of magnetization assuming the Brillouin formula and taking $j = \frac{1}{2}$. The calculation broke down for demagnetization from those fields which were so low that the level splitting was comparable with the energy of magnetization, but we may accept with caution the values for the lower temperatures produced by demagnetization from the higher fields. It appears probable that the susceptibility becomes extremely large at 0.05° K., so that we might expect ferromagnetism near this temperature. The lowest point reached with copper sulphate was 0.08° K. (0.03° T*), but no hysteresis was observed with a ballistic galvanometer, though the arrangement was amply sensitive to detect the effect in ferric alum.

While it would be rash at this stage to attempt a detailed explanation, the general conclusion must be drawn that in copper sulphate there does exist a splitting of the energy levels such as to give a high specific heat in the helium range. Unless the effect is due to exchange forces, which seems improbable in view of the high dilution, it must be assumed that the electric field of the lattice can, in certain circumstances present in copper sulphate but absent in copper potassium sulphate, produce a level splitting even in an ion which is effectively in an ¹S state owing to the quenching of its orbital momentum.

Sparking Potential of Deuterium (Heavy Hydrogen)

THE sparking potential of heavy hydrogen between parallel electrodes was recently measured in this laboratory, and the influence of the material of the cathode was also examined. In accordance with the general theory of the discharge, the effect of a change of cathode material was most pronounced at the minimum sparking potential, which was found to be characteristic of the metal of the cathode after it had been de-gassed. Further, for any given metal the minimum sparking potential was found to be very sensitive to the state of the cathode surface even after it had been de-gassed in a vacuum furnace, as exposure of the cathode to the gas for any length of time had a marked effect in lowering the sparking potential.

The value of the minimum sparking potential of heavy hydrogen characteristic of a steel cathode was found to be 339 volts, as the experiments indicate that lower values, obtained after the metal had been exposed to the gas at pressures exceeding about 20 mm. of mercury, were probably due to adsorbed layers of the gas on the cathode surface. However, in many cases, bombardment of the cathode by positive ions in a discharge was able to restore the higher values of the sparking potential. Similar effects were also observed with light hydrogen, and the minimum sparking potential with a steel cathode was found to be more than 10 per cent greater than that recently given for a platinum cathode¹.

Hence the results show that typical diatomic gases like hydrogen and deuterium behave like the monatomic gases^{2,3}, in that the minimum sparking potential is strongly characteristic of the cathode material, and increases with the work function of the cathode, a result which was not supported by the early measurements with the diatomic gases.

In comparing the two isotopes, it was found that for six different cathodes the minimum sparking potential of deuterium was greater than that of hydrogen by about 3 per cent, but that when the spark parameter pd was about 5 (mm. of mercury $\times$ cm.) the sparking potential V of the two gases was the same. The normal cathode fall is also known to be greater in deuterium than in hydrogen⁴. Now, it is reasonable to assume that the coefficient of ionization of deuterium by electrons is not very different from that of hydrogen, especially at high values of the ratio of V/pd , a view supported by the measured values of the force in the positive column⁵. On this assumption, then, the difference between the sparking potentials of the two gases can be accounted for if at the same value of V/pd , the deuterium positive ion is 20 per cent less effective than the hydrogen ion in liberating electrons from the cathode, although both ions have the same potential energy. The difference must therefore be due to the lower velocity of the deuterium ion. Further, if this constitutes the main difference between the electrical properties of the two gases, it also accounts for the equality in the sparking potentials when pd is about 5.

Penetration of the Potential Barrier and Formation of AlH

SEVERAL investigators have observed peculiar anomalous intensities in the band system ¹II — ¹Σ of the spectrum from AlH. Generally the lines from rotational levels $J > 17$ in $v = 0$ and $J > 7$ in $v = 1$ ¹II are weakened or absent according to the circumstances in the light-source.

In order to investigate whether formation of AlH takes place in the ¹II-state, I have repeated an experiment of Wurm¹, who investigated the spectrum of aluminium in a hydrogen atmosphere in an electric furnace. My spectrograms show that all

lines from upper levels with $J > 19$ in $v = 0$ and > 7 in $v = 1$ have appreciably greater intensities than lines from levels with lower J -values. These enhanced lines are those absent at low pressure in the spectrum of the arc, that is, lines emitted from the predissociating levels above the limit of dissociation in $^1\Pi$. In the furnace, however, at all pressures investigated (1-400 mm.) the AlH-spectrum is the appearance mentioned above, if the exposures are taken immediately after the furnace was filled with fresh aluminium and hydrogen. The great intensities of the enhanced lines show that a considerable new formation of AlH-molecules takes place in these states. This is a direct proof and demonstration of molecular formation by the hydrogen atom penetrating the potential barrier.

During the investigation of this problem, the following observations were made:

(1) When the temperature is increased in the tube, the intensity is shifted toward larger J -values of the enhanced lines.

(2) The (1,1) band is more intense than the (0,0) band and the (1,2) band more intense than the (0,1) band. These intensity relations are the opposite to those in the spectrum of the AlH arc.

(3) In the (0,0) band the enhanced lines of the β -branch have almost the same intensities as the corresponding lines of the Q -branch and considerably greater intensities than the corresponding R -branch lines.

(4) The effects mentioned in (3) are not appreciable in other bands of $^1\Pi - ^1\Sigma$ investigated.

(5) If several exposures are taken successively without changing the conditions of the light-source, the spectrograms show that the intensities of the bands, especially the intensities of the enhanced lines, decrease, so that the enhancing effect is gradually diminished.

(6) The effects of (5) develop faster at low than at higher pressures.

(7) The intensity ratio between the enhanced and the remaining lines is greater in the (0,0) band than in the other bands.

(8) In the (0,0) band, Q_1 and P_2 are superposed, and this line has on all my plates anomalous low intensity.

Further work in this line, which is in progress, will be published later in detail in connexion with discussions regarding the origin of these very distinct facts. Further, I shall try to apply the results obtained to explain the anomalous intensities in the spectrum of HgH and the pressure effects in AlH.

Stress Tensor and Particle Density in Special Relativity Theory

THE stress-momentum-energy tensor of a relativistically perfect fluid in the absence of exterior forces

$$T_{ij} = -(\rho + p)\delta_{ij} + pg_{ij}, \quad (1)$$

where δ_{ij} , $i, j = 1, 2, 3, 4$, g_{ij} is the fundamental tensor of space-time (signature $---+$),

$\frac{dx^k}{ds}$ is the Minkowskian velocity of the macro-

scopical motion ($\delta^k_k = 1$), p the pressure and ρ the proper energy-density. Elsewhere¹ I have shown that a fluid is only perfect in the relativistic sense if it is 'perfectly perfect', that is, if not only viscosity but also heat conduction is negligible. So long as (1) holds, no transition of heat between adjacent parts of the fluid occurs and the motion takes place without increase of entropy.

The question has been raised by Eddington² whether ρ/mc^2 can be identified with the proper particle density if the fluid is chemically homogeneous, m being the mass of one molecule. Eddington's answer is in the negative; according to him, the particle-density is ρ_0/mc^2 where $\rho_0 = -T^i_i = \rho - 3p$. Recently Synge³ has shown Eddington's result to be incorrect and re-established ρ/mc^2 as the particle density.

It can be shown, however, that the proper particle density is neither ρ/mc^2 nor ρ_0/mc^2 but a third quantity, say, $\bar{\rho}/mc^2$, independent of both and not even derivable from T^i_i at all. But for an ideal gas of not excessively high temperature, $\bar{\rho}$ is approximately the mean value of ρ and ρ_0 . Hence, though Eddington's value ρ_0 for the proper particle density was wrong, his criticism against Schwarzschild's value ρ was right. The general discussion will be given elsewhere; here the following elementary argument may suffice. Though the result is valid in general relativity also, it has been formulated here for special relativity theory only. For simplicity, factors $\sqrt{-g}$ have been dropped.

The argument depends upon the fact that the molecules have motions different from the macroscopical motion. Let v be the proper particle density of molecules moving with a definite Minkowskian velocity

$$e^k = \frac{dx^k}{ds} (\delta^k_k = 1), \text{ so that } v \text{ is a function of } e^k \text{ and}$$

that ndV is the number of molecules contained in a 3-dimensional element dV orthogonal to their world-lines, that is, to e^k . Elements like dV are supposed to contain still a large number of molecules. Then the number of molecules contained in an arbitrary 3-dimensional element of magnitude dV and normal to the unit-vector n^k is $ve^k dV_k$, where $dV_k = n^k dV$. Hence the total momentum and (negative) energy of these molecules is $-mc^2 ve_k e^k dV_k$. After summation with respect to all directions e^k this must become $T^k_k dV_k$ hence

$$T^k_k = \Sigma - mc^2 ve_k e_k. \quad (2)$$

In particular, $\rho_0 = -T^i_i = \Sigma mc^2 v_i$. Moreover, choosing orthogonal co-ordinates at rest with respect to the macroscopical motion (so that $\delta^1_1 = \delta^2_2 = \delta^3_3 = 0$, $\delta^4_4 = 1$), $e_k = 1/\sqrt{1 - v^2/c^2}$, where v is the ordinary velocity belonging to e^k . Hence

$$\rho = -T_{44} = \Sigma mc^2 v(e_4)^2 = \Sigma mc^2 v/(1 - v^2/c^2) \sim \rho_0 + \rho_1 + \rho_2, \quad (3)$$

where $\rho_1 = \Sigma mv^2 v$, $\rho_2 = \Sigma mv^4/c^2 v$, and powers of v^2/c^2 higher than the second have been neglected.

The number of molecules $\bar{\rho} dV/mc^2$, however, contained in an element dV orthogonal to the macroscopical world-lines, that is, to δ^k_k is $\Sigma ve^k \delta^k_k dV = \Sigma ve_k dV$; hence

$$\bar{\rho} = \Sigma mc^2 ve_k = \Sigma \frac{mc^2 v}{\sqrt{1 - v^2/c^2}} \sim \rho_0 + \frac{1}{2}\rho_1 + \frac{1}{2}\rho_2. \quad (4)$$

The equation of state for an ideal gas (which is valid in relativity theory also⁴) leads to the relation $p = kT\bar{\rho}/mc^2 = \tau$, where kT is the proper temperature measured in energy units, so that $\tau = kT/mc^2$

is a very small number (of the order of about $10^{-12}T$); ρ_1 is of the order of τ and ρ_2 of the order of τ^2 . As, moreover, $p = \frac{1}{2}(\rho - \rho_0)$, we have:

$$\rho = \bar{\rho} + \frac{1}{2}p + \frac{1}{2}\rho_2 = \bar{\rho}(1 + \frac{1}{2}\tau) + \frac{1}{2}\rho_2 \quad (5)$$

$$\rho_0 = \bar{\rho} - \frac{1}{2}p + \frac{1}{2}\rho_2 = \bar{\rho}(1 - \frac{1}{2}\tau) + \frac{1}{2}\rho_2 \quad (6)$$

In the second member of (5), the first term corresponds to the sum of the proper energies of the molecules (which is smaller than the proper energy of the element of matter they constitute), the second term to the classical kinetic energy of the relative translatory motion, and the third term to the relativistic correction. If the latter is neglected (which means neglect of v^2/c^2 in (3), (4)), we obtain from (5), (6):

$$\bar{\rho} \sim \frac{1}{2}(\rho + \rho_0) \quad (7)$$

Finally, it may be remarked that in the case where p is a function of $\bar{\rho}$ alone, so that the hydrodynamical integral $P = \int d\rho/\bar{\rho}$ exists, $mc^2(1 + P)$ is the average value per molecule of the so-called proper *enthalpy* or heat-content $E + pV$, so that¹

$$T\dot{\eta} = -\bar{\rho}(1 + P)\dot{\eta} + p\dot{\eta} \quad (8)$$

Motion of the Spiral Nebulae

THE shift of the spectrum lines of the spiral nebulae towards the red is commonly accepted as evidence of a high velocity in the line of sight away from the solar system.

I venture to suggest that the shift may not be a Doppler effect at all; but the well-known genuine slowing down of atomic vibrations predicted by the Lorentz-Larmor electromagnetic theory, which has recently been conclusively demonstrated in laboratory experiments in the case of hydrogen canal rays by Ives and Stilwell¹.

On this interpretation, all the extra-galactic nebulae must be regarded as rotating about the galaxy as centre, so that we have a velocity of revolution instead of a radially outward one; but its magnitude is even more staggering than the required radial velocity. If $\Delta\lambda$ is the increase in the wave-length, λ , the required radial velocity u is given by $\Delta\lambda/\lambda = u/c$, where c is the velocity of light; but the required transverse velocity v is given by $\Delta\lambda/\lambda = (1 - v^2/c^2)^{-1/2} - 1$; or by $\Delta\lambda/\lambda = v^2/2c^2$ if v^2/c^2 is negligible. In this case the relation between v and u for the same shift is $v^2 = 2cu$.

Thus, taking the typical nebulae velocities at distances of 10^7 and 10^8 light-years as 1,700 and 17,000 km./sec. respectively, the required transverse velocities work out as 32,000 and 100,000 km./sec. respectively. So nebulae at these two distances would take 580 and 1,850 million years respectively to perform one revolution; this gives proper motions too small to have been detected so far.

Since the radial velocity u has been found to be proportional to the distance r , we shall have v^2/r constant. Thus all the nebulae possess approximately the same radial acceleration. If the nebulae occupy a spherical volume, with rough symmetry, this means that the total mass inside a sphere of radius r is proportional to r^3 . But the radial acceleration requires a much greater amount of mass than appears actually to be present. I find that the number of nebulae, each of mass 3,500 million suns, which would be required inside spheres of 10^7 and 10^8 light-years, works out at 2×10^8 and 2×10^{10} respectively. This latter seems about 10,000 times too great. The acceleration might be accounted for by the supposition of cosmic dust between the nebulae, of densities 2.7×10^{-10} and 2.7×10^{-12} gm./c.c. at 10^7 and 10^8 light-years respectively, which shared in the general rotation of the system of nebulae. This would give a mass (about 12 grams of material per sq. cm. of cross section, lying between distances of 10^8 and 10^9 light-years, which, although it is only about 1 per cent of the earth's atmosphere, will be difficult to reconcile with no more absorption than actually exists, unless the material exists as separate atoms or molecules instead of as dust particles.

This possible rotation of the whole system of spiral nebulae makes the estimated rotation of the galaxy require further investigation.

I put forward this suggestion on the motion of the spiral nebulae to see if it can be found tenable in the face of criticism. I know it has its difficulties, especially as far as I know, no evidence of symmetrical distribution with respect to any axis has been discovered among the spiral nebulae; but it avoids some of the difficulties associated with the idea of radial velocities.

Influence of Micelle Formation on Flotation

It has been noted¹ that cetyl-trimethyl-ammonium bromide is a collector for (that is, induces floatability of) several different types of mineral. The minimum effective concentration of the compound (threshold concentration) required to induce flotation differs from mineral to mineral, but when the concentration has been increased to a value lying between 100 mgm and 500 mgm. a litre, flotation ceases to be possible for all minerals. This is about the concentration (280 mgm. a litre) at which micelle formation of the ammonium salt becomes considerable².

We have recently found that flotation ceases to be possible in solutions of certain other paraffin chain compounds, for example, sodium cetyl sulphate and potassium laurate, at the concentration at which micelle formation occurs. Moreover, neutral salt such as sodium and calcium chlorides, which diminish the concentrations necessary for micelle formation also diminish the concentrations necessary to prevent flotation. It is concluded that there is a direct correlation between micelle formation and prevention of flotation.

Flotation is dependent upon orientated adsorption of the collector at the mineral surface, which enables contact with the air bubble to occur, but contact is hindered¹ when the air bubble is 'armoured' by adsorbed paraffin chain molecules and micelles. The

proved by the fact that, in solutions just below the strength required for micelle formation, contact between mineral and a newly formed bubble may be possible when contact with an aged bubble is impossible.

Structure of Alginic Acid

ALGINIC acid, the industrial importance of which is increasing, constitutes a large proportion of the dry weight of certain seaweeds. It is noteworthy among polysaccharides in that it appears to be built up entirely of *d*-mannuronic acid residues, although its resistance to hydrolysis is so great that no quantitative transformation to *d*-mannuronic acid has been achieved¹. The results we have recently obtained from a study of the action of methyl alcoholic hydrogen chloride on the polysaccharide show that high yields of *d*-mannuronic acid are obtainable from alginic acid.

Furthermore, we succeeded in isolating, by the use of the same reagent, a partially degraded form of alginic acid of comparatively low molecular weight. Except for the lower viscosity of its solutions, this material differed little from the original alginic acid, but it was more amenable to chemical transformation. From it, by use of thallium ethoxide and methyl iodide, we obtained the corresponding fully methylated derivative. This methyl derivative was exceptionally stable towards hydrolytic agents, but two methods were developed which gave insight into its chemical structure. When boiled with strong nitric acid it underwent hydrolysis, followed by degradative oxidation, with formation of *meso*-dimethoxy succinic acid (v). This indicated that in each of the mannuronic acid residues the methyl groups were attached at C₂ and C₃.

Conclusive proof of this was provided as follows. Methylated alginic acid on drastic treatment under pressure with methyl alcoholic hydrogen chloride

gave the methyl ester of 2:3-dimethylmannuronide (ii). The latter, after hydrolysis followed by oxidation (bromine water), yielded 2:3-dimethyl mannosaccharic acid (iii), and this in turn was oxidized by periodic acid (reagent for oxidative degradation of α β glycols²). The products were glyoxylic acid (iv), and the half aldehyde of *meso*-dimethoxy succinic acid from which the crystalline methyl *meso*-dimethoxy succinate (v) was then obtained quantitatively. It follows that in the methylated alginic acid the methyl groups were situated at C₂ and C₃, respectively, and it appears that alginic acid is composed of *d*-mannuronic anhydride residues linked glycosidically. In addition, it is clear that in alginic acid there occurs a chain of *d*-mannuronic acid residues in each of which the hydroxyl groups at C₂ and C₃ are free. The glycosidic linkage must therefore be either 1:4 (pyranose ring structure) or 1:5 (furanose ring structure).

In view of the extreme stability of alginic acid and its large negative rotation, it is highly probable that the ring structure is pyranose and that the linkage between the residues is 1:4. We conclude therefore that at least the major portion of the alginic acid molecule is composed of β -*d*-mannuronic acid residues linked as shown in (i). At present, owing to the experimental difficulties connected with the hydrolysis of such intractable material, it is not possible to say whether the whole of the alginic acid molecule is so constituted, and further work on this subject is in progress.

The structural resemblance between (i) and the formula for cellulose (chains of β -*d*-glucopyranose units with 1:4 linkage) is apparent, and a further point of interest is that in pectic acid³, as shown recently in this laboratory and by Dr. F. Smith of the University of Birmingham, a similar structure is encountered, the residues in this case being α -*d*-galacturonic acid (pyranose form) linked glycosidically through positions 1 and 4.

Further Experiments on Homing in Storks

As previously stated¹, white storks have a prominent instinct of direction. In order to obtain further information on this problem we carried out the following experiments in 1938: (1) to ascertain the maximal distance from which birds may be carried and still remain capable of homing; (2) to ascertain whether the birds show differences in their homing abilities, when they are taken in different directions; (3) to examine the possible influence of terrestrial magnetism on homing.

We succeeded in catching in Butyny near Lwów twelve adult birds. Thanks to the help of Polish Airways 'LOT', as well as to the co-operation of naturalists in Finland, Estonia, Germany and Portugal, the storks

have been taken: to Lisbon (2,700 km. to the west; maximal distance in air-line); to Berlin (680 km. to the west; problem of magnetism and of the west direction); and to Harviala in Finland (1,132 km. to the north; problem of magnetism and of the north direction).

Each of these three groups was composed of four birds, specially marked with bright colours and rings, so as to be easily recognized on return to their nests in Butyny. Besides that, after long preliminary experiments we succeeded in fastening magnets to the heads of three birds of each group destined for Germany and Finland. The magnetic fields of the magnets were calculated according to the formula of Gauss. They were several times stronger than the magnetic field of the earth, which would mean, according to Stresemann's hypothesis, that they ought to eliminate its influence.

Our experiments did not give quite satisfactory results. That was partly due to difficulties in obtaining a larger amount of experimental material, and also to very unfavourable meteorological conditions in the second half of June 1938 when the experiments took place.

With regard to the first problem, though the birds behaved in identically the same way as others did in our first experiments in 1937, not one of the four birds of the Portugal group landed home. Of course the maximal distance from home had been exceeded (2,700 km. by air-line in comparison to 2,260 km. of the preceding year Lydda (Palestine) to Butyny). On the other hand, it is possible that the obstacles caused by the desert-plateau of Spain, the Pyrenees and the Alps were very difficult to overcome, and the air currents, of which storks take generally great advantage, were unfavourable.

In the second experiment, three birds, out of four released near Berlin, came home. Their flight homewards was much slower this time. It varied between 43 and 107 km. daily, in comparison to 165 and 188 km. in the year 1937. It is yet impossible to give a definite decision concerning any influence that the earth's magnetism may exercise on the capacity of homing in birds, because of two control birds without magnets one came home. Yet comparing previous experiments (when birds had mostly been transported to the south, that is, along their usual migration direction) the return of birds of the Berlin group proves that they are capable of homing not only from great distances but also from directions and countries hitherto unknown to them.

The results observed of the transport of birds to Finland are still more striking. In this group three birds had magnets fastened to their foreheads and one bird a control bar, of the same weight. Owing to the fact that storks appear rarely in Finland, and owing also to the help of the members of the Zoological Museum in Helsingfors, we were well informed about the flight of the birds in Finland and partly in the neighbouring countries as well. Not one of the birds came home; two of them perished for unknown reasons. The most interesting fact is that the birds, after having left Harviala, were seen in many parts of the country, mostly on the beach of the 100 km. wide Finland Bay, which lies in between the straight and shortest air-line to Poland. From there they went back to Harviala at different intervals. Most probably the birds found the bay too wide to fly over. (The Straits of Gibraltar, the Bosphorus, Sea of Marmora, their usual routes,

are much narrower.) Their return to Harviala proves a curious attachment to a new locality.

Further experiments will be conducted in 1939.

Hypospadias and Non-descent of the Testes caused in Rats by Progesterone

Hain¹, Wiesner², Greene and Ivy³ have reported the occurrence of hypospadias in young female rats following the injection of oestrogens or androgens (oestrone, androstanediol, testosterone) into the pregnant mothers or into the young soon after birth. Lacassagne⁴ has observed a similar lesion in a male rabbit treated from birth with oestrone. I also have observed hypospadias in female rats and mice treated from birth with oestrone or testosterone. The males have not shown any malformation of the penis; but their testes have failed to descend into the scrotum at the normal time. In a recent experiment, fifteen new-born Wistar rats were given subcutaneous injections of 0.5 mgm. progesterone in sesame oil on each of the three post-natal days, and 1 mgm. was given three times a week until the twenty-third day, after which no further treatment was applied except that on the forty-fourth day 2 mgm. progesterone were given to each of the males. At this time the eight females all showed hypospadias and the seven males all had undescended testes. On the sixty-fifth day two only of the males have testes in the scrotum. Normally the testes would have descended not later than the fortieth day.

The comparable results obtained by all these three types of gonadal hormones seem to be worth recording.

The progesterone used was most kindly given by the Ciba Company.

New Data on Spontaneous Mutations

Among the factors that are of decisive importance in the development of the individual, but do not influence directly its germ-cells, the nutritive regime must be mentioned in the first place. The purpose we had in view was to study the rapidity of mutation process in *Drosophila melanogaster* under conditions of an avitaminous B₃ regime.

We made use of the line 'white' for investigation. By way of many times repeated transfers of the flies (Guyénot method, 1911) a complete elimination of microflora was achieved and an aseptic line obtained.

Three groups of individuals could be employed for genetical purposes: (1) the control individuals

which developed on a yeast medium (10 days duration of development); (2) individuals that had the vitamin B₁ given them on the twentieth day of their larval life (the flies began to emerge on the thirtieth day after the eggs had been laid); (3) individuals which had fed on yeast medium for a period at the longest of twenty-four hours after hatching and continued their development on an avitaminous B₁ medium (10 days duration of development).

The adults of group (2) did not differ from the controls in regard to duration of life and fertility (males only were studied). But these individuals in the period of their larval life preceding the addition of yeast medium have quite certainly been subjected to a strong and unfavourable effect of an avitaminous B₁ regime (when no yeast medium is added more than 99 per cent of individuals die on the eighteenth or the twenty-second day of their larval life). In adults of group (3) the duration of life and fertility are greatly diminished: the vitamin B₁ not only influences metamorphosis (a minimal amount suffices for securing the setting in of the pupal stage and the emerging of the fly), but the organism as a whole is likewise strongly influenced by it.

The rate of lethal mutations found in the X-chromosomes (method *OLB*) of the control ♂♂ (0.21 ± 0.08) and the ♂♂ of group (2) (0.15 ± 0.07) is about the same in both cases (difference = 0.06 ± 0.11). At the same time, if the number of originated mutations corresponded to the time elapsed, the percentage of mutation brought into evidence in the experimental material (duration of development thirty days) should have been three times as large as in the control (10 days duration of development).

The percentage of lethal mutations found in the II chromosomes (method *Cy sp/L**) in experimental ♂♂ of group (2) (1.07 ± 0.16) is about on a par with the rate of mutations in the II chromosomes in the control (0.66 ± 0.13) or even somewhat lower than the latter (difference = 0.41 ± 0.21). Statistically the difference between the number of mutations found in II chromosomes of group (2) and the number of mutations to be expected if the rapidity of the mutation process did not depend on the rapidity of individual development is quite real (difference = 43.07 ± 8.30). The experiment just described contains, moreover, the data indicating that the suggestion of a germinal selection acting in our experiment has no validity: the relation of the percentage of mutations found in ♂♂ of group (2) to that in the control is about the same for the X as for the II chromosome.

The question arises whether it is a simple coincidence that the percentage of mutations relative to the number of chromosomes studied proves to be about equal in ♂♂ of group (2) and in control ♂♂. Does not this fact indicate that in ontogenesis forces are acting that occasion accumulation of a certain number of mutations in the individual's germ-cells up to the close of metamorphosis? For the solution of this problem individuals of group (3) were employed (their development as in control group lasts 10 days).

The percentage of lethal mutations found in the II chromosomes in group (3) and in the control group is the same in both cases (difference = 0.01 ± 0.43). Thus we may consider it as proved that the decrease in rapidity in the mutation process, brought into evidence in the preceding experiments in which ♂♂ of group (2) were studied, is due to the fact that in this group the development is of longer duration. The decisive role may quite possibly belong here to

a slowing down of the process of spermatogenesis, or more exactly, in connexion with the latter, a slowing down of the rate of reproduction ('multiplication') of the genes.

Centripetal Xylem in the Pedicel of a Monocotyledon

THE centripetal xylem in the stem among the vascular plants is confined to the Pteridophyta and lower gymnosperms, the Pteridosperms and the Cordaitales. The vegetative stem of Cycadales and Coniferales lacks centripetal xylem; but it occurs in a poorly developed condition in certain conservative regions like the reproductive axes and the leaf traces. In the Gnetales and the angiosperms the axial organs show exclusively the endarch condition, and the centripetal xylem is altogether absent from the primary vascular bundles.

In my study of the floral anatomy of *Gagea fascicularis* Salisb., however, I have seen distinct traces of centripetal xylem in the vascular bundles of the pedicel. The pedicel in this species at its distal end shows six bundles. Three of these are large and three alternating are small. The smaller bundles frequently show in addition to the

normal centrifugal xylem one or two vessels to the inside of the first-formed narrow protoxylem elements. The structure is shown by the accompanying figure. Details will be published elsewhere.

The structure of the vascular bundles in the flowers of *Gagea fascicularis* is also interesting in showing a distinct intrafascicular cambium.

Ethmoplax, a New Name for *Stratiphyllum* Smyth

At a meeting of the Royal Irish Academy held on May 8, 1933, I proposed the name *Stratiphyllum* (as *Stratophyllum*) for a Carboniferous tabulate coral from Tournai, Belgium. The name was not published until September 8 of that year¹. Dr. Stanley Smith has directed my attention to the fact that in the meantime Dr. Walther Scheffen had published the same generic name for some Silurian rugose corals from Norway².

I therefore wish to rename the Tournaisian form *Ethmoplax* (ἔθμος, a strainer; πλάξ, anything flat and broad, a plain).

Kinetochore or Centromere?

IN his recent communication¹, Dr. Mather seems to have no argument against the applicability of 'kinetochore'. He sponsors 'centromere' largely because it is used by a number of investigators. But I, for one, am not convinced that it is the "best term in use to-day". To Dr. Mather 'centromere' may imply a visible particle, but to many it will connote a part that is centrally placed in a topographical sense. No such meaning is of course intended. My advice concerning the confusion that may arise from the addition of still another to the series of words involving 'centre' rests on my experience as a teacher. Perhaps the validity of such advice will be more apparent if I point out that in 1936 Darlington² himself used 'centrosome' when he evidently meant 'centriole'. The argument that no such confusion has attended the use of a series of terms involving 'chroma' is not well chosen, for in one place in the same paper (p. 266) Darlington writes 'chromosome' when he means 'chromomere'.

So far as priority is concerned there seems little room for argument. Sharp proposed the term 'kineto-

chore' in 1934. Nebel³ adopted it in 1935 and myself⁴ first used it in June 1936. Darlington², in 1936, was still using "spindle attachment chromomere" and, if I am not mistaken, it was not until December 1936, six months after my publication, that he employed 'centromere', probably unaware of its previous use in a different sense by Waldeyer. He made no reference at all to 'kinetochore' which, as I have said, does not carry the disadvantages of the term sponsored by himself.

I suggest that we submit the matter to the proper committee at the coming Congress of Genetics at Edinburgh. I, for one, should be quite willing to accept its decision.

Points from Foregoing Letters

J. ROTBLAT compares the increase in the neutron effect obtained by means of uranium with that produced by aluminium and copper, and concludes that v. Halban, Joliot and Kowarski are correct in ascribing the uranium effect to the increase in the number of neutrons resulting from the fission of uranium nuclei, rather than to the simple reaction ($n, 2n$).

O. R. FRISCH compares the radioactive decay curve of the uranium fission products with a calculated curve, the calculation being based on simple statistical assumptions about the distribution of decay periods. The good agreement indicates that the individual features of the decay curves are very nearly eliminated on account of the large number of decay periods.

J. ASHMEAD has measured the specific heats of copper sulphate and copper potassium sulphate below 1° K. The curve for copper potassium sulphate has only a maximum due to magnetic interaction, but copper sulphate has also a maximum at higher temperatures. This indicates that there may be a contribution to the specific heat from Stark splitting even when the orbital momentum would normally be considered quenched, leaving the ion in an ^4S state.

The minimum sparking potential of deuterium is found by F. LLEWELLYN JONES to be strongly characteristic of the cathode material, and is about 3 per cent greater than that of hydrogen. At higher pressures the sparking potentials are identical.

G. STENVINKEL states that the emission spectrum of AlH from an electric furnace shows that AlH is formed in an activated electronic state. This formation is a function of the time. There are several anomalies in the intensity relations of this band spectrum.

D. van DANTSIG considers that the particle density of a chemically homogeneous, relativistically perfect fluid cannot be calculated from the stress tensor, as it depends upon the temperature also. For an ideal gas the relations between these quantities can be

determined explicitly. This is done to a second approximation.

A. EAGLE suggests that the whole system of extragalactic nebulae may not be retreating from the galaxy but revolving about it; the displacement of the spectrum lines being due to a change of period of vibration due to the velocity.

E. L. HIRST, J. K. N. JONES and Miss W. O. JONES show that the polysaccharide alginic acid, which is an important constituent of certain seaweeds, can be transformed into a less viscous form of low molecular weight. A major feature of the structure of alginic acid is a chain of *d*-mannuronic acid residues linked together by glycosidic links connecting the 1:4 positions. This structure is compared with that of cellulose and that of pectic acid.

Further experiments on homing in white storks carried out by K. WODZICKI, W. PUCHALSKI and H. LISCHE, attempted to examine the influence of the magnetic field of the earth and the reactions of birds taken in different directions.

The three main types of gonadal hormone will produce in some circumstances a similar biological effect. A new example is recorded by H. BURROWS, who finds that, given to rats on the day of birth and afterwards progesterone, like oestrone or testosterone, will cause hypospadias in females and delayed descent of the testes in males.

J. M. OLSEN states that the percentage of lethal mutations found in the X and also in the II chromosomes in *Drosophila melanogaster* individuals that had vitamin B₁₂ withheld until the twentieth day of their larval life is about the same as in the control group. If the number of induced mutations corresponded to the time elapsed, the percentage of mutations brought into evidence in the experimental group (duration of development thirty days) should have been three times as large as in the control (duration of development ten days). The decrease in rapidity in the mutation process may be due to a slowing down of the process of spermatogenesis.

Research Items

Origin and Physical Qualities of the Minoan Shield

THE peculiar shields represented on seal stones, etc., of the Middle and Late phases of the Minoan bronze age culture have been repeatedly discussed, especially since they were claimed by Wolfgang Deibel as the type described in the Homeric poems. The construction of this kind of shield and its connexion with certain other shields is discussed on strictly archaeological evidence by Prof. J. L. Myres in *Man* of March 1939, while Prof. A. E. H. Love considers its shape and physical qualities. The famous Lion Hunt inlaid bronze dagger from Mycenae shows two types of shield: (a) a rectangular shield, and (b) the 'figure of eight' shield. The former is also seen in side view as an upright semi-cylinder—the 'tower shield'. Both were worn suspended by a strap from the left shoulder, either in front or behind, leaving both hands free. The shields are recognizably of ox-hide, and were flexible. They were stiffened around the margin by a metal rim or reinforcement of leather, affixed with stitches or rivets. Nothing quite like these Minoan shields is known from neighbouring cultures. They were evolved, not from the Egyptian parrying shield, but from some such protective wrapping as that shown on a fragmentary case of silver from Mycenae, where the fighting men wear a loose body protection slung over the shoulder and hanging to the knees. The elaboration of this protection was in two directions: (a) if the ox-hide were stiff enough, it could be bent permanently into a half-cylinder, resulting in the 'tower shield', or (b) if a lighter and more flexible hide were used, it buckled with its own weight, but the buckling was utilized to produce the 'figure of eight' shield, with its peculiar combination of rigidity along the two lines of folding and elasticity elsewhere, increasing towards the margin. When manipulated in action by the two hands exerting pressure at the point of rigidity and suspension, it assumed the 'figure of eight' shape, essentially two obtuse cones intersecting along the two halves of the original fold, which Prof. Love suggests are the stiffest of the generators of such cones.

Individual Interests and Vocational Adjustment

J. G. W. DAVIES has recently published an account of the place of interests in vocational adjustment (*Occup. Psych.*, 13, No. 1). Vocational adjustment is satisfactory when a person's occupation provides a sufficient outlet for his abilities, interests and disposition characteristics. The degree of vocational adjustment is infinitely varied, and most people occupy a position near the mean, but the standards of the mean might be raised by scientific vocational guidance. Most people desire an interest in their job, therefore it is important to discover if there is any kind of general stability in the interests of children from pre-adolescent years to maturity. There is some evidence suggesting that several important interests can be expected to remain permanent. The author divides interests into three main categories, intellectual, practical and social, and using the genetic method he shows what kind of pursuits would be followed in childhood by people

whose dominating interests are in one or other category. Then, presupposing that anyone who is in one of these groups will in adult life continue to have the same interests, he shows the types of occupations most likely to satisfy him. It is, of course, necessary to discriminate between interest and ability, and also to understand the motives that lie behind certain ambitions. Some light is thrown on the major mental mechanisms and emotional disturbances which must be considered in order to give appropriate weight to the enthusiasm of adolescent decisions regarding vocation. The article shows how advice, founded on scientific insight, can be used to prevent unnecessary vocational maladjustment, and can give some guiding principles to be observed in making a wise choice.

Fibrillary Contractions Produced by Physostigmine

J. Szeloczey and J. Horváth (*Magyar Orvos Archiv.*, 39, 671; 1938) have found that intravenous injection in rabbits and intraperitoneal injection in rats of 0.37 mgm. physostigmine per kgm. of body weight produced fibrillary contractions lasting thirty minutes. Neither atropine nor calcium stopped the contractions, but only weakened them for a short time. Previous administration in rats of a nearly lethal dose of atropine might prevent occurrence of the contractions. No relationship was observed in the rabbits between the strength of the contractions and the calcium content of the blood. Potassium chloride did not increase either the duration or the strength of the contractions in rabbits. These findings show that the fibrillary contractions produced by physostigmine are not the result of any conservation of acetylcholine, but are manifestations of the specific effect of the drug.

Scyphozoa of the Red Sea

THE Scyphozoa of the Red Sea have recently been critically described by G. Stasny (*Verh. Konin. Nederland. Akad. Wetens. Amsterdam*, 1938). The author has already published an account of the specimens of this group collected by the John Murray Expedition. Since then the examination of further material from the Red Sea and from the museums of Leyden, Paris and London has made possible a more comprehensive study of the forms from that area which, up to now, have not been well known. No representatives of the Cubomedusae or Stauro-medusae are recorded. Four species of the Semastomae are described, and in addition two specimens of a form that is obviously congeneric with *Cyanea* but does not allow of specific identification. Similarly, in addition to the eight members of the Rhizostomae there is also an unidentified species of *Mastigias*. The author adds a note on the prevailing winds and currents of this interesting sea.

A New Parasitic Slime-Fungus

G. A. LEDINGHAM has recently issued an account of a new member of the Plasmodiophorales which has been found parasitizing the roots of wheat in

Ontario (*Canadian J. Res.*, 17; 1939). In addition to spore clusters, large, septate zoosporangia are present with conspicuous tubes for zoospore discharge. In the development of resting spores, naked multinucleate myxamobae develop first, then segment to form spore clusters. All zoospores have two flagella of unequal length. The somatic nuclear divisions are characterized by the simultaneous division of both nucleolus and chromatin within a persistent nuclear membrane; prior to the segmentation of the myxamobae to form spore clusters and in all divisions during growth of the zoosporangia, the nucleoli and nuclear membranes disappear, and the divisions are of the ordinary mitotic type. Since the zoosporangial characters of this fungus differ from those of other genera in the order, it is suggested that it be placed in a new genus, and the binomial *Polymyza graminis* is proposed.

Colchicine in the Production of Polyploid Plants

THE discovery by Blakeslee and Avery of the value of colchicine as an agent for the production of polyploids in plants has stimulated investigations by a large number of workers in various parts of the world. The practical possibilities for the plant breeder have made it desirable for a review of all available information. J. L. Fyfe, of the School of Agriculture, Cambridge, has issued a report on the subject (Imperial Bureau of Plant Breeding and Genetics 576.356.5:581.04). A description of the different types of polyploids is given and the ways in which they arise. The value of a not too laborious method for their production is stressed. The chemical formula of colchicine differs from other alkaloids in having no heterocyclic ring, its nitrogen atom being in a side chain. It has been recognized for some time as a specific for gout, but its action on mitosis has been appreciated only recently. A number of accounts of the influence on mitosis have been offered, but that of Levan is detailed as being the clearest. Colchicine inactivates the spindle mechanism, prevents anaphase separation of the daughter chromosomes, and this leads to doubling. This doubling may be repeated several times. Influence on meiosis is also discussed and the way in which it differs from that on mitosis. Methods of application vary from that of soaking the seed to painting of shoots or spraying of flowers. Dilutions used vary from 1.6 per cent to 0.02 per cent, according to the technique employed. Experimenters often give scanty details, and methods of identifying polyploidy do not always render results convincing. The only concrete achievement reported is that of the production of a tetraploid *Zinnia*. The review ends with an account of acenaphthene as a substitute for colchicine.

Flower Colour in the Sweet Pea

G. H. Beale, G. M. Robinson, Sir Robert Robinson and R. Scott-Moncrieff (*J. Genetics*, 37, 375; 1939) give the results of a combined genetical and chemical analysis of *Lathyrus odoratus*. Purple flowers are *EE Sm* or *Ee sm* in constitution while red flowers are *e Sm* and salmon flowers are *e sm*. Chemically, *e* and *sm* control the state of oxidation of the anthocyanin molecule; purple flowers contain derivatives of delphinidin, red flowers contain cyanidin and salmon flowers contain pelargonidin. The gene *d* for dullness exerts its bluing effect on flower colour by raising

the pH of the cell sap and does not, as formerly supposed, affect the methylation of the anthocyanin. There are at least seven genes concerned in the quantity produced of anthoxanthins and anthocyanins; but it is interesting to note that the type anthoxanthin does not change no matter whether the anthocyanin is delphinidin, cyanidin or pelargonidin in type. The leuco-anthocyanins of the seed react in accordance with the anthocyanin of the flower to changes in the genetical constitution.

Mycorrhizal Fungi

E. J. BUTLER has investigated the distribution and morphological characters of the vesicular-arbuscular mycorrhizal fungi (*Trans. Brit. Mycol. Soc.* 22, Pts. 3 and 4, 274, Feb. 1939). The chief characteristic of this group of organisms is the production of bladder-like vesicles, the arbuscular-sporangial apparatus, within the roots of their host plants. These vesicles are apparently concerned with the accumulation of fatty material and its transfer to the plant. Accessory nutrients may also be stored therein. The fungi concerned are closely related to the Endogonaceae, and the generic name *Rhizophaga* is considered to be the first legitimate name applicable to a member of the group, which is thought to consist of a number of allied species in this genus. The species are widely distributed in the soil, and probably form mycorrhizal associations with most plants.

Comet Notes

NEW orbits of comet Kosik-Peltier have been computed, using observations over nearly a month, and it is now established that it is a long-period comet the eccentricity being about 0.995. Mr. Przybylski has undertaken the work of computing a definitive orbit of this comet. J. G. Porter and A. E. Levi used Cowell's method for the computation of the perturbations of comet Pons-Winnecke during two revolutions, 1927-33 and 1933-39, and published the results of their work in "Handbook of the British Astronomical Association" for 1939. From the new orbit and ephemeris, Jeffers, at Harvard, rediscovered the comet on March 17, very close to its predicted position. It was diffuse, with central condensation magnitude 17. The assumed date of perihelion passage was June 23.5042^d, and the observation shows that a correction of -0.76 day gives practically exact agreement with the ephemeris. The comet will make its closest approach to the earth about July 3 and it will be then 10 million miles away. On March 14.9215^d U.T., the comet Vaisala (1939 b) was observed at Turku by Vaisala, its position being R.A. 9^h 37.1^m, Dec. 23° 07' (equinox 1939.0) and its magnitude 15. The following orbit has been computed by Oterma and Vaisala, earlier observations of the object, which was at first considered a minor planet, being used:

Epoch	1939 Feb. 9-000 U.T.	
<i>M</i>	352° 25'	
<i>e</i>	44 23	} 1960.0
<i>Q</i>	135 30	
<i>i</i>	11 04	
<i>s</i>	0.63433	
<i>μ</i>	352° 8	

The period is about ten years.

Relations of the Flora and Fauna of Ireland to those of other Countries*

As the most western land of the great Eurasian continent, Ireland is of peculiar interest. It, like Great Britain, stands on the Continental shelf and is surrounded by a mere film of water as compared with the oceanic depths prevailing to the west. Terrestrial and faunal movement has been chiefly east to west. The opposite has been rare, as suggested by the few organisms in the British Isles which are restricted in area, and have a range, often discontinuous, which suggest relict rather than insipient distribution. They would appear to be mostly broken-remnants of past invasions rather than the first colonies of new species destined to push eastward. The high winter temperature has allowed of the migration northward of plants and animals which elsewhere in Europe are confined to lower latitudes—the Mediterranean region and the Spanish peninsula chiefly. Mixed with these, in Ireland, especially in the west, are a small number of plants and one animal—the freshwater sponge *Heteromoyenia ryderi* which belong to North America. There are many other problems of distribution which give to the flora and fauna of Ireland a special interest.

In spite of the instability of the earth's crust and climatic conditions in and around the British Isles during recent geological times, the occurrence of various extraneous elements derived from the north and from the west, as well as the absence from the British Isles—one or both—of many widespread continental types raise interesting questions. The effects of intermittent water barriers must also be considered.

In spite of the generally low level of the British Isles, submergence has been only very partial from the beginning of the Tertiary period, and only in the eastern and south-eastern England do Tertiary marine deposits point to the disappearance of that region as a land surface during much of the Eocene, Oligocene and Pliocene periods.

The sea forms a very effective barrier to plant and animal transport, except for winged creatures. Even seeds, plants cannot travel very far by sea, for the author has shown that the seeds of 786 different British plants sank either at once or within the course of a few days. Transport of seeds by wind is not very successful. Only plumed seeds have attained a high efficiency. Reduction in size in the seeds of nanerogams has not gone far enough, and winged seeds are not efficacious. The best results are obtained with seeds which combine reduction in size with a plume of hairs such as those of *Typha* and *Epilobium*. Clearly, normal transport by wind may for practical purposes be ruled out except for a few especially efficient seeds and for very narrow barriers.

Transport of seed by animals over sea must be confined to birds. They are, indeed, efficient agents of dispersal, provided the barriers are not wide, for migration in birds is very rapid. Migrating birds have been shown to arrive empty of food and without seeds adhering to their feet or feathers.

Furthermore, success does not follow merely from

the surmounting of the barrier. The main difficulty—successful colonization—still confronts the individual.

The flora of Ireland as compared with that of Britain, and of Britain as compared with that of adjoining Continental countries, do not display any undue proportion of those plants which, by having floating seeds, might have arrived by water; or those which, having flying seeds, might have come by air; or those which are eaten but not destroyed by birds, and might, therefore, have arrived through their agency.

The case for terrestrial, and not trans-marine, immigration is greatly strengthened by considerations of the fauna, and thus are we led to looking for land-connexions in order to account for the present peopling by plants and animals of the British Isles.

Land-connexions have existed during a good deal of recent geological time, and the question follows as to the period or periods of immigration. This raises the problem as to how much of the pre-existing flora and fauna was exterminated by the Ice Age and how much survived. Forbes in 1846 concluded that certain groups in Ireland, including the southern or Lusitanian element, survived the Ice Age, while the bulk of present plants and animals owe their presence to terrestrial immigration in post-Glacial time. Forbes also accounted for the comparative paucity of the Irish flora and fauna in relation to those of Britain by the breaking down of the Irish-British land-connexion prior to the severance of Great Britain from the Continent. Though many agree with Forbes, others have expressed divergent opinions—several, such as Stapf and J. R. Mathews, expressing the view that practical extermination took place during the Ice Age.

The crux of the problem rests on whether during the Ice Age there were ice-free areas with reasonable climatic conditions or whether there was a continuous ice sheet. In the later event, complete extermination seems inevitable and post-Glacial immigration must have been vigorous. But there is no evidence of simultaneous glaciation over the whole of Ireland. In fact, evidence is to the contrary. Thus there is no need to postulate complete extermination during the Ice Age. Further support is given by present-day Greenland, which is probably no better now than Ireland was during the Ice Age, and in Greenland there are four hundred flowering plants and ferns and more than 1,500 lower forms of plants. The same refutation of extermination can be made for England.

The present-day Lusitanian flora and fauna are represented on the Continent chiefly in Spain. These reached the southern British Isles by overland dispersal. The American species in Ireland are of the northern American type, and since none of the species occurs in Siberia, presumably followed the shorter Atlantic route via Greenland and Ireland. None of them occurs in Europe south of Ireland. They probably arrived in Ireland during a pre-Glacial epoch. There is a corresponding group of

* Substance of the Hooker Lecture delivered by Dr. J. Lloyd Sager before the Linnean Society of London on May 11.

European plants in a limited area of north-eastern North America; this clearly represents a similar migration in the opposite direction. These species, both in America and in Ireland, by their very nature could not have migrated across wide stretches of sea. A relatively high land-level may have existed in the late Pliocene, but it must be admitted that the whole matter of these migrations bristles with difficulties.

The flora of Ireland (1100 species of Phanerogams and vascular cryptogams) is only little more than half that of Great Britain. The greater area, range of latitude, and diversity of surface and soil of the latter cannot wholly explain this paucity in flora and fauna of the former. There is little doubt that

many of these British species would have invaded Ireland had they been able, but the Irish Sea forms the barrier to western migration, while Britain is still connected by land with the Continent.

There are, too, many interesting, but puzzling cases of discontinuous species in Ireland, occur only in one or a few bare patches. It is possible that they have been introduced by air from across channels to places unsuited for them. There are, also, certain species more successful in Ireland than in the British island. The outstanding problems of the Irish flora and fauna are still many and varied, and the study of fossils and of peat can be expected only to reveal part of the story. But research is going apace.

Medicine in the Renaissance

THE Institute of the History of Medicine at Johns Hopkins University in Baltimore, which is the only one of its kind in the United States of America, was the last creation in 1929 of that remarkable and radiant personality, William Henry Welch. "My ambition," he wrote to Dr. L. W. Weed, dean of the Medical School, in a letter dated November 21, 1927, "is to create a real institute of medical history with a good reference library and a salaried staff, where facilities are offered not only for teaching, but for serious study and research. A 'Lehrstuhl' merely is not enough". The professorship in the history of medicine in the University was originally intended as a retirement chair for Dr. Welch who, however, insisted on the organization of a properly equipped department. He was succeeded by Dr. Henry E. Sigerist, a former director of the Institut für die Geschichte der Medizin at Leipzig, who, with his magnetic personality, relentless energy, and immense erudition, has built up a magnificent institute serving the triple purpose of research, education, and nucleus for medico-historical activities in the country. Supported by a grant from the Rockefeller Foundation, it is situated on the top floor of the William H. Welch Medical Library. Dr. Sigerist is ably assisted by his associates Drs. Owsei Temkin, Ludwig Edelstein, John Rathbone Oliver, and Sanford V. Larkey. Initially designed as a house-organ, to contain papers written by members of the Institute and by others connected with the University, in January 1933 the *Bulletin of the Institute of the History of Medicine* began to appear as a supplement to the *Johns Hopkins Hospital Bulletin*, from 1935 functioning as an independent organ. At the beginning of 1939 it changed its name to "Bulletin of the History of Medicine. Organ of the American Association of the History of Medicine and The Johns Hopkins Institute of the History of Medicine".

So successful was the first Graduate Week in Medical History held at the Institute in April 1938 that a similar course was planned for the week of April 24-29, 1939. While last year's programme dealt with the principles and methods of research and teaching, the subject this year was "Medicine in the Renaissance". The course was attended by thirty-nine medical historians and students of the Renaissance, including Prof. Leicester Bradner, of

Brown University; Dr. Iago Galdston, of the New York Academy of Medicine; Prof. Richard Shryock, of the University of Pennsylvania; Kate Campbell-Hurd Mead; Dr. Benjamin Speck and Dr. Richmond C. Holcomb. Each morning lecture, illustrated by an exhibit of the most authoritative literature, and followed by a discussion, was given by Dr. Sigerist and by members of his staff, and the afternoons were devoted to informal round-table seminars. The programme was carefully planned as to leave sufficient time for individual work and conversation with the director and his associates.

In the opening lecture on April 24, entitled "Economic, Social, and Political Foundations of the Renaissance", Dr. Sigerist described the medieval world as a static world in which man was born in a definite place and function. Everything was dominated by religion. When the new period started the system of feudalism began gradually to disintegrate. The struggle between the old and the new orders lasted for three centuries, for feudalism in Western Europe was only overthrown by the French Revolution. The Reformation had enormous economic repercussions: it broke the doctrine of the Church that production is for service only and that the idea of profit is sinful. The fifteenth century witnessed great development in finance and banking, better and shorter ways of traffic were sought, Western Europe was linked with the New Worlds, and navigation proved a great stimulus to science. Everywhere men felt his individuality, which he desired to apply to a definite purpose. The afternoon's seminar was given up to a discussion of "The Concept of the Renaissance". The term "Renaissance" was first used in art by the sixteenth century Italian art critic and painter Giorgio Vasari. Its technical use dates from Jacob Burckhardt's book "Die Kultur der Renaissance in Italien", 1860. In the evening a play was performed at the Baltimore Museum of Art "The Black Dart of Death", adapted by Dr. Larkey from William Bullein's "A Dialogue against the Fervent Pestilence", 1564.

The following day's programme included a lecture by Dr. Edelstein on "Ancient Traditions in Medieval and Renaissance Thought", a seminar on "Bibliographic Problems of Renaissance Literature", and an evening meeting of the Cordell Historical Society, the University of Maryland in the chemical hall.

sh had witnessed the bestowing of honorary degrees on Lafayette and Ephraim McDowell. On April 26, Dr. Sigerist spoke on "Science and Technology in the Renaissance", and to the afternoon's dinner on "Some Biological Problems of the Renaissance". Dr. Larkey contributed an account of anatomical text-books of the period, while Dr. Aikin discussed the anti-Aristotelian movement. April 27, Dr. Temkin, lecturing on "The Physician in the Renaissance", attributed the esteem in which he was held not to his efficiency (in contemporary times he is more freely attacked than the surgeon), rather to the academic and financial difficulties attending the acquisition of the M.D. in the sixteenth century. Bearing in mind that the average lifetime man in those days was not more than fifty years, the end of his training the young doctor had already spent more than half his life in study. The medieval physician was restricted in his interests, all scientific knowledge being centred in the philosophers and the theologians. With the Renaissance, the physician began to enter the field of mathematics, mineralogy, chemistry, zoology, and literature. The afternoon's seminar dealt with "Diseases prevailing in the Renaissance and their Interpretation". On

April 28, Dr. Larkey spoke on "Hygiene and Public Health in the Renaissance", the subject of the afternoon's discussion being "Medical Literature in the Vernacular: English, German, French, Italian". The closing address of the course was delivered by Dr. Alan M. Chesney, dean of the Medical School, who dealt with the early history of the Johns Hopkins Hospital, the fiftieth birthday of which is commemorated this month.

The intellectual fare of the Graduate Week was temptingly seasoned with tea and cocktail parties, dinners and visits to shrines of interest, such as the Tudor and Stuart Club of Johns Hopkins University, with which the name of Revere Osler, Sir William's only son, is inseparably linked.

The following exhibits had been arranged: Leonardo da Vinci; medical books from the Renaissance presses; and recently published literature in medical history.

At the banquet on April 28, Dr. John Rathbone Oliver spoke on "The Oxford of Anthony Wood", and a presentation was made to Dr. Sigerist and to the very efficient and charming machine behind his brain—his secretarial staff.

WALTER BETT.

Soil Mechanics

PROF. KARL VON TERZAGHI delivered the forty-fifth James Forrest Lecture at the Institute of Civil Engineers on May 2, taking as his subject "Soil Mechanics: a New Chapter in Engineering Science".

At the opening of his address, Dr. von Terzaghi contrasted the empirical methods which were in general use until about twenty-five years ago with the much greater reliability which is now obtainable by allowing for the effects of soil movements and pressures. So satisfactory to progressive engineers had the old procedure become of ascertaining the bearing capacity of subsoil that concerted action was taken to study its properties and behaviour of soil and to place it on a sound basis in accordance with the laws of mechanics. The new study was designated 'soil mechanics', a name which in 1936 received confirmation when the first International Conference on Soil Mechanics and Foundation Engineering was held at Harvard University in Cambridge, Massachusetts. Dealing with the first section of his subject, "The Pressure of Earth on Lateral Supports", Dr. von Terzaghi showed that Coulomb's theory, which is the more reliable of the two in use and dates from 1773, is based on several untenable assumptions. The modifications made in the formulae as now used have arisen from the discovery that the intensity and distribution of earth pressure depend on many more factors than were realized by earlier workers. Dr. von Terzaghi indicated the nature of, and justification for, these modifications.

Passing to the closely related problem of earth pressures involved in the stability of slopes, Dr. von Terzaghi showed that the old method was to prescribe that slopes of fills and cuts should be established at angles somewhat smaller than the appropriate angles of repose. Mention was made of what is known as

the Swedish method of determining the degree of stability of a slope, which is based on the empirical fact that the profile of the surface of sliding always approaches the form of a circular arc. For masses of earth having little cohesion and subjected to seepage forces, as in the case of an embankment for water storage, the formulae adduced in recent studies were shown to give satisfactory results. In the case of clays, however, the determination of the shearing resistance is far more difficult and the position at present is still highly controversial.

A submerged body of soil with little cohesion and in a loose state is liable on the least disturbance to behave as a liquid and to flow on a horizontal surface, a phenomenon which is known as 'flow-slide'. Here the condition was shown to be that the material should be loose enough to be capable of reducing to a denser state as a result of the applied deformation. Flow-slide was thus shown to be associated with porosity, and no flow failure can occur unless the volume at this occurrence is less than the initial volume. The necessity, therefore, of specifying that the porosity of water-retaining embankments should be well below the critical value was thus made clear.

The compaction of embankments is an effective means of limiting the amount of settlement, as in the case of fills for road making, and R. B. Proctor has demonstrated that the degree of compaction produced by a given method depends on the moisture content, being greatest for a certain medium water-content, determinable by experiment. These observations have led to fill-construction methods in which moisture-content controls are introduced. In Germany, the compaction of sandy soil by vibration has been brought to a high state of perfection, and it has been found that the greatest compacting effect is

produced when the frequency of the vibrator is equal to the specific vibration of the soil. The same process is also used for comparing the degree of compaction of fills before and after completion.

Dr. von Terzaghi then dealt with the failure of dams due to piping, a subject which is nearly allied, from the point of view of its mechanics, to the stability of slopes subjected to seepage forces. Bligh's empirical rule was faulty in that it was based on the tacit assumption that the critical percolation factor depends only on the grain size of the subsoil. By model dams so constructed that, by Bligh's rule, the critical head should have been the same for all, it was shown by the highly divergent results that the assumption is greatly in error. Dr. von Terzaghi explained how he came to the conclusion that piping can be eliminated by the provision of an inverted filter between the body of the dam and the foundation, and he described such a filter which he has designed for incorporation in a rock-fill dam in Algiers.

The time factor in relation to earth pressures and movements was next discussed. Using a cylinder filled with water and having a perforated piston supported by springs as an illustration, Dr. von Terzaghi pointed to the fact that, when a constant load is applied, the piston can only descend as the water percolates through the interstices in the piston. At first the water pressure supports the load, but it falls off as the descending piston compresses the spring. A similar process occurs in clay when loaded, and the mechanics of it can be expressed, in terms of time, by a partial differential equation of the second degree. This is known as the fundamental equation of the processes of consolidation. The case was quoted of a power-house where, for a supply of water, a well was driven through the clay to water-bearing gravel below. As a result, the time-rate of settlement of the power-house increased alarmingly, and within a few months the corner nearest the well had subsided more than a foot. When the well was closed, the settlement practically ceased. Dr. von Terzaghi pointed to other instances in which the operation of the theory of consolidation is exemplified, and explained that settlements of this nature can now be computed with reasonable accuracy.

University Events

CAMBRIDGE.—Dr. J. D. Cockcroft, lecturer in physics in the University and fellow of St. John's College, has been elected Jacksonian professor of natural philosophy as from October 1 (see also p. 846).

LONDON.—The following representatives have been elected by Convocation to the Senate: *Medicine*, Sir Ernest Graham-Little, M.P.; *Science*, Prof. G. B. Jeffery, Prof. Major Greenwood; *Engineering*, Sir Charles Breesey.

A Keddey Fletcher-Warr studentship, of the value of £300 a year for three years, has been awarded to Dr. Vernon E. Coslett (Birkbeck College), for research on the application of electron optics to the design of X-ray tubes and to the measurement of X-ray diffraction patterns.

SHEFFIELD.—Alfred Wright, at present research assistant in mining, has been appointed lecturer in mining; J. W. Watson has resigned from his post of assistant lecturer in geography.

Science News a Century Ago

Wells in the London Clay in Essex

IN a paper read to the Geological Society on Feb. 22, 1839, Dr. Mitchell dealt with "The Wells in Gravel and London Clay in Essex". The greater part of Essex, he said, consists of London Clay. Its greatest thickness of the clay is not known, but probably exceeds 400 ft. Extensive districts covered by gravel, sand and detritus. In the district composed of London Clay, no land springs occur. The wells generally penetrate to the bed of a between the Clay and the chalk. The Clay is various colours, the lower beds being sometimes blue but it is sometimes blue at the bottom. In districts where it is thickest, it is often interstratified with two or three beds of sand, but near the site Fairlop Fair, it was found to consist of 398 ft solid clay. Dr. Mitchell gave a list of nineteen wells selected from a very large number, the deepest being in Foulness Island, 460 ft. Artesian wells have been productive of the greatest benefit in Essex.

Photography with the Aid of Incandescent Coke

IN the *Athenaeum* of May 25, 1839, it was under the heading "Photogenic Drawing", that "Mr. Robert Mallet has communicated to the Royal Irish Academy a notice of the discovery of property of the light emitted by incandescent coke to blacken photogenic paper; and proposed it a substitute for solar light, or that from the ordinary hydrogen blow pipe with lime. One of the most important applications of the photogenic process, yet suggested, is its adaptation to the self-register of long-continued instrumental observations. Few artificial lights emit enough of the chemical rays to act with certainty on the prepared paper; while those which are known to act well, as the ordinary hydrogen light, are expensive and difficult to manage. A considerable time since, the author discovered that the light emitted by incandescent coke at a 'Twyer' (or aperture by which the blast is admitted of a cupola or furnace for melting cast iron, contained the chemical rays in abundance; and lately trying the effect of this light on the prepared paper, he found it was intensely blackened in about forty-five seconds.

Robert Mallet (1810-80), engineer and physicist was a graduate of Trinity College, Dublin, and was a partner with his father. Among his works was the Fastnet Lighthouse. He was well known for his study of volcanoes and earthquakes. He was elected a fellow of the Royal Society in 1834.

A Criticism of Davy's Safety Lamps

THE *Mechanics' Magazine* of May 25, 1839, published a report of a lecture by Faraday at the Royal Institution on May 10, on "Some General Remarks on Flame". Faraday had referred to Davy's safety lamps, and in his comments on the lecture, the *Mechanics' Magazine* said: "We have no disposition whatever to detract from the merit or brilliancy of Sir H. Davy's discovery as a scientific fact, but his lamp is a poor fragile thing. . . . Thus instead of protecting the light in a strong lantern he (Davy) contented himself with merely placing around it a flimsy tissue of wire, which besides numerous other objections, is, by its gloomy effect, ever tempting the miner to remove it, or to use a better but more dangerous light."

Societies and Academies

Paris

Academy of Sciences (C.R., 208, 1081-1124,

April 3, 1939).

- .. GUILLERMOND and R. GAUTHERET: The so-called reducing power of the chondriosomes towards *ius green*.
- I. GODCHOT and Mlle. G. CAUQUIL: Application of the Raman effect to the study of some cyclanones.
- t. DEDBANT and P. WHEHL: Turbulent motion.
- .. GLANGEAUD and Mlle. Y. BONNICHON: Dynamics of the variations of turbidity and of solid content in the maritime Garonne and the Gironde in course of the tides.
- .. A. PROGA: The fundamental length relating to elementary particles.
- .. ROUBAUD-VALETTE: Possibility of constructing the wave equations relating to particles of multiple spin of $\frac{1}{2}(h/2\pi)$.
- .. GUASTALLA: Very dilute films of some proteins; attempt to determine the molecular masses. A weighed quantity of protein is deposited on water in surface manometer, and the film is compressed and area measured.
- J. GILLOD: A new method of stabilization of an atomometer lamp.
- B. KWAL: A phenomenon observed with a Rutherford-Geiger tube-counter submitted to relatively strong radiation.
- .. G. BECK and P. HAVAS: Dissymmetry of the capture of uranium.
- Mlle. N. GOLDOWSKI: Solution potential: the case of aluminium in presence of different gases.
- P. SIE: Thermal equilibrium between Nb_2O_5 and H_2O .
- Y. DEUX: Isomerization of phenyl-1 vinyl-2-oxy-1,2 butane in phenylvinylethylacetaldehyde, and dehalogenation of the corresponding iodohydrate phenyl-3 hexene-1 one-4.
- O. SACKUR: Action of organo-magnesium derivatives on chloro-1 cyclohexylmethylketone and chlorocyclohexylphenylketone; secondary replacement of chlorine by pinacolic transposition.
- Mlle. P. RAMART-LUCAS: Structure and absorption of hydroxylated colouring matters of triphenylethane; existence of isomeric forms of hydroxy-chalcones.
- Mlle. D. Biquard: Contribution to the spectral study of β -tetralone and β -indanone.
- J. EISENSTEIN: Influence of temperature on the elasticity and the rupture of crystals. A discussion based on the probability of abnormally large displacements of the position of equilibrium of one or more atoms.
- J. NORDLIE: Volcanism and nuclear chemistry. It is suggested that volcanism is due to localized accumulation of neutrons which are enabled to set up nuclear disruption with release of energy much as occurs in the disruption of uranium.
- Mlle. M. JOUVENEL-MARCOILLAC: Meiosis in *Lophomus sativus*.
- G. MANGENOT: Rootlet development and colchicine. Giant cells with single nuclei which are polyploid to a high degree are formed.
- R. COMBES and Mlle. M.-T. GERBUDE: Contribution to the study of the biochemical possibilities of a plant species. Submitting *Veronica Anagallis*

to illuminations down to one sixth of normal, to high altitude and to immersion produces changes in its chemical make-up; thus reducing glucides vary from 0.77 to 10.23, soluble nitrogen compounds from 0.15 to 1.44, and so on.

G. DELOFFRE: Wound phenomena of nuclear growth in the lupin.

M. ROSE and J. BERTHELOT: Production of experimental tumours in higher plants by inoculation with the venom of the cobra *Naja tripudians*.

H. DES ABBAYES: Geographical distribution of the lichens *Cladonia alpestris* and *C. rangiferina*, and the true identity of *Lichen giganteus* Bory.

P. REX: Effect of removal of the principal lobe of the hypophysis on the annual cycle of the male sexual cells of *Bufo vulgaris*.

Mlle. S. THÉVENET: Viscosity of solutions of serum albumin in media of different hydrogen ion concentration. Viscosity is a minimum at about the iso-electric point.

A. BOUTARIC and Mlle. M. ROY: Study of the variation of optical activity of protein solutions in alkaline media.

M. FRÉREJAQUE: Presence of *d*-arabitol in *Fistulina hepatica*.

Washington, D.C.

National Academy of Sciences (Proc., 25, 55-111, Feb. 15, 1939).

E. W. SINNOTT: Growth and differentiation in living plant meristems. Seeds of some of the smaller grasses are made to germinate on moist paper on microscope slides, and the root tips observed under a water-immersion lens. The meristem cells can be observed directly at regular intervals of time. The cells are in regular longitudinal rows, and new walls are generally transverse, tending to join the side wall half-way between the nearest cross-walls. 'Sliding growth' was not observed. Root-hairs are usually early differentiated.

E. D. CHAPPEL: Quantitative analysis of the interaction of individuals. The separate actions of two interacting individuals alternating with their silences or inactions were recorded; an improved apparatus for this purpose is being made.

O. STREVE, K. WURM and L. G. HENVEY: Astrophysical consequences of metastable levels in hydrogen and helium.

E. B. WILSON and JANE WOBESTER: Resolution of six tests into three general factors.

W. J. CROSBY: Temperature and the critical intensity for response to visual flicker (2).

J. BARDEN and J. H. VAN VLECK: Expressions for the current in the Bloch approximation of 'tight binding' for metallic electrons.

G. E. HUTCHINSON, E. S. DAVEY, jun. and ANNE WOLLAKE: Oxidation-reduction potentials of lake waters and their ecological significance. Data for some North American lakes suggests that when the water half a metre above the deepest mud has a potential of 0.4 volt, the mud has a *Tanytarsus* fauna; when the potential is below 0.3 volt, a true *Chironomus* fauna is found.

J. F. RETT: Ideals of differential polynomials.

M. RMADE and E. F. BROCKENBACH: Generalizations to space of the Cauchy and Morera theorems.

G. H. FRENKEL: An equivalence theorem for series of orthogonal polynomials.

E. KASNER and J. DE CICCO: Curvature element transformations which preserve integrable fields.

Appointments Vacant

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

GEOLOGIST in the Geological Survey of Great Britain—The Director, Geological Survey and Museum, Exhibition Road, South Kensington, S.W.7 (May 31).

ASSISTANT LECTURER IN GEOGRAPHY in the University of Manchester—The Registrar (June 5).

SENIOR DEMONSTRATOR IN PHYSIOLOGY in St. Bartholomew's Hospital Medical College—The Dean (June 10).

DEMONSTRATOR IN ZOOLOGY in Bedford College for Women, Regent's Park, N.W.1—The Secretary (June 15).

Research in Civil Defence

WE are to-day faced with conditions hitherto almost unknown in history. Whereas, prior to the Great War, wars were fought between professional armies comprising a comparatively small section of the population, to-day war means that the whole community is involved in a life-and-death struggle. Air attack as a weapon used for the destruction of lives and property and as a means of undermining the morale of a nation is a very potent one, and there can be no doubt that until nations abandon aerial bombing, whatever the type of bomb used, whether it be high-explosive, incendiary or gas, it is imperative that the best resources of a country should be enlisted to reduce the effects of such enemy action and to maintain the confidence of the people in their strength and ability successfully to resist such attacks.

The organization of Great Britain for this purpose has now been in progress for some time. Much has been done to devise means for protecting the civilian population from the effects of aerial bombing, particularly by the provision of gas masks constructed on a scientific basis and later by the provision of steel shelters which will give some measure of protection against the effects of modern high-explosive bombs. Pamphlets and handbooks have been issued dealing with a variety of subjects giving the best-known means of protection from exploding bombs and gas, and for reducing the risks from fire. These publications give the latest information actually available, but the work of research goes on and there are many problems still awaiting solution. In the early days of the work of A.R.P., a considerable amount of valuable work was done by the Department of Scientific and Industrial Research. With the rapid expansion of the Air Raid Precautions Department, however,

it became increasingly clear that the special problems that arose demanded the setting up of a special section of the Department to deal with them.

A few weeks ago, a new Division of the Air Raid Precautions Department of the Home Office was accordingly set up to deal specially with problems which may arise in connexion with air raid precautions, and requiring scientific research and experiment. This work is under the direction of Dr. R. E. Stradling, director of building research of the Department of Scientific and Industrial Research. But to speed up as rapidly as is desired, it is necessary to enlist every suitable and available facility for scientific research.

It is therefore to ensure, so far as practicable, that the population is given the greatest degree of protection which the skill of science can devise that Sir John Anderson has now brought into being a special Committee for Civil Defence Research. This Committee, the members of which were announced in *NATURE* of May 20, p. 847, is not only an advisory body. It is also intended that through it the Department will be able to make use of the resources of the universities and scientific institutions in Great Britain for the solution of problems as they arise. Facilities undoubtedly exist for conducting experiments; but it is earnestly to be hoped that they will be made freely available to assist in the extensive and intensive work now in hand. Great Britain is now alive to the risk of being unprepared to meet attack from the air, and the whole country is steadily being organized to resist the menace. Members of scientific bodies will no doubt be prepared to give their services to assist in the prevention and amelioration of suffering, and the Government is now in effect inviting all who can

to contribute to the task of research and experiment to this end. Much has already been done, but there is still much to do. The difficulties with which investigators are faced are often new, and call for fresh methods of approach. It is one matter to devise weapons of destruction, but quite a different problem to devise methods of mitigating the effects produced by that weapon or of rendering it innocuous.

This important extension of the work of the Air Raid Precautions Department will, we believe, meet with general approval. Not only is the help of scientific workers necessary to the country, but also men of science themselves have shown that they desire to help. The new Committee will meet under the chairmanship of Dr. E. V. Appleton, who is secretary of the Department of Scientific and Industrial Research. The field of investigation that lies before it is large and involves practically every branch of science—chemistry, mathematics, physics, geology, engineering and biology among many others. There is, in fact, no limit to the scope of such investigation.

The Committee, as at present constituted, consists of some leading men of science in Great Britain, but drawn exclusively from the physical and engineering sides. This would appear to be deliberate, for the immediate task of the Committee is to deal with questions arising out of the provision of shelters for the civil population, and it is believed that physical aspects will need first consideration. No doubt it will be possible to widen the basis of the inquiries undertaken in due course, by extending the membership of the Committee to cover other subjects.

The conditions under which we have lived hitherto are not intended to meet a menace such as a modern air attack. Homes suitable enough for times of peace are not constructed to withstand the shock of a modern high-explosive bomb. Some alternative protection must be provided that will withstand most of the shock that it may possibly receive. Thousands of workers employed in factories must be protected, and employers will expect advice from the Government with regard to the best means of constructing shelters for employees who are working in older types of buildings, and also to assist in the design and layout of protected quarters in new buildings. There are also questions arising in connexion with obscuring internal lighting of factories, and on the various means of giving satisfactory warnings of an approaching raid. These are only a few of

the more obvious matters that in their many variations must be dealt with, and for which solutions are needed, not some day, but immediately, so that appropriate steps may be taken.

Among the problems that call for research are problems on which there is at present little or no information, are the effects of explosion on structures of different types. This involves large-scale experiments. A clear space having a radius of a mile, and with suitable subsoil, on which full-scale experiments can be conducted, is required to be put at the disposal of the Department. Such sites are very difficult to obtain in Great Britain as the failure to obtain one will inevitably handicap the work of research in this important matter. It is understood that the Department has not yet found such a site, and would welcome assistance in the matter. Research into the many problems arising in connexion with the effects of explosion—for example, transmission of shock, equivalent static pressure of blast, pressure waves produced in the ground by an explosion, and physiological effects of explosive pressures—are among the matters that call for early solution. Many other problems arising in connexion with anti-gas measures, obscuration of lighting and air-raid warning suggest that the field for research is very wide.

The full weight of scientific knowledge is now being marshalled in the services of the Air Raid Precautions Department. It is a bitter comment on international affairs that scientific effort should have to be devoted specifically to this end, but failing the effective prohibition of aerial bombing no other course appears to be open. Indeed the call for service is now urgent, for if Great Britain is to maintain its independence and its civilization, the country must be protected effectively and speedily from what is probably the worst form of warfare yet devised by man.

While condemning, with all reasonable men, the utter folly of war, scientific workers must recognize the dangerous qualities of the times in which we live, and will welcome the formation of the Civil Defence Research Committee. The investigations it will institute can scarcely fail to make contributions which, in the long run, will prove of value to mankind; further, its immediate task, which is directed towards the amelioration, if not the prevention, of suffering on the part of hundreds of thousands who in past years would have been respected as non-combatants, will appeal to all who are imbued with the spirit of service to humanity.

Zoological Miscellany

estschrift zum 60. Geburtstage von Prof. Dr. Embrik Strand.

enthaltend dem Jubilar gewidmete Arbeiten ländischer Zoologen und Palaeontologen. Vol. 1. Pp. ii+644+14 plates. Vol. 2. Pp. ii+652+37 text-figures. Vol. 3. Pp. ii+608+20 plates. Vol. 4. Pp. ii+784+16 plates. Vol. 5. Pp. ii+750+11 text-figures. (Riga: Prof. Dr. Embrik Strand, Sistēmatiskās Zooloģijas Institūta, Pasta kastīte 802; London: H. E. Knowles, 1938-39.) 24s. 6d. each.

It is customary in some countries, particularly in Germany, to honour a distinguished man of science on the anniversary of his sixtieth or seventy-fifth birthday by the issue of a volume containing papers written for the occasion by former pupils and other friends and admirers. In order to preserve the element of surprise for the *Jubilar*, it is understood that the matter is kept a secret. Prof. Dr. Embrik Strand, professor of zoology and rector of the Systematic-Zoological Institute and the Hydrobiological Station of the University of Latvia at Riga, evidently did not like the usual proceeding and, dispensing with secrecy, invited all and sundry to send manuscripts for a festive publication in commemoration of the anniversary of his sixtieth birthday.

The promise to publish all was most generous, at the present time when scientific periodicals are overwhelmed with manuscript. The response was equally generous, the result being a *Festschrift* such as has never before been issued in honour of any zoologist. The five volumes contain 194 articles, which occupy more than 3,400 pages and are illustrated by 687 text-figures, 6 text-plates and 3 line and half-tone plates. Most articles are in German, others in English, French and Italian. The editor has extended great hospitality to some authors, one of whom contributes no fewer than fourteen articles and some others five, six or seven, which shows that there was a demand for such publication. Although English is the language of eighteen articles, Great Britain shines rather by absence, only one article of two pages being contributed from England. The invitations were duly received, but did not create enthusiasm among British zoologists, who are unaccustomed to this kind of publicity and evidently do not like it. It is no reflection on Dr. Strand's reputation.

The articles were obviously printed more or less in the sequence in which they were received, there being no attempt at co-ordination. The absence of order presents some difficulty to the reader

who is interested in a particular subject, but the editor supplies the want in volume 5, which brings a list of the articles grouped according to subject and an index to the scientific names used in volumes 1-5. Dr. Strand being an entomologist and arachnologist of world-wide reputation, it is very appropriate that most of the contributions deal with spiders and insects; but there are articles on all classes of animals from Protozoa to Mammalia and on a variety of subjects of more general import; every zoologist, inclusive of geneticists, will find a paper of some interest. Many of the authors begin their articles with an appreciation of the work of Dr. Strand, sometimes employing superlatives which must have brought a gratified smile to the stern face of the professor who frowns at the world from the frontispiece to volume 1. It is unfortunate that in Prof. Špaček's article on Dr. Strand as a lepidopterist special stress is laid on the discovery of a new sub-family of Castniidae in Madagascar; in reality, Dr. Strand was misled by an Agaristid with the antenna more strongly clubbed than usual.

Taxonomy and purely descriptive work take up the greater part of the volumes, and many of the new forms described are named in honour of Dr. Strand. In Dr. Obenberger's article on new Buprestidae, some fifty names are derived from Embrik and Strand singly and combined. The longest contribution (more than 400 pages) are Dr. Breuning's three articles on exotic Cerambycidae, from various collections, inclusive of that of the British Museum. The monograph of the colliurine carabids by Herr Liebke and the survey of the Palearctic Troginae (*Lamellicornia*) by Dr. Balthasar are welcome comprehensive publications; Herr Liebke's account would have been still more helpful for future specialists if references to original descriptions had been given, as Dr. Balthasar has done; the addition would have made no appreciable difference to the length of an article occupying more than 100 pages. Both these papers are mainly concerned with the characterization of the various species and sub-species. Dr. Auber's contribution, "Die Rassen- und Artenkreise des Genus *Eos* Wagler (Aves)", stands on a very different level. The author goes deeply into systematics as a science of relationship and discusses the question of the phylogeny of the forms composing the genus, illustrating his arguments with numerous figures of the details of coloration. The account is of great value for all who study the problems of species and subspecies.

Systematists will welcome Dr. F. Poche's research on the dates of issue of Esper's "Schmetterlinge" and his supplement to Sherborn's "Index Animalium"; physiologists will be interested in Prof. O. Polimanti's observations on the sleep of domesticated and wild mammals and birds, Dr. Molitor's experimental research on the colour-sense of sphegid wasps, Prof. Monti's paper on the effect of gamma rays on the reproduction of *Cladocera*, and Dr. and Mrs. Szabo's papers on physiological and old-age deaths and on duration of life and senescence.

A contribution of a very ambitious kind is Dr. G. von Kolosváry's "Generic System of the Phenomena of Life", where the evolution of organisms is explained on the basis of endogene development. According to him, the environment has no directing influence in the origin of new species, but only stimulates a predestined development. He mentions as an example the fauna of caves, and says that the modifications in the morphology of cave species are not the result of living in caves as generally supposed, but were acquired before these organisms became cave dwellers; the species having become unfit for the

conditions of a life in the open, retired into caves where they found shelter and could go on existing. An entertaining thought, but not new! An instructive paper is not very easy to read, as the author seems to contradict himself occasionally. For example, speaking of Linneons (= species and Jordanons (= subspecies or races) he says p. 196 that "the Linneon splits up into races; this division does not originate new species, that is to say, the Jordanon does not develop but into a new Linneon", a mere assertion, and p. 198 we read on the contrary "... the collected Linnean species (Linneons) have been divided into elementary species, so-called Jordanons ...". A Jordanon is a rudimentary species, it develops into a species; in fact, many Jordanons have all the characteristics of species. Erroneous conclusions are not without merit, if they are conducive to stimulating thought and research.

The reviewer sincerely congratulates Prof. Embrik Strand on the production of a unique publication which contains much valuable information, and expresses the hope that he will continue his activities in good health for a long time.

KARL JORDAN.

Progress in Seismology

Earthquakes and other Earth Movements

By John Milne. New edition, revised and rewritten by Dr. A. W. Lee. Pp. xiv+244+24 plates. (London: Kegan Paul and Co., Ltd., 1939.) 10s. 6d. net.

SINCE the sixth edition of Milne's book in 1913—the year of his death—nothing has been published in Great Britain to take its place, although with the great development of seismology in post-War years the book has long been completely out of date. The wealth of material and its wide range make the task a formidable one, and Dr. Lee is to be congratulated warmly on the discrimination, even more than on the skill that he has shown, in completely rewriting the book. It would be quite fair to say that he has used Milne's "Earthquakes" rather as an example of the spirit in which a treatise should be written.

The specialist, as well as the general reader, will find the opening chapters of great interest. They deal with the visible results of earthquakes, and are copiously illustrated with photographs of earth fissures, fault movements and damage to buildings, bridges and water-mains. There is, too, an interest-

ing chapter on "Earthquakes and Construction". The chapter on seismographs is extremely lucid and the diagrams, as throughout the book, are very clear; in spite of his intimate acquaintance with several types of instrument (or perhaps because of it), Dr. Lee avoids the temptation to go into too great detail. Of great historic interest are the reproductions of the Milne seismograph records at Kew of five famous earthquakes, including the shock that wrecked San Francisco in 1906.

To give in reasonable space an account of the onsets observed in seismograms, the working up of the records of a given earthquake, and the inferences that have been drawn concerning the interior of the earth, is a forbidding task, and it is a great achievement on Dr. Lee's part that he has managed to make this section reasonably complete without overloading it in detail. There is sufficient indication of method to show how conclusions are arrived at, yet the geologist or the general reader will not be irritated at the length of description or technique. The rather diffuse topic of the distribution of earthquakes in space and time is presented with a good sense of balance, and an adequate account is given of modern work. As one would

spect, the chapter on microseisms, a subject on which Dr. Lee is the leading authority, deals fairly and informatively with a very controversial subject. The final chapter, on seismic prospecting, includes an account of recent work on the ocean floor, by which the nature of the continental shelf

of the eastern coast of the United States has been made out.

The typography and general arrangement are good, and Dr. Lee has done his work so well that there are few loopholes for adverse criticism.

R. STONHLEY.

Structure and Existence in Mathematics

Le Progrès de l'Esprit

by Dr. Albert Lautman. 4: *Essai sur l'unité des sciences mathématiques dans leur développement actuel*. Pp. 60. 15 francs. 5: *Essai sur les notions de structure et d'existence en mathématiques, 1: Les schémas de structure*. Pp. 82. 5 francs. 6: *Essai sur les notions de structure et d'existence en mathématiques, 2: Les schémas de genèse*. Pp. 83-160. 20 francs. (Actualités scientifiques et industrielles, 589-591.) (Paris: Hermann et Cie., 1938.)

IN the introductory volume of his work on questions of structure and existence in mathematics, M. Lautman is mainly concerned with Prof. Weyl's distinction between the two types of modern mathematical systems in which the analysis of the infinite is contrasted with the synthetic methods of algebra and group theory. He shows that this distinction need not be conceived of as a fundamental opposition between two irreducible disciplines. On the contrary, among the modern theories of analysis, it is possible to discover points of view which are characteristic of algebra and group theory. For example, the theory of equations with an infinity of variables, the arithmetical theory of algebraic motions, the theory of non-Euclidean metrics, the theory of continuous groups, the analytic theory of numbers and the theory of Pfaffian forms, all occupy an equally intermediary position between algebra and analysis. For in all these, the methods are algebraic and the results extend to analysis; and although there is a certain analogy between contemporary physics and contemporary mathematics, in that both present a spectacle of facts which can be interpreted either by the calculus of the continuous or by that of the discrete, this duality of method, which is the principal source of the difficulties inherent in contemporary physics, is evidence of the profound unity of the mathematical sciences.

In the second volume, on structural schemes, M. Lautman maintains that with the concept of autology, the Russell school of logicians eliminated the idea of a reality corresponding to mathematical concepts. Thus for Wittgenstein and Carnap,

mathematics is nothing more than a language—or hierarchy of languages—which is quite indifferent to the content which it expresses. This, in M. Lautman's opinion, is a consequence of the deductive method which attempts to construct all mathematical concepts from a small number of primitive ideas and by means of which the qualitative nature of the theories thus constructed is lost.

In the course of three chapters on what he calls the "local" and "global" nature of mathematical theories, M. Lautman emphasizes the variety of logical relations which lie at the heart of mathematics. The solidarity of the whole and its parts, the reduction of relational to intrinsic properties and the passage from the incomplete to the absolute, are all forms of structural organization which confer upon mathematical entities a movement towards completion, by means of which their existence is established. But this existence is not solely dependent upon the fact that the structure of these entities is an imitation of the ideal structures to which they may be compared. On the contrary, it turns out that the fulfilment or complete designation of one entity gives rise at the same time to the genesis of others. It is in the logical connexions subsisting between essence and existence that these new creations are to be found.

Problems concerned with the passage from essence to existence, with examples derived from many different branches of mathematical theory in which this passage is either effected directly from the basic domain to the newly created entities—as in group transformations and algebraic functions—or indirectly by means of intermediaries which M. Lautman calls "les mixtes" and which are exemplified in Hilbertian space, occupy most of the third and final volume of M. Lautman's most interesting analytic study. Although these questions arise chiefly from the development of mathematical logic, the author takes the view that logic is only to be considered as one of the mathematical disciplines, and that the genesis manifested here are comparable with those to be observed in other mathematical

domains. Thus, M. Lautman's exposition of the metaphysics of logic is equivalent to an introduction to a general theory of connexions which unite structural and existential propositions. He calls the first period in the development of mathematical logic, dating from the early works of Russell to the year 1929, the "naïve" period; and the second, dating from the meta-mathematical researches of Herbrand and Gödel, the "critical" period. It is in the investigations of the critical period that M. Lautman finds confirmation of his theory of the connexions between essence and existence—a theory which differs both from the logicism of the formalists and from intuitionist constructivism. For, from these connexions he

deduces a philosophy of mathematical genes which goes far beyond the domain of logic itself and in this he has been immensely assisted by the work of Bernays on Hilbertian meta-mathematics.

For the rest, M. Lautman considers that the structure of experience cannot be detached from experience itself, and that reality consists in the discovery of an organizing structure in relation to matter, which is animated by its relations. It is of the opinion that in physics, as in mathematics, we are led to the Platonist conclusion that the nature of reality, its structure and the conditions of its genesis, only become knowable when we re-ascend to the ideas of which science incarnates the connexions. AMSTER VON ZEPPELIN.

Engineering Facts and Figures

(1) *Kent's Mechanical Engineers' Handbook*. Vol. 2: Design; Shop Practice. Founded by the late Dr. William Kent. Eleventh edition, rewritten by Robert Thurston Kent. (Wiley Engineering Handbook Series, Vol. 3.) Pp. xx+1378. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 25s. net.

(2) *The Engineer's Year-Book of Formulae, Rules, Tables, Data and Memoranda for 1939*. A Compendium of the Modern Practice of Civil, Mechanical, Electrical, Marine, Gas, Aero, Mine and Metallurgical Engineering. Originally compiled by H. R. Kempe and W. Hanneford Smith. 45th annual issue, revised under the direction of L. St. L. Pendred. Pp. lxxv+xii+2824. (London: Morgan Brothers (Publishers), Ltd., 1939.) 31s. 6d. net.

(1) **T**HE science and practice of mechanical and electrical engineering have, in recent years, developed so rapidly and to such an extent that, in the matter of the provision of suitable handbooks, the publishers of these are confronted with a problem of some complexity. Messrs. John Wiley and Sons have sponsored a number of such books in the past and, appreciating the trend of affairs, have dealt with the problem by appointing a board of editors to consider the best arrangements for future editions. They have recommended the adaptation of the handbooks which this firm publishes so as to form a co-ordinated series. The first volume deals with "Engineering Fundamentals" and contains the kind of information which an engineer associated with any branch of the profession would require to have in a readily accessible form, while the remaining four volumes of the series are devoted to the more specialized

information pertaining to distinct branches—mechanical and electrical engineering. The new arrangement will be found to have brought several advantages in its train; it has permitted a more thorough and more detailed treatment of the material included in the earlier editions; it has provided a better opportunity for the inclusion of new subjects; it has eliminated a large amount of duplication of information such as could not be avoided in a number of unrelated handbooks.

The volume now under consideration is the third of the series and retains its original title "Kent's Mechanical Engineers' Handbook". It is devoted to the two branches indicated by the subtitles "Design" and "Shop Practice", and in its preparation the advantages mentioned are much in evidence. In the first part it deals with the materials of engineering, ranging from iron and steel through all the metals and alloys used in construction to the non-metallic materials. Here are included particulars of welding as it is now applied in structures and in manufacturing processes. Corrosion-resistant metals and the methods of protecting against corrosion in different situations also find a place. The important alloys of aluminium receive appropriate treatment, and so do those of nickel and of magnesium. In the section on non-metals, the data supplied regarding cork, rubber, asbestos, carbon and the refractories are particularly valuable as they are not, as a rule readily obtainable.

The second part of the book is given over to the forms, proportions and other information relative to machine details and the thousand and one items which constitute the elements of shop work. Nystrom advised that "Every engineer should make his own pocket book, as he proceeds in

udy and practice", but while this remains good advice, the accumulation of engineering facts and figures now far exceeds any one man's practice, and he must be largely guided by the experience of others. The importance of standardization in any details also makes such a handbook a necessary part in the equipment of the engineer. Much of the information here is of the usual nature, but especial value is attached to many items by reason of their novelty, their growing importance and their reliability, for each section has been prepared by an expert in his subject. These include such matters as control mechanisms, vibration and noise, safety equipment, dust collection, and the illumination of workshops.

The general arrangement of the book should simplify the work of reference to such a vast store of information. Despite the large number of pages, the book is of convenient size and its flexible binding enables it to remain open at any selected page.

(2) There is another side to this question of handbooks, for it may, of course, be stated with certainty that every engineer feels the need of having at hand some reliable source from which he can readily obtain information, both descriptive and quantitative, on practically all branches of his profession. For a period now of forty-five years, "Kempe's Engineer's Year-Book" has been the leading publication of this kind and also the

most complete, and has become, like the slide-rule, one of those essential items that must always be within reach. Year by year it has entered upon a new edition, on each occasion being brought up to date by the excision of all that has become obsolete and the introduction of what is new and established.

The issue for 1939 is now available and once again the opportunity has been taken to incorporate new material and, where necessary, to effect the revision of tables. The information has been presented in the most concise form by experts in their several branches, and the general revision has been made under the direction of the editor of the *Engineer*. Of its two main parts, the first contains general principles and data. The second, entitled "Descriptive Sections", is devoted to practical applications of these principles in civil, mechanical, electrical, naval, automobile and aeronautical engineering works. There are also sections dealing with ancillary subjects such as acoustics, explosives, paints, depreciation, and legal notes for engineers, to name but a few of these.

The increasing revisions and additions in order to keep the book up to date with current practice have brought the 1939 volume up to 2,824 pages. It is profusely illustrated by diagrams and half-tone illustrations, and contains valuable descriptions of the products of many important engineering firms.

Expanding Horizons

Geography in the Middle Ages

By George H. T. Kimble. Pp. xi + 272 + 20 plates. (London: Methuen and Co., Ltd., 1938.) 15s. net.

MR. KIMBLE has made a valuable contribution to the history of geography in this volume. His title is somewhat misleading, for the last two chapters take us beyond the strict limit of the geography of the Middle Ages and introduce the great Age of Discovery. The author shows how, for example, Fontana blended traditions of Marco Polo with knowledge gained by the Portuguese in West Africa, and laid stress on the importance of a habitable land south of the equator. This idea may have influenced Columbus—as others have pointed out—to shape his course towards the south-west rather than due west.

An important chapter deals with medieval maps. The author goes far to establish the point that many of these maps were forgeries or at least contained inaccurate information. He instances the map of Fra Mauro and the globe of Behaim, both of which were based on Portuguese material

and both of which do not accurately represent Portuguese accomplishments, as evidence that the Portuguese policy of secrecy led to the falsification of material supplied to cartographers and to the general scarcity of Portuguese maps.

Two chapters deal with 'expanding horizons' in Asia and in Africa. In the latter, Mr. Kimble puts up a good case for the genuineness of the work of the anonymous fourteenth century Spanish Franciscan who seems to have had some knowledge of the west coast of Africa at least as far as Sierra Leone.

A number of well-produced photographs of early maps, and a select bibliography complete a work on which both author and publishers are to be warmly congratulated. To the latter a special word of thanks is due for encouraging the publication of works by English writers on the history of geography and thereby filling a serious gap in geographical literature. Mr. Kimble's book is worthy to stand by any of its predecessors.

J. N. L. B.

Kleine Erdbebenkunde

Von Prof. Dr. Karl Jung. (Verständliche Wissenschaft, Band 37.) Pp. v+159. (Berlin: Julius Springer, 1938.) 4.80 gold marks.

THIS admirable little book contains a large amount of information in a small space and, although succinct, is eminently readable. The nine chapters include such topics as macroseismic effects, the geography, nature and cause of earthquakes, the method of obtaining seismograms and information concerning shocks, the propagation of earthquake waves, microseisms, and the application of earthquake knowledge chiefly to seismic prospecting. Dealing with the cause of earthquakes, Prof. Jung says: "Concerning the fundamental causes of the formation of mountains, of earthquakes, and volcanicity there are only suppositions partly substantiated, and no one theory has yet found general recognition". Thereafter a nice balance is maintained between the various current theories, and an adequate discussion is given of the materials of the earth's crust and beneath the crust, which materials have sufficient strength to cause and maintain oscillations and yet yield to the forces required by isostatic theory.

The illustrations in the book are very clear and often give the results of much mathematical investigation without using a single mathematical symbol. The text is well informed and up to date. For more detailed information the student must consult the publications listed at the end of the book, which he must also do for the authors of the original works mentioned whose names are often omitted. The book is of handy pocket size and is very well printed.

E. T.

African Odyssey

By Joseph Crad. Pp. 286. (London: John Gifford, Ltd., 1939.) 12s. 6d. net.

MR. CRAD'S story of his youth and early manhood in South Africa is an "Iliad" rather than an "Odyssey"; for its main interest lies in combat of the truly heroic type. His story of life in South Africa, nearly fifty years ago, when he was pioneering in the country of the Matabele, is Homeric in its zest for battle. He took part in the Matabele War, which ended in the death and defeat of Lobengula; and then for a period was in East Africa, working in Zanzibar and making a trading journey on foot to Lake Tanganyika, when he was attacked by raiding Masai. He then travelled in other parts of the world; but of his adventures we are not told, his narrative being concerned with Africa only. In addition to service in the Boer War, he fought with the Natal forces in the suppression of the Zulu rising of 1906-7.

Mr. Crad's view of the native peoples of South Africa, notwithstanding his experience of the cruelties practised in their raids in his early days, is impartial, and for certain sides of their character he has no little admiration. In the light of his knowledge of the native he confidently anticipates that trouble, similar to that which caused the Zulu rising in 1906, is likely to recur.

The book, in view of its intimacy of detail is a record of a phase in the relations of black and white, now completely passed away, which is of more than ephemeral interest. It is also a vivid picture of the practical working of the Matabele and Zul military organization.

Capri

Per Immanuel Friedlaender. Tradotto da Angel de Angelis. Pp. 168+12 plates. (Roma: Societ Italiana Arti Grafiche, 1938.) 25 lire.

ALTHOUGH Capri, the small island lying at the entrance to the Bay of Naples, has a total area of only some four square miles, it has an extensive literature. Its many interests have brought it fame since the days when it was the resort of Roman emperors. Prof. Friedlaender attempts with considerable success to survey all aspects of the island. The peculiar geological structure of the caves and caverns of the island is fully discussed and the flora and fauna receive special notice. The second half of the book deals with the story of the people, the antiquities and the history, and concludes with a bibliography. If the volume contains little that is new, it collects much scattered matter in an accessible form. There is a map on a scale of 1:12,000 in an end pocket.

Practical Organic Chemistry

By Dr. Frederick George Mann and Dr. Bernard Charles Saunders. Second edition. Pp. xiii+418. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1938.) 8s. 6d. net.

THIS new issue is unchanged, except that it contains an account (2 pp.) of Middleton's sodium carbonate-zinc method for detecting nitrogen, halogens and sulphur in organic compounds, with the addition of some useful tables of physical constants (m.p. and b.p.) of organic compounds (12 pp.). The publication of a second edition of this work two years after its original appearance testifies to its fundamental soundness. It meets admirably the requirements of general degree courses in practical organic chemistry, and may be heartily recommended also to more junior students.

J. R.

Principles of Genetics

By Prof. Edmund W. Sinnott and Prof. L. C. Dunn. (McGraw-Hill Publications in the Botanical Sciences.) Third edition. Pp. xiv+408. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 21s.

WITHOUT an appreciable increase in size, this edition includes adequate treatment of recent work, such as position effect, somatic crossing-over, salivary-gland chromosomes, cytoplasmic inheritance and heterosis. This has been achieved by considerable rewriting, which appears to have improved the text. This third edition contains a remarkably complete and well-illustrated simple statement of the elements of genetics for biological students. The subjects of crossing-over and the chromosome theory of heredity, highly important in modern genetics, are dealt with particularly well.

Fission of Heavy Nuclei : a New Type of Nuclear Disintegration

By Dr. N. Feather, Cavendish Laboratory, Cambridge

THE first indication that the transmutation of heavy nuclei could be effected in a laboratory experiment was obtained by Fermi in March 1934. Curie and Joliot had just discovered that short-lived radioactive species are produced as the result of α -particle bombardment of certain light elements, and Fermi, accepting the appearance of such 'induced' radioactivity as proof of transmutation, very soon showed that the nuclei of almost all elements, even those of highest atomic weight, undergo transformation when neutrons are used. From his early experiments Fermi concluded that in general the neutron is simply captured by the nucleus, and he went on to show that this process of capture is usually more efficient—and sometimes very much more efficient—when the neutron is moving with a small ('thermal') velocity, before the collision, than when its energy is large. Eventually he found that negative electrons were emitted in the disintegration of the radioactive products obtained in all these capture transformations, and thus the final result of the combined process of neutron capture and β disintegration was in every case shown to be the production of a nucleus having both mass and charge numbers greater by one unit than the mass and charge numbers of the nucleus bombarded.

In June 1934¹, Fermi and his collaborators obtained negative electron activities from thorium and uranium under neutron bombardment, and they quite naturally supposed, on the basis of their previous investigations, that in the latter case a nuclear species of atomic number $Z = 93$ must remain after disintegration of the unstable product first formed. Further examination showed that not one but several distinct radioelements were produced as a result of the bombardment of uranium, and rough chemical tests proved that one of these, at least (half-value period $\tau = 13$ minutes), was not attributable to an element of atomic number $Z = 92, 91, 90, 89, 88, 83$ or 82 . It seemed quite clear, then, that after the uranium nucleus had captured a neutron, not less than two or three transformations followed, and consequently that a new element, for which Z was not less than 94 , was ultimately produced. These conclusions at once gave rise to much argument amongst chemists as to what the chief chemical properties of these hypothetical transuranic elements might be, but a great deal of careful research in many physical laboratories throughout the world only served to

strengthen the assumption that, apart from any preconceived ideas about chemical behaviour, such elements were certainly formed when uranium was bombarded by neutrons.

By May 1937, Meitner, Hahn and Strassmann² had recognized the existence of nine separate species arising from this transformation, and had suggested genetic relations between them which supposed that every element of atomic number between (and including) 92 and 97 was represented, either as intermediate or end product of a series. They identified three of these nine products ($\tau = 10$ sec., 40 sec., 23 min.) as unstable isotopes of uranium, and the remainder, which could all be obtained by precipitation with platinum as sulphide in acid solution, as the transuranic elements already mentioned. The scheme presented certain difficulties, it was admitted, (no evidence for the final return of the unstable nucleus within the ordinary range, Z less than 93 , could be found, and awkward questions concerning isomeric forms were raised in an acute form) but it was the best that could be done.

Then, in October 1937, Curie and Savitch³ discovered a tenth activity of about $3\frac{1}{2}$ hours period, and at once proceeded to investigate the chemical nature of the element to which it belonged. They showed that this radioelement did not separate with the platinum precipitate and soon discovered that it bore a close resemblance to lanthanum in chemical behaviour. At first the most plausible suggestion appeared to be that the new species was an isotope of actinium ($Z = 89$). Then two very disturbing facts were encountered. First, a body of the same period and almost identical properties was among the active products formed in the disintegration of thorium by neutrons, and, secondly, it was found possible to separate actinium almost completely from the new body by a lanthanum fractionation. In September 1938, Curie and Savitch⁴ wrote, "On the whole, the properties of $R\ 3.5$ h. are those of lanthanum, from which it appears that until now it has not been separated".

The work of Curie and Savitch immediately prompted a further search for activities belonging to elements of atomic number less than 92 produced in the uranium transformation, and, as a result, Hahn and Strassmann⁵ discovered two other lanthanum-like and three barium-like products. These workers believed that they had

demonstrated the production of each of the former species from one of the latter, but at that time they still inclined to the view that actinium and radium isotopes were really in question. However, in January of this year, they reported⁶ that fractionation of the new bodies with mesothorium and barium (or lanthanum) invariably concentrated the neutron-produced activity with the lighter carrier and resulted in a complete separation of mesothorium 1 (radium), or mesothorium 2 (actinium). The conclusion now appeared inescapable that active isotopes of barium and lanthanum were among the products of the bombardment of uranium with neutrons.

At this stage, Meitner and Frisch⁷ discussed the problem on the Bohr theory of heavy nuclei, making particular use of the essentially classical 'water-drop model' of the highly condensed system of particles of which such a nucleus is constituted. They concluded, "It seems therefore possible that the uranium nucleus has only small stability of form, and may, after neutron capture, divide itself into two nuclei of roughly equal size. . . . These two nuclei . . . should gain a total kinetic energy of c. 200 Mev. . . . This amount of energy may actually be expected to be available from the difference in packing fraction between uranium and the elements in the middle of the periodic system". Then Frisch⁸ obtained direct evidence for the projection of fission fragments with approximately the energy predicted, being able to detect the production of large bursts of ionization in a uranium-lined ionization chamber which was irradiated by neutrons. Similar results were obtained when thorium was substituted for uranium in the chamber, and it was concluded that some of the activities previously ascribed to isotopes of radium and actinium, in this case also resulted from fission of the nucleus under neutron bombardment.

The investigations begun by Meitner and Frisch were rapidly followed by many others in physical laboratories both in Europe and in the United States: the confirmation of the findings of Curie and Savitch by Hahn and Strassmann had indicated quite clearly to many workers that something new was involved. In Paris, in Berkeley, in Washington, New York and Baltimore, direct proof of the fission of uranium and thorium was obtained within the space of a few days. Now, some three and a half months after the original announcement, so much has been published that rigorous selection is necessary in any report on the subject. For the remainder of this survey, therefore, only the most interesting features of the new phenomenon can possibly be included.

Perhaps the first such feature concerns the radioelements of the platinum precipitate, of

which the previously supposed transuranic nature was now in question. Before the fission process was discovered, both in Berkeley and in Cambridge, projects had already been formed of investigating these elements for natural X-radiations, in the hope of being able to deduce the atomic number from the energy of the radiations (natural X-radiations) as determined by the method of critical absorption. This problem became much simpler once the presence of medium-heavy elements was suspected, since K-radiations could be looked for instead of the more complex radiations of the L-series. Almost at once, Abelson⁹ and Feather¹⁰ and Bretscher¹¹ found evidence for the natural K-radiations of iodine from the long-lived activity of the platinum precipitate, and, guided by this observation, were able to identify chemically a tellurium and iodine two products previously described as eka-iridium and eka-platinum, respectively. Then several workers found other of the so-called transuranic activities in the product collected by recoil from bombarded uranium. Observations concerning the rates of decay of these recoil activities¹²—and the results of chemical tests¹³—left little doubt that almost all the previous assignments had been seriously in error. At the present time, one might justly say that it cannot definitely be maintained, concerning any of the activities separable from uranium, that it does not arise in a process of fission of the uranium nucleus.

There is, however, one important activity, of 23 minutes half-value period, which is not separable from uranium and for which, in consequence, the fission process cannot be assumed to be responsible. This non-separable activity arises in a process of resonance capture of neutrons of about 25 ev energy, and the fact that negative electrons are involved must clearly indicate that a species for which $Z = 93$ is formed as the result of the disintegration. Yet, in spite of much careful investigation, no radioactivity of any kind has been discovered which is unquestionably due to the transformation of this species. Furthermore, in respect of the parent species (the uranium isotope for which $\tau = 23$ min.), this is clearly a quasi-stable modification of the body which undergoes fission in the majority of cases, and Meitner and Frisch and Bohr¹⁴ have discussed this aspect of the phenomenon. They have pointed out that there is nothing intrinsically incomprehensible in the occurrence of resonance capture (emission of γ radiation) rather than fission in certain circumstances. In any event, division of the nucleus into two fragments must be preceded by the concentration of the available energy in a type of nuclear motion of large deformation, and this concentration may be very unlikely if the original state of the system, after capture of the neutron, is one of

nsiderable symmetry. Or if, as Bohr has assumed, the effect of thermal neutrons in producing fission in the case of uranium (such neutrons are quite ineffective when thorium is bombarded) is ascribed to capture by the rare isotope ^{235}U , and the resonance effect and the fission process due to fast neutrons are ascribed to ^{238}U , it may even be that, at the resonance energy, the compound nucleus is not formed with sufficient energy of excitation for the neutralization of the small probability of form which it naturally possesses. As regards the whole of this question, more definite conclusions must clearly await further experiments: Joliot¹⁴ has reported a variation in the relative proportions of the different fission products as the energy of the neutrons is altered—and this might be held to favour the suggestions of Bohr—but Bjerge, Brostrom and Koch¹⁵ have failed to establish any difference in the decay of the products obtained with high-energy neutrons and thermal neutrons, respectively.

Hitherto, the process of fission has been spoken of without any precise statement regarding the nature of the fragments which result from the primary act of division of the nucleus, and in fact very little exact knowledge is as yet available on this point. Determinations of the range of the fission products provide some information. In the first place, they indicate that (with uranium and fast neutrons) the process occupies less than 1×10^{-12} sec. from the time of capture of the neutron (the forwards range is slightly greater than the backwards range, showing that very little of its original momentum is lost before the compound nucleus divides¹⁶), and, secondly, they appear to favour a very small number of competing primary processes, rather than a large number of possibilities¹⁷. On the other hand, chemical investigation reveals such a wealth of active products¹⁸ (with atomic numbers lying between 35 (Br) and 57 (La), if not more widely distributed) that some adequate explanation of their complexity must certainly be found. It would appear that the discovery that very frequently neutrons are emitted almost instantaneously by the original products of fission¹⁹ already provides a basis for such explanation (nuclei, first formed, presumably, in states of high excitation, emit either neutrons or quanta of radiation in passing to longer-lived states). Also, even after these states have decayed with β -emission, experiment shows that occasionally product nuclei result, still with sufficient energy of excitation for the 'evaporation' of neutrons to be a possible alternative to radiative transitions leading to more stable states. In this connexion, Roberts, Meyer, and Wang²⁰ and Booth, Dunning and Slack²¹ have reported delayed

neutron periods of about 12 sec. and 45 sec., when uranium is bombarded, whilst a similar feature has also been established in the case of thorium.

The frequency of the neutron-evaporation process accompanying fission, and the energies of the neutrons so produced, have been studied by many workers, but so far most exhaustively by Joliot²² and his colleagues, and by Fermi²³ and others in New York. The general result appears to be that, for each process of fission with uranium, at least two neutrons, having a mean energy of the order of 10^6 ev., eventually evaporate from the residual fragments. Since neutrons of less than this energy are still capable of producing fission on their own account (probably in ^{235}U , as already suggested), the possibility of a cumulative process of exothermic disintegration has to be considered. Clearly, if the probability of removal of neutrons in processes other than those which result in fission is sufficiently reduced, the latter process must eventually build up in any solid substance containing uranium. Direct experiments on this aspect of the matter have not yet been reported in the scientific literature, but at this stage it may be pointed out that, even in pure uranium, it is well known that a non-fission capture process takes place (*v. sup.*), whilst the unlimited generation of energy in the solid material would ultimately increase the energy of the 'thermal' neutrons until their efficiency as agents for fission was greatly reduced. Already several attempts have been made²⁴ to calculate the course of the phenomenon using existing data, but the assumptions upon which they have been based have generally been so severely idealized that no confidence in numerical values is at present likely to result.

The Concept of Instinct

By Dr. J. A. Loeser, formerly Professor of Psychology,
University of Berlin

WHEN a hen has laid eggs for the first time in her life she immediately sits on them. She does not know why she does this for she does not consciously know what an egg is, nor what incubation is, nor can she take any interest in the hatching of the future brood. Hitherto science has called this a typical example of animal instinct. Without any consciousness of the biological purpose, it is said the animal finds the right thing to do because it was born with a mysterious instinct, which is inherited from the experience gained by its ancestors in primeval times.

THE CONCEPT OF INSTINCT

What is the real truth of the matter? Careful investigation has proved that the animal certainly has personal motives for sitting, but they are not biological ones. Shortly before the beginning of hatching-time the animal's breast shows the so-called hatching spot. Here the feathers fall out and there is a bald spot which feels hot, as if from inflammation (probably caused by hormones). This evidently causes the animal pain, for it seeks cooling substances, which must necessarily have a curved shape to be effective. After the eggs have been laid, these offer what is required. But we may just as well give the hen stones or billiard balls to sit upon; she will 'hatch' them in exactly the same way, because all she wants is to soothe the discomfort of her body. It is also possible to soothe the 'hatching irritation' in an entirely different way, that is, by holding the animal's breast in cold water. These are experiments which even the peasant knows and often makes for practical reasons. Only a bird which has these 'spots' sits on the eggs, and with many species frequently it is the cock. Similarly, the bird takes no more interest in its own eggs than in those of another bird, if these are put into its nest soon enough to become familiar. There is, therefore, no such thing as purposeful hatching. The hen only sits on her eggs while the irritation from the 'hatching-spot' lasts. When the eggs have been hatched, others may be substituted, and she will continue to sit on them. But when the irritation has ceased, the hen does not continue to sit but forsakes the eggs, which decay.

Usually, however, this subjective conduct on the part of the bird serves a purpose, for the

consequence generally is that the eggs are hatched. The hen turns the eggs so that she may sit on the cool parts, and without meaning to do so she thus causes all parts of the egg to be equally warmed.

This example shows animal behaviour in an entirely new light. The conclusions to be drawn from it are the following:

(1) Every animal acts only in accordance with *personal* or *subjective impulses*; it only satisfies its personal needs. The hen merely wishes to soothe the pain of the 'hatching spot'.

(2) The *means* to do this may vary a great deal; they are *fundamentally variable*. It is a matter of indifference to the hen whether she sits on eggs or on other subjects, or whether cold water is used for satisfying her needs.

(3) Biological purposes are not aimed at either consciously or unconsciously, that is instinctively. The 'personally' motivated behaviour is often biologically useless or harmful. The hen is indifferent to the fate of the eggs. Frequently however, subjective (psychological) aims and objective (biological) purposes coincide.

The theory of the *psychological autonomy of action* in all living creatures, which I evolved on these lines a few years ago, cast doubt on all mechanistic conceptions of human and animal behaviour and therefore to the ancient conception of instinct, which had persisted for more than two thousand years. This conception had completely dominated the theory of organic behaviour. All actions were traced to fundamental instincts, even the actions of the apparently free will, for at long last the motives for these too were believed to consist in vital impulses.

In opposition to this conception, the new theory postulates the fundamental 'uniformity of all organic action' from the simplest reaction of the Protozoa to the voluntary action of man. The prototype of all reaction, indeed, is this *voluntary action*. Its principle is *variability* in the choice of the means to obtain its ends.

The aim of voluntary action is always a personal motive, a psychological experience, which represents the subjective reason for the reaction. The motives themselves may be of an inferior or of a superior nature, that is at present theoretically unimportant. Every organic action, therefore, is merely the satisfaction of an impulse, without

gard to the question as to how far self-preservation and race-preservation, the two impulses generally recognized in biology as the only influential ones, are guaranteed.

These two great unconscious motives in the theory of instinct and all biological psychology must be eliminated; they do not exist; they are either conscious nor unconscious impulses of organic behaviour. If then there is no instinct as the imaginary basis of action, neither is there instinctive action or reaction, in short no unconsciously suitable action (that is, no action for the purpose of self-preservation or race-preservation); there is no pre-formed reaction which intervenes, as an inherited factor, between the sensation and its expression.

Only in a certain percentage of cases do self-preservation and race-preservation occur in Nature as the *consequence* of purely individual action.

VOLUNTARY AND REFLECTIVE ACTION

The first and fundamental question here is the transition of ideas in the line which leads from true voluntary action (or action of the free will) by way of rigid instinct, occasionally modifiable, it is true, yet essentially and fundamentally invariable, to true *reflex action*. If this continuous line cannot be sharply divided, the result will always be: instinct is in the end a reflex-chain and the action of the will is only a relaxed action of the instinct; this was how it was described even in the most recent publications. Instinct is actually only an 'extended organ'—this was the rigid and materialistic conception of what is in truth free responsive action.

So we must first find a short and correct definition of reflex action. It is characterized by movement independent of the personal will, such as it can be found in the action of the internal organs of the body. Reflex action needs a nerve centre the existence of which has in many cases been proved. As it does not emanate from the ego, it is not directed towards the ego's purposes; how far it is biologically useful is another question. But this is not our concern for the moment.

In contrast to these *involuntary* processes all others appear as *voluntary actions*, modelled on the true action of the will. To these belong the voluntary closing of the eyelids or voluntary breathing, whereas involuntary breathing is a reflex. To these belong also, however, as I have proved by a number of examples, most of the so-called instinctive actions—not, it is true, taken as a whole (as described in the famous old alternative: conscious action of the will or unconscious action of the instinct), but analysed and broken up into a series of "small voluntary actions".

Thus every true action (action of the free will) is a natural product of all the circumstances, a product consisting of three main factors. That is, *psychological* and *physical* tendencies and abilities can only be effective in the animal's natural *surroundings*. In short, every living creature acts in any given situation so far as possible under the impulse of pleasure or pain.

SENSATION AND REACTION

Most investigators pay too little attention to the decisive factor, *sensation*, which they generally treat as of minor importance. Instinct is mostly defined as unconsciously purposive activity. But why should there be any sensations, pleasure or pain, and whence do they arise, if they do not cause a reaction and, moreover, a fitting reaction? Does not every living creature, as the simplest observation shows, act in a manner which leads, for example, to the satisfaction of the painful sensation of hunger? On these occasions biologically inexpedient activity frequently occurs, such as the eating of injurious food, only because it has a pleasant taste. It is only personal impulse, that primarily controls and guides action.

A striking example of instinct seems to be that of the *swallow*, the instinct of which appears to impel her to a sticking activity, even when there is no reason for it, when, for example, she has a perfect nest. The sticking is an instinctive impulse, it is said. But birds which build with saliva—swallows as well as nuthatches and salanganes—have special salivary glands, which swell during brooding-time and obviously drive them to secrete the salivary fluid, as is the case with all animal secretion. Alfred Brehm has pointed out that the pain caused by the swollen glands impels the animals to get rid of the secretion of these glands by pressing and rubbing movements. So here, too, there is no question of the irresistible beginning of a purposive instinct but of a subjective activity on the part of the bird, of a significant reaction to a painful stimulus, a reaction which may, however, be purposeless.

One of the chief examples of instinct, the piercing reaction of the lanneret (*Lanius collurio* L.) has since been proved, in complete agreement with my theory, to be the result of suitable actions according to the principle of trial and error, knowledge of the thorn being only acquired after long investigation (Lorenz). Another pillar of the instinct theory has therefore fallen.

A splendid new example of instinct analysis according to my theory is solving the famous problem of the *cuckoo's egg*. This was formerly a problem which evidently defied solution. How is it that the cuckoo's eggs found in other birds'

nests always correspond in colour to those of the owner of the nest? How can the cuckoo sometimes put bluish-green eggs, then again white ones with brown spots, or speckled or unspeckled ones into the strange nest? If the eggs differed from those of the host, they would, of course, be thrown out of the nest. But it is just these fundamental problems that have been solved quite naturally. Each cuckoo has been bred in a certain kind of nest and has been fed with a certain kind of food. This influences the colour of the eggs, for example, the bluish-green colour of the garden redstart's eggs. We now know almost for certain that for the purpose of laying her eggs, the cuckoo generally only chooses a nest like the one in which she herself has been reared and with which she is therefore familiar. This is easily explained. So her eggs are laid beside eggs of a different nature but of the same colour, and are therefore not thrown out by the host but hatched by her. In this way, a particularly complicated problem has been solved in a perfectly natural way in conformity with my theory, according to which purely physiological factors (the same colour resulting from the same food) generally co-operate in these complicated cases with psychologically motivated reactions (choice of the familiar kind of nest). Here, therefore, we have series of truly voluntary actions, and analysis has led to the solution of the problem.

It is therefore evident that there is always a *personal reason* for the action, and that nothing takes place *without* such a motive.

The second decisive point is the *reaction* to emotion. Every action is *always* and *only* the response to an emotion. Where the psychological basis is very narrow and slight and the physical possibilities very unmistakably re-formed, the response may be of an exceedingly stereotyped nature. In such cases the impression gained from superficial observation will be that the actions are really mechanical.

It is well known that ichneumon flies sting strange caterpillars or grubs which they find beneath the bark of a tree. The explanation of this mystery was found by means of an experiment which once more proved the exclusive effect of personal impulse. In this case, the impulse was provided by the smell of the victims. It was proved that the ichneumon flies also stung small paper cornets filled with the blood of the caterpillars or grubs, this blood providing the characteristic smell. If there were an instinct or some complete reaction unconsciously serving a vital purpose, it would necessarily *include* the strange insect as the *object* of the action, for without this insect as its object the action itself would be *useless*. It is therefore clear that here too the stimulus merely

leads to its own satisfaction irrespective of an object or purpose, whereupon a true inner organ reflex action takes place, which causes the laying apparatus to function.

The well-known experiment made in Germany a few years ago with *young storks* in order to subvert their instinct to an *experimentum crucis* ended in a real catastrophe for this conception. The bird which had been brought from east Prussia to the Rhine and which had not hitherto migrated should have moved in a south-easterly direction according to the instinct theory. This is usual with storks the home of which is in eastern Germany, a fact hitherto explained by the 'instinct of direction', that is a south-easterly instinct. The result, however, was that the storks scattered in all directions. Some were sighted in the Alps, some in France, but not a single one in the east. The reason for this is that all the storks in eastern Germany, being 'water-birds', must naturally move along the river valleys, etc., where they find their food, and finally in the direction of the Black Sea and the Bosphorus, whereas when taken to western Germany they pursue the opposite course, that is like the west-German storks, they fly along the Rhine-Rhone valley to the western Mediterranean and North Africa. In this case, however, the most natural thing was for them to scatter, as storks 'traditional flyers', mostly migrate under the leadership of old ones, and this leadership was lacking.

THE PROBLEM OF PURPOSE

In all these occurrences in Nature as well as in all experiments, we have repeated evidence of the uncertainty with which biological aims are achieved. A glance at 'fundamental instincts' will prove this; for example, the important and decisive *food instinct*, where the fundamental divergence between the significant reaction to stimuli (taste and smell) and the biological utility of this procedure is clearly evident. Every living creature, from the protozoan to man, directs its actions primarily and exclusively according to such subjective stimuli; only in the second place does the problem arise as to how far satisfaction of the stimulus is conducive to health. Even in the animal kingdom this problem may become a momentous one, as when certain tribes of ants cause the downfall of their community through excessive consumption of the intoxicating secretion of the plant-louse. It must be remembered that there is no question here of *abnormal behaviour*. On the contrary, it is in such extreme cases that the fundamental law is most clearly evident, the law of reaction to a sensation.

The frequently destructive behaviour in the animal's *care of its young* is perhaps the most

striking example of all. The fact that with many species the devouring of eggs and offspring is not an abnormality, but almost a normal procedure, with ants, bees, bumble-bees, also with some kinds of fish, is clearly in favour of the exclusive principle of the subjective satisfaction of impulse, a principle which rules even in opposition to elementary biological purposes.

On the other hand, I have already given a detailed description of cases in which 'genuine' care of the brood, that is the care of the young animal itself, as well as genuine friendship and love in animals, are found.

With regard to the problem of the so-called instinctive goal, *migration of birds* of passage is of special interest. It used to be said that the true migratory instinct determined both, the *passage* and its *destination*. But there is scarcely another instance which proves so unmistakably that all is variable. At most it can be said that the impulse of flying is constant, the impulse which is the fundamental phenomenon of the migration, and which I have already described in detail elsewhere. This impulse signifies the beginning or breaking forth of a *completely undirected* storm of motion—probably due to the action of hormones. In this storm the moving stimulus is once more recognizable, the stimulus to which all migration is the natural reaction. But the two factors essential to the instinct, that is, the *way* and the *goal*, are by no means pre-formed. On one hand, suitable adaptation to circumstances is again possible, leading to the only action which is biologically (relatively) expedient. On the other hand, the loss is naturally very great, due to the difficulties of the flight and to the inadequate intelligence of the birds, which are not able to gauge the difficulties that face them. Frequently they make fatal mistakes, as when the great flocks of singing birds fly over the Black Sea by night and perish in thousands, because their wings are frozen. The bird knows nothing, it neither recognizes its danger consciously, for it evidently does not even know that it is flying over a great expanse of water, nor does instinct guard it unconsciously, but all the more surely, from destruction.

RESULTS

So the nature of organic action proves to be quite different from what has always been assumed. For the assumption of instincts makes the living creature an automaton, which, if properly constructed, cannot make mistakes. (The famous struggle for existence constitutes only an apparent exception. For it is those individuals who have been most favourably predisposed from the beginning which automatically survive through the

process of selection. There can scarcely be any question of a real struggle.) The theory which I have propounded, that of the *risk* of organic life, is something fundamentally different. For every organism, from the lowest to the highest, acts in conformity with it, according to the same principle of adaptation to circumstances under the *egis* of subjective impulses and experiences. Thus we have genuine reflection and genuine risk. We also have error as a necessary ingredient of life, not as the abnormal breaking-down of an automatic machine. A real risk, and in consequence a real struggle worthy of the name, are only possible where there is that which in its highest sense is called free will. It always rests on the same principle—the possibility of *selection* among various reactions. What we term *psyche* or *consciousness* is needful, that is real psychological experience, the recollection and estimation of which leads to the corresponding action.

What becomes of organic purposiveness? The only thing we must state as an indisputable fact in Nature is the presence of a certain pre-formed harmony. Every living creature is born with an organism which enables it to exist within certain limits. Part of this constitution is a disposition to experience certain stimuli. The fact that sugar has a sweet taste and therefore a pleasant one rests on constitutional factors. But the behaviour which satisfies such pleasurable impulses and wards off painful ones is by no means, and cannot be, pre-formed, for the ever-changing circumstances of life necessitate a constantly renewed adaptation to them.

I must once more state emphatically that the instinct hypothesis is in direct contradiction to every result of the modern theory of heredity. It has been proved again and again that only a certain disposition to receive impressions on one hand, and to general emotional attitude and bent of mind on the other is inherited; for example, a profoundly emotional nature or a generally intelligent disposition. We have never known, especially in practical life, anything like an inborn impulse to action or hereditary knowledge. We may inherit a talent for languages, but not a knowledge of French. Neither can knowledge that an object is there for a special purpose be inherited; for example, the hen has not inherited the knowledge that sitting on an egg will hatch it. We see that man's knowledge and actions emanate from his mental and emotional disposition and as their result, but nothing more. There is no 'born murderer' as such, except in so far as a man is predisposed to murder by his general mental and emotional life. Instinct has been defined as 'inherited experience'. Science has proved that such a thing does not exist.

The Aurora Polaris and the Light of the Night Sky

THE relation of the aurora to the light of the night sky formed the topic of a Geophysical Discussion at the Royal Astronomical Society on May 19, under the chairmanship of Lord Rayleigh. Prof. S. Chapman opened the discussion.

Owing to its often striking appearance, the aurora polaris has long been studied. Dr. J. M. Stagg gave an account of its appearance and changes as observed at Fort Rae, near the auroral zone, during the second International Polar Year (1932/3); one remarkable feature he described was the occasional repetition, on two successive nights, of unusual and distinctive auroral appearances.

The situation of auroral arcs and rays and sheets and diffuse clouds has for many years been determined with considerable accuracy by the methods introduced by Prof. C. Störmer, whose long-continued and fruitful work was rewarded, not long since, by the discovery that the very high auroras, extending up to 600 km. or even more, are generally in the part of the atmosphere which, though visible from the ground after sunset or before sunrise, is still illumined by the sun's rays.

Naturally, the auroral light was also examined by the spectroscopist; the spectrum includes several bands, some of which have long been known to be the so-called negative bands emitted by excited positive molecular ions of nitrogen (N_2^+); in addition, it contains a bright yellow-green line.

A similar line was found to be present in the light of the night sky. But in other respects this light differs considerably from the auroral light, as was first clearly emphasized by Lord Rayleigh; it does not contain the N_2^+ bands: it is diffuse and formless, but always present, in all latitudes; its variations are much less rapid and less great than those of the aurora.

The wave-length of the green line in the night-sky spectrum was determined very accurately in 1923 by Babcock, using an interferometer; it is 5577.35, and its width is very small, only 0.030 Å. A few years ago, Harang and Vegard (who has been one of the most assiduous and successful workers on the auroral spectrum) determined the wave-length of the green auroral line in the same way, and thus proved that the line is the same in the two spectra. These interferometer measures show that the line is of atomic origin and not part of a molecular band. Harang and Vegard have also demonstrated the atomic character, and found the accurate wave-lengths, of two red lines, 6300 and 6364, in the auroral spectrum.

The same two lines, and also the yellow double of neutral atomic sodium, have been observed interferometrically in the night-sky spectrum: this was done in France, where several spectroscopists of the highest skill—Cabannes, Dufay, Gauzit and Bernard—are studying this light. The lines named above are the only ones in the auroral or night-sky spectra the atomic character of which has been established by use of the interferometer. The suspected presence of a line due to atomic nitrogen has not yet been confirmed or disproved by this method.

Recent years have seen a great advance in the accuracy with which the lines and bands in the two spectra are measured, and in the range of the spectrum observed. For the night sky, the observations have been extended far into the ultra-violet (notably by Gauzit) and into the infra-red (by Slipher). Gauzit has made the remarkable discovery that the night-sky spectrum extends to at least 2950 Å. in the ultra-violet; he suggests that this light comes from the lower part of the ozone layer, which would absorb such light if it came from above (as it absorbs the sunlight of the wave-length, during the day).

The origin of the green line 5577 long remained mysterious, and it was not produced in the laboratory until 1925, when McLennan, with Ireton, and others of his Toronto fellow-workers began a brilliant series of researches which, aided by other discoveries of the time, by Frerichs, Rubinowicz, and Bowen, established that the line is due to neutral atomic oxygen. The atomic transition involved is from the metastable ^1S state, with a mean life-time of about 1 second, to a ^1D state, lifetime about 100 seconds, these times having been calculated by Stevenson. Transitions from the latter state to the (multiple) ground state $^3P_{2,1}$ give the red lines 6300, 6364 already mentioned. Thus the nature of the atomic lines in the auroral and night-sky spectra is now definitely ascertained.

Kaplan's laboratory experiments on nitrogen mixed with oxygen have closely reproduced the two spectra, and in particular have led to the recognition and understanding of some of the principal (Vegard-Kaplan) bands in them. Though some important bands still remain unidentified, it seems likely that all the principal bands, in both spectra, are due to molecular nitrogen (neutral in the night-sky spectrum, and both neutral and ionized in the auroral spectrum). The two spectra differ greatly in the degree of excitation involved: that of the night-sky spectrum (about 7 volts

being much less than for the auroral spectrum (about 20 volts).

Dr. W. C. Price described the energy-level diagrams for nitrogen and oxygen, indicating the nature of the various nitrogen emission bands, and also explained how the oxygen molecules, but not the nitrogen molecules, become dissociated by sunlight in the high atmosphere; both also become partly ionized, the nitrogen in the *F* layer and the oxygen (O_2) in the *E* layer. The energy of the night-sky light probably comes from the recombination of some of the oxygen atoms throughout the night, and Chapman has outlined the processes by which this energy can be transformed into the observed light. The auroral light is probably due to the impact upon the molecules in the high atmosphere of fast-moving particles coming from the sun.

The temporal variations in the intensity of the night-sky light have been studied in a remarkable series of researches, carried on for eleven years under the exceptional difficulties of English skies, by Lord Rayleigh. He devised a simple instrument, which was described by the Astronomer Royal, containing a permanent weak comparison light-source (a radioactive uranium salt) and which by means of six simple colour filters enabled the intensity of the faint night-sky light, in three spectral regions, to be estimated within a range of no fewer than thirteen grades. Copies of this instru-

ment were used by other observers, and notably for about eight years at the Cape and Canberra Observatories, in a co-operative research organized by Lord Rayleigh. Variations of annual, semi-annual and eleven-year (sunspot) periods were observed, as well as irregular day-to-day changes. McLennan, and independently Lord Rayleigh, also found a variation during the night, with maximum at 12 or 1 p.m., which has since been confirmed also by Russian observers. In addition, Lord Rayleigh made the very difficult determination—of great theoretical interest—of the absolute photometric intensity of the green night-sky light (5577); this indicated that 1.8×10^{12} atomic oxygen transitions ($^1S_0$ to $^1D_2$) occurred per second in each square centimetre column of the atmosphere.

In Lord Rayleigh's own contribution to the discussion, he stressed the difficulty of work on the night-sky spectrum, owing to its faintness, which makes it impossible, in the ordinary way, to get luminous spectra with much dispersion, unless large and expensive prisms are used. He considered that his father's tube-spectroscope might find a useful application in this field; this instrument consists of a tube, with lenses at each end, which contains numerous, perhaps twenty, glass prisms in a liquid, carbon disulphide, of very similar refractive index; it can give great dispersion with little loss of light.

Obituary Notices

Sir Robert Bolam, O.B.E.

THE death of Sir Robert Bolam, which took place at his home in Newcastle-upon-Tyne on April 28, not only removes an outstanding personality of the medical profession from the north of England, but also one who by reason of his activities in larger spheres of medical interest had made a name known and respected in the profession all over Great Britain.

Bolam's name will always be connected with the two bodies to which he gave such long and valued service, the General Medical Council and the British Medical Association. He was first a member of the General Medical Council in 1920, being elected as a direct representative for England; then from 1928 until his death he represented the University of Durham. It was only natural that his acumen and capacity for attention to detail led ultimately to his appointment as Chairman of Business, and this no doubt, had he lived, would have been followed by yet higher honour in the Council.

In the British Medical Association, Bolam was an active member for forty years, and here again his administrative ability, shrewdness and clear thinking soon brought him into prominence. He became a

member of Council in 1915, acted as chairman of the Journal Committee and of the Hospitals Committee; finally in 1920 he became chairman of the Council. His energy and initiative were responsible for the transfer of the Association's headquarters in London from the Strand to its present site in Tavistock Square. In this move to what is now rapidly becoming the intellectual quarter of London, Bolam displayed foresight and faith which have since been justified abundantly.

In spite of the energy which Bolam expended in the services to the General Medical Council and the British Medical Association, either of which would have been an ample occupation for a man of normal activity and talents, he gave his best services over a long period of years and in many capacities to his old school, the University of Durham College of Medicine and the associated Royal Victoria Infirmary. The posts he held were various; in the College of Medicine he was in turn lecturer on physiology and pathology, joint lecturer on physiological physics and chemistry, professor of medical jurisprudence, sub-governor of the museum, while in the Infirmary he was assistant physician and pathologist. Later he

became the first honorary physician in charge of the Skin Department and held this position until his retirement from the Infirmary staff in 1931. The accompanying lectureship in dermatology in the College of Medicine he held from 1914 until 1937.

But as in London, so in Newcastle, Bolam was outstanding in his committee and administrative work. He was an active member of the senate of the University for many years and in 1931 was made pro-vice-chancellor, and was vice-chancellor in 1936-37. He acted as registrar of the College of Medicine in succession to Prof. R. Howden, and in 1934 was elected its president.

During the years following, Bolam's main object was to see the College rehoused on a site facing the Royal Victoria Infirmary, and to this task he applied himself with his customary vigour and enthusiasm.

Following the merging of the College of Medicine and Armstrong College into the present King's College in the University of Durham, Bolam continued as chairman of the Building Board, in which capacity he was able to see the realization of his dreams. In spite of periods of ill-health during the last six months, he was able to receive H.M. King George VI and H.M. the Queen and to conduct them around the finished building on the occasion of the official opening in February of this year.

An obituary of a man of such widespread activity as Sir Robert Bolam must necessarily tend to take the form of a catalogue of his services, in the recital of which the personal character is not given due weight. To those who knew him well, the memory of Bolam will be found not in a monument of brick or stone, not in the records of the minute books of the many committees on which he served or which he directed, but in the personal memory of the man himself. In this, his statesmanship, sincerity and directness of purpose will be remembered, but his never failing courtesy and kindness will above all be abiding to those who may claim to have been honoured by his friendship. R. B. GREEN.

Sir William Butler, Bart.

THE death on April 5 of Sir William Waters Butler, Bart., deprived Birmingham, its neighbourhood and its University, of one of their most generous philanthropists.

Educated at King Edward's School, Birmingham, Sir William entered his father's business, which later became Mitchells and Butlers, Ltd., brewers. Further studies in the sciences were pursued at the evening classes held at the Midland Institute, and he became a fellow of the Chemical Society. To the last he maintained an interest in the technology of his trade, and on more than one occasion told me that the most pleasant times in his routine week were spent in the brewery discussing technical matters on Sunday mornings when the distractions of workaday business activities could be temporarily banished.

The British School of Malting and Brewing at the University of Birmingham, set up by subscription from a number of brewing firms in 1899, was strongly

supported from the first by Sir William's firm. In 1919, he initiated the endowment of the Adria Brown chair of brewing, and in 1926 personally defrayed the entire cost of the new Department at the Edgbaston site. Without this donation, the erection of the new biology block there would have been virtually impossible. He also made repeated donations to various departments of the University; two of his most recent ones, £10,000 each, were respectively for the endowment of scholarships in science and commerce and for the University Medical School. In addition he had served since 1917 on the Council of the University, and was known to possess wide sympathies in all educational matters, and to be ever ready with business advice and help.

R. H. HOPKINS.

Mr. G. E. Blundell

THE National Museum of Wales has lost a good friend by the death of Mr. G. E. Blundell. For many years science master at Wellington College, Blundell retained his interest in scientific matters when he became lord of the manor at Newton Nottage near Porthcawl, paying special attention to chemistry and geology, and eventually to archaeology. He was a keen observer, always ready to bring new discoveries to the notice of those to whom the information was likely to be useful, with the result that although he seldom published the results of his own investigations, he contributed much that was of real value to the work of others.

It was this generous attitude that brought Blundell into contact with the National Museum of Wales. In 1922, when the Museum was preparing to open its doors for the first time, he became a member of the committee concerned with archaeological matters, and in 1926 he was elected to a seat on the Council.

As an example of Blundell's indirect contributions to archaeology we might take the discovery, made in association with his wife (a daughter of the late R. H. Tiddeman of the Geological Survey), of bronze objects and fragments of crucibles with adherent bronze, associated with fragments of iron and slag, pot-boilers and bones, in the sand dunes at Merthyr Mawr in Glamorgan. This proved to be the first Early Iron Age settlement to be found in Wales, and it was afterwards described by (Sir) Cyril Fox in "*Archaeologia Cambrensis*" in 1927.

To geology, Blundell rendered useful service by recording excavations made in the vicinity of his home, and by his interest in the early history of the subject. The latter is understandable since he was related to the descendants of William Buckland, and as a result of it, interesting manuscripts relating to Buckland's work in Wales have been deposited in the National Museum of Wales by Dr. Mervyn H. Gordon, one of the Dean's grandsons. F. J. N.

We regret to announce the death of Prof. S. L. Loney, professor of mathematics in the Royal Holloway College (University of London), from 1888 until 1920, on May 16, aged seventy-nine years.

News and Views

Dr. E. D. Merrill

THE Linnean Medal of the Linnean Society of London was presented to Dr. E. D. Merrill through a representative of the American Embassy on May 14. When in 1900 the new administration of the Philippines established a scientific service, Elmer Drew Merrill, then fresh from college, was one of those appointed. The botanical position there had been rendered difficult because of two fires; one in 1897 had destroyed the herbarium of the Forestry Bureau, Manila, and the other had destroyed the herbarium of the Guadalupe Convent during the Spanish-American War of 1898. Thus in the space of two years the work of Vidal and of the priests who had followed Blanco was largely obliterated. The problem facing young Merrill was one which would have daunted many much more experienced taxonomists, but he faced it with characteristic energy and common sense. To know what the older explorers had found and described necessitated visiting the same areas and making large collections. Thus not only did he collect in all parts of the Philippines as they became accessible, but also the extensive herbarium he built up contained specimens from all adjoining areas. His first administrative post was that of Director of the Bureau of Science, Philippine Islands, to which he was appointed in 1919. He rounded off his botanical work for the islands by the publication of "An Enumeration of Philippine Flowering Plants" (1925-26) in four volumes.

In his intensive studies of the Philippine flora, Dr. Merrill did not confine his attentions to Philippine plants but investigated also the neighbouring Indo-Malayan floras. Borneo, Amboina (where Rumphius had worked in pre-Linnean times), and Indo-China (where Loureiro had botanized) all received his attention. His "Bibliographie Enumeration of Bornean Plants" appeared in 1921, and at intervals between 1917 and 1935 he published his invaluable interpretations of the species of the earlier Asiatic botanists whose specimens, from one cause or another, had largely disappeared. In 1917 came his "Interpretation of Rumphius's Herbarium Amboinense", in the following year his "Species Blancoanae", in 1921 his "Review of the New Species of Plants Proposed by N. L. Burman in his Flora Indica", and in 1935 his commentary on Loureiro's "Flora Cochinchinensis". Since leaving the Philippines Merrill has filled arduous administrative posts, first as dean of the Faculty of Agriculture in the University of California, then as director of the New York Botanic Garden and now, as administrator of botanical collections of Harvard University. In all these he has worked with the same energy and success. At the same time he has contrived to do what many holders of high administrative posts find impossible: to continue his old scientific work. During this latter period he has turned his attention chiefly to the botany of south-eastern China, and in

collaboration with the enthusiastic young Chinese botanists has published numerous contributions on the flora of the region; and only a year ago he published, with E. H. Walker, a comprehensive "Bibliography of Eastern Asiatic Botany", of more than seven hundred pages.

Rev. E. O. James

THE Rev. Ernest Oliver James, professor of the history and philosophy of religion in the University of Leeds since 1933, has been appointed Wilde reader in natural and comparative religion in the University of Oxford for a period of three years as from October 1 next. Dr. James is well known for his studies in comparative religion in the school of Robertson Smith and Sir James Frazer. He was president of the Folk-lore Society in 1930-32, has edited *Folk-Lore* since 1932, and presided over the section of religions in the International Congress of Ethnological Sciences which met in London in 1934. In 1916-20 Dr. James acted as a secretary of the Anthropological Section of the British Association, and in 1928 was an extra-mural tutor in anthropology in the University of Cambridge. From 1911 until his appointment to a professorial chair, Dr. James was engaged in pastoral work in the Church, among the parishes of which he was incumbent being Limehouse in the East End of London, where between 1917 and 1921 his activities in eradicating the gross abuses prevalent among the Chinese population attracted no little public notice. He is the author of a considerable number of works on anthropological topics, among which may be mentioned "Primitive Ritual and Belief" (1917), "An Introduction to Anthropology" (1919), "The Stone Age" (1927), "The Origins of Sacrifice" (1933), "Christian Myth and Ritual" (1933), "The Old Testament in the Light of Anthropology" (1935) and "Introduction to the History of Religions" (1938).

U.S. National Academy of Sciences: Medal Awards

THE following medals of the National Academy of Sciences were presented at the annual dinner of the Academy on April 25: *Agassiz Medal*, for oceanography, awarded to Harald Ulrik Sverdrup, of the Scripps Institution of Oceanography of the University of California, La Jolla, for his personal oceanographic explorations in Arctic regions and his numerous contributions to physical oceanography and the inter-relations between the sea and the atmosphere; *Daniel Giraud Elliot Medal* for 1933, and accompanying honorarium of 200 dollars, awarded to Richard Swann Lull, of the Peabody Museum of Natural History, Yale University, in recognition of his work entitled: "A Revision of the Ceratopsia or Horned Dinosaurs", published in the *Memoirs* of the Peabody Museum of Natural History; *Daniel Giraud Elliot Medal* for 1934, and accompanying honorarium of 200 dollars, awarded to Theophilus Shickel Painter, of the University of Texas, in recognition of his work

on the chromosomes of the salivary glands in *Drosophila* in relation to the problems of mutation and genetics, published in *Genetics* and the *Journal of Heredity* in 1934; *John J. Carty Medal*, and award for the advancement of science, consisting of a gold medal, bronze replica, certificate and 3,000 dollars, awarded to Sir William Bragg, of the Royal Institution, London, for his fundamental work in X-ray crystal analysis; he has shown how to reveal the constitution of crystalline forms and accurately measure them, and his studies have given birth to a new tool which is bringing to light important facts regarding such complex structures as the larger organic molecules.

U.S. National Academy of Sciences: Elections

At the annual meeting of the National Academy of Sciences, Dr. Frank B. Jewett, president of the Bell Telephone Laboratories, was elected president for a term of four years, to succeed Dr. Frank R. Lillie, emeritus professor of zoology of the University of Chicago, who will retire on June 30. The following were elected members of the Academy: Gregory Breit, professor of physics, University of Wisconsin; Detlev Wulf Bronk, Johnson professor of biophysics and director of the Johnson Foundation, University of Pennsylvania; William Bosworth Castle, associate professor of medicine, Harvard Medical School, director of the Thorndike Memorial Laboratory, Boston City Hospital; Frederick Gardner Cottrell, president, Research Associates, Incorporated, Washington, D.C., consulting chemist, Bureau of Chemistry and Soils; Frederick Parker Gay, professor of pathology and bacteriology, College of Physicians and Surgeons, Columbia University; Albert Baird Hastings, Hamilton Kuhn professor of biochemistry, Harvard University; Vladimir Nikolaevich Ipatieff, research director of the Universal Oil Products Company, professor of chemistry, Northwestern University; Merkel Henry Jacobs, professor of general physiology, University of Pennsylvania; Zay Jeffries, General Electric Company, Cleveland, Ohio; Donald Forsha Jones, geneticist, Connecticut Agricultural Experiment Station, New Haven; George Bogdan Kistiakowsky, professor of chemistry, Harvard University; Warren Judson Mead, professor and head of the department of geology, Massachusetts Institute of Technology; Oscar Riddle, investigator, department of genetics, Station for Experimental Evolution, Carnegie Institution, Cold Spring Harbor, N.Y.; Adolph Hans Schultz, associate professor of physical anthropology, School of Medicine, the Johns Hopkins University; Philip Edward Smith, professor of anatomy, College of Physicians and Surgeons, Columbia University.

The following were elected foreign associates: Sir Joseph Barcroft, professor of physiology, University of Cambridge; Sir William Bragg, director, Royal Institution of Great Britain and Fullerian professor of chemistry and director of the Davy Faraday Research Laboratory; Dr. F. A. Vening Meines, professor of geodesy and cartography, the University of Utrecht.

Franklin Medals

FRANKLIN Medals have been awarded by the Franklin Institute, Philadelphia, Pa., as follows: Edwin Hubble, Mount Wilson Observatory, Carnegie Institution of Washington, Pasadena, "In recognition of his extensive study of the nebulae, particularly those outside our galaxy, as a result of which the dimensions of observed space have been greatly increased"; Albert Sauveur (posthumously), professor emeritus of metallurgy and metallography, Harvard University, "In recognition of his outstanding work in the science of metallography and of his many contributions to this branch of metallurgy which have been in a large measure responsible for changing the heat treatment of steel from an art to a science".

Rare Frankliniana

VISITORS to the recent exhibition of "Frankliniana" at New York City's Grolier Club (March 16-April 1) were impressed alike by the incomprehensible versatility of Benjamin Franklin's genius and by the fascinating rarity of many of the exhibits displayed. Printer, journalist, statesman, advocate of inoculation, inventor, and the most widely travelled American of his day, Franklin crossed the Atlantic Ocean eight times. That he was not unaware of the perils of travel is revealed by an obsolete will "written by my own hand while waiting for a passage to England" in 1757. By his classic kite experiment in 1748 he proved the identity of lightning and electricity, and his book "Experiments and Observations on Electricity", London, 1751, with a preface by his physician and friend Dr. John Fothergill, carried his fame over the civilized world. "Somerset Account of the Pennsylvania Hospital", Philadelphia 1754, recalls that Franklin was instrumental in founding what is regarded as the oldest hospital, in the modern sense of the term, in the present United States. He served as the first clerk to the board of management and later as president. "Proposals for Promoting useful Knowledge among the British Plantations", 1743, is believed to be the earliest suggestion in printed form for an American Philanthropic Society, to which the author offers his services as secretary. The pamphlet shown is described as one of two copies known. His first book "Dissertation on Liberty and Necessity, Pleasure and Pain", London, 1725, the young Franklin grew to dislike so violently that he destroyed all remaining copies except one. Other exhibits included a selection of his famous almanacs, so rare to-day, though originally issued in editions of 10,000 copies.

Chaston Chapman Gift to the University of Leeds

IN 1933 Mrs. Chaston Chapman presented to the University of Leeds her late husband's extensive working library of modern books on chemistry together with complete runs of a large number of periodicals. Mrs. Chaston Chapman has now presented his collection of works on alchemy to the University of Leeds, where they are housed in the Brotherton Library. There is a small section of French books and a more extensive section of

English books. Noteworthy among the latter are "The Mirror of Alchimy, Composed by the thrice-nous and learned Fryer, Roger Bacon", London, 177; the rare "Secrets Reveal'd: or, An open entrance to the Shut-Palace of the King: Containing the greatest Treasure in Chymistry, Never yet so fully Discovered", 1669; Plat, "The Jewel House of Art and Nature", 1653; and many other rare works. Translations into English include Geber, "The Works of Geber, the most famous Arabian chemist and philosopher", 1678; Beguin, "Tyroium Chymicum", 1669; Paracelsus, "The Chymical Transmutation of Metals", 1657; Glauber, "The Golden Ass Well Managed", 1670; Geener, "The newe Jewell of Health", 1576; Le Febvre, "A compleat Body of Chymistry", 1670; the 1677 and 1686 translations of Lemery, "A Course of Chymistry" and "New Curiosities in Art and Nature", 1711, by the same author.

Of large folios from the Chaston Chapman Collection there are good copies of the works of Agricola, Cardanus, Josephus, Lucretius, Manget, Paracelsus, Pettus, Petronius, Sennert, van Helmont, and others. There are some two hundred works by German and Dutch seventeenth-century authors. Becher and Stahl, the two founders of the phlogiston theory, are well represented. There are also certain editions of the strange work "De secretis", composed by Alexis of Piedmont, a narrative revelation to the world of the secret remedies that might have saved a patient's life. Special attention was also paid by Mr. Chaston Chapman to Black, Boerhaave, Boyle, Newton, and Priestley, and there is an interesting series of old and modern books on brewing and fermentation, commencing with "A Perfitte platforme of a Hoppearden", 1578. A whole case is devoted to the Royal Society, with the first, second, and fourth editions of Sprat's history of the Society. With the single exception of Lord Brotherton's books, this carefully selected library is the most valuable collection of rare books that the University has ever received.

Bledialoe Medal for Native Agriculture

In the recently issued report of the Rhodesia-Nyasaland Royal Commission (see NATURE, May 20, p. 829) stress is laid by members of the Commission on the expression of their individual views regarding certain matters, on the importance of the development of the native for the future of all three territories like. In this development, agriculture and native husbandry are assigned the foremost place, more specially in the two protectorates, of which the future prosperity can only be based upon agriculture. In the memorandum appended by the chairman, Lord Bledialoe, and Mr. P. A. Cooper, it is said that Education is a crying need of the African, but its foundation should, in his case, be knowledge of the land and its proper treatment on the one hand and of the basic principles of nutrition and hygiene on the other. These lessons are even more vital to his true welfare than reading and arithmetic, and should

take precedence of them." They go on to point out that they are inclined to the view that both land and labour are at present wasted, adding a caution against dogmatic pronouncement that large areas of territory are permanently unsuited to human occupation or economic utilization. In order to encourage the development of the native as agriculturist, Lord Bledialoe has now instituted a silver medal for presentation annually in appropriate numbers to the chiefs of the various tribes of Southern Rhodesia who have done most to induce their tribesmen to adopt improved methods of husbandry. The medal bears on its obverse the figure of a native Afrikaner bull with the inscription "Southern Rhodesia Mutungamiri Umtungameli", the Bantu and Sindabele terms for leader or guide. The reverse bears an ear of maize and the inscription "The Bledialoe Medal for the Advancement of Native Husbandry".

Treasure at Delphi

A DISCOVERY, which would seem to be remarkable even in the annals of Mediterranean archaeology for the quantity of objects of gold brought to light, is reported from Delphi, where excavations have been in progress under Prof. Delacotte on behalf of the French School of Archaeology at Athens during the past two years. A dispatch from the correspondent of *The Times* in the issue of May 10 states that in the course of raising and relaying the pavement of the Sacred Way from the eastern side of the Sanctuary in the direction of the Temple of Apollo in a search for inscriptions, a cavity has been found in the centre of the Stoa of the Athenians, in which was a mass of objects, covered with dust and ashes, and including a large number of gold articles. Of these the most important is the gold overlay of a chryselephantine statue, of which the ivory has been carbonized. The robe, diadem, ear-rings, bracelets, curls, heads and flowers, which formed the decorations of the robe, and the girdle, all in gold, have been recovered. A bronze statuette holding a receptacle for the burning of aromatic woods, which is complete and of remarkable workmanship, is dated at 500 B.C. In addition, there is a quantity of material in clay, copper and bronze. Expert opinion at present is that the finds show evidence of Oriental influence, possibly originating from the Greek cities of Asia Minor. A further discovery is a second cavity, found in working in a northerly direction from the Sacred Way, which was full of bronze and copper objects, all much encrusted, but otherwise in good preservation. Here also Eastern influence is discerned.

Television and the Provinces

MR. C. O. STANLEY, chairman of the Television Development Committee of the Radio Manufacturers Association, spoke at Manchester on May 13 outlining the great progress recently made with television. He pointed out that it is necessary to have a universal service for the whole of Great Britain in order to enable manufacturers to develop the export industry. The first step is to extend television to the provinces. While the mentality produced by experimental tele-

vision remains, the public will not purchase sets. Even if only one provincial station were started, it would show that television has been accepted and would give a tremendous stimulus to the industry. The United States has studied the possibilities of television and by next September there will be twenty stations in operation. If good progress had been made in Great Britain in providing provincial stations and services, manufacturers in this country could have produced sets in such quantities that the initiative could have been taken in the South American countries, in South Africa and in other places. Unless the rate at which we are now moving is accelerated, the stations to be provided in these places will be American stations, and if this were so, the sets now being produced in Great Britain would not work when connected to them.

Changes in Bird Population

In a civilized country, where social changes are rapid and often extensive, the wild population, whether of birds or other creatures, is undergoing constant readjustment. Much of the change passes unnoticed, and much, even if it be observed by local residents interested in natural history, goes unrecorded. The Royal Society for the Protection of Birds is doing good work in stimulating interest in the changing phases of bird population by offering the Medal of the Society and money prizes for the best paper on "Changes in the bird population of Britain during the present century, in a district or districts known to the writer, in regard to the increase or decrease of species named, what cause or causes can be assigned, and what (if any) effect has been observed". The causes which suggest themselves to the Society include—the universal use of the motor-car and the popularity of 'rambling', opening up hitherto secluded places; afforestation; road development; the disappearance of hedges; the invasion of the open country by factories; the replacement of open ditches by underground drains. There is also deliberate encouragement of birds to be reckoned with, by the creation of bird sanctuaries, the influence of the law's protection, and the altered outlook of the people towards the amenity of bird life generally. The competition should prove to be interesting and useful, although it is obvious that great care will have to be taken in sifting and adjudicating upon the causes alleged to be responsible for any change. The competition is referred to in the spring number (1939) of *Bird Notes and News*.

The National Physical Laboratory

THE report of the Laboratory for the year 1938 is a royal octavo pamphlet of 147 pages published by H.M. Stationery Office at 2s. 6d. The general report of the Executive Committee occupies 14 pages and is followed by reports of the superintendents of the separate Departments of Physics, Electricity, Radio, Metrology, Engineering, Metallurgy, Aerodynamics and Ship Propulsion, which enter into more detail, extending to 114 pages, and each concludes with a list of papers published by the Department

during the year. They seem remarkably free from obscure technical expressions and can in consequence be read with ease by the general public. The changes of staff have been more important than usual. Three directors have been in charge during the year as one superintendent has become director of research in another Government department, while industrial and Government departments have absorbed other members of the staff. Lectures on the work of the Laboratory have again been given in large industrial centres (17), and as usual a large number of requests for scientific information on points arising in industrial work have been answered by the Laboratory without charge.

Utilizing Sunshine

DR. C. G. ABBOT, the secretary of the Smithsonian Institution, has published a description of recent devices he has used in converting sunshine into power (*Smithsonian Misc. Coll.*, 98, No. 1, March 30, 1939). In general, the sun's rays are focused by a cylindrical mirror on to an axial glass tube through which, for the distillation of water, the generation of steam, water flows, and for cooking purposes a black liquid of boiling point above 350° C. The mirror is now made of flexible sheet known as 'Aloe' and the axial tube is surrounded by a concentric vacuum tube. While coal is cheap, Dr. Abbot does not expect extensive use of such device but under favourable conditions small units up to five horse-power with an efficiency of conversion of solar to mechanical energy of the order of 15 per cent and a cost of a farthing per horse-power hour may be possible. At present the initial cost of the apparatus is high, but when thousands are required prices will fall.

Books on International Relations

A "SHORT List of Books on International Relations" recommended by the Education Committee of the League of Nations Union (15, Grosvenor Crescent, S.W.1) includes 141 titles arranged in two lists, the first consisting of books for boys and girls and the second of books for students and teachers. The latter is arranged in six sections dealing with the League of Nations, with education, with international relations, with special problems, with collective security and peaceful change and with colonies and raw materials, respectively. The majority of the books are of the descriptive type, but a number of constructive critical works are included, mostly from rather a Left Wing point of view. In addition, the list gives the titles of a number of songs and celebrations as well as of maps and periodicals, and forms on the whole a useful introduction to the study of international relations.

A Mosquito Invasion of South America

THE possibility of the introduction of a disease into a country at present free from it by air-transport of the infected insect-vector has long been recognized for example, yellow fever by its infected mosquito carrier. That this menace is real and not hypothetical

is demonstrated by the fact that an African species of malaria-carrying mosquito, *Anopheles gambiae*, has become established in South America. According to the Service, this mosquito has been found at Natal, Brazil, and in localities two hundred miles west and north of Natal, and has already caused several outbreaks of malaria. This mosquito was probably introduced as a stowaway on one of the aeroplanes of the French airline between Dakar in West Africa and Natal in Brazil.

Cadmium Pigments

We have received from Messrs. Johnson and Matthey, Hatton Garden, London, E.C.1, a copy of a booklet on cadmium pigments. These have cadmium sulphide as a basis, and the sulphide itself can be obtained in any colour from pale yellow to orange. Redder shades are obtained by the incorporation of selenium, so that it is possible to get a complete range from pale yellow, through orange and red, to deep maroon. Cadmium lithopones are also available. The properties of the pigments are described.

High Vacuum Distillation

THE *Transactions of the Society of Chemical Industry* (58, No. 2; 1939) contain several papers presented last November to a meeting of the Chemical Engineering Group which dealt with the industrial applications of high-vacuum distillation. Pressures of the order of 10^{-6} mm. are concerned and the technical apparatus is described with drawings. One important application of the technique is to the concentration of vitamins from oils.

Earthquake in Solomon Islands of April 30, 1939

FURTHER news has come to hand concerning this shock. According to the Bureau central seismologique de Strasbourg, from reports received from thirty seismological stations the epicentre of the most severe shock was at 7.5° S., 159.6° E., depth of focus probably 100 km. and starting time 2h. 55m. 35s. G.C.T. According to reports from the islands, the shock and after-shocks lasted for several days. One of the islands most seriously affected was Guadalcanar, where a number of buildings were wrecked, and where a wave following the shock swamped a number of native villages. On Yasabel Island houses were damaged, and in the Cape Marsh district of the Russell Islands wharves and houses were wrecked. In the island of Savo, surface faults were visible, but there was no loss of life. Altogether nine children and three adults of the indigenous population were drowned.

Earthquake near Japan

Using reports from the seismological stations at Honolulu, Victoria, Tucson, Manila, Huancayo, Zikawei, Burlington and Philadelphia, the United States Coast and Geodetic Survey has made a preliminary determination of the epicentre and initial time as follows: lat. 37° N., long. 142° E., November 30, 2 h. 29 m. 52 s. G.C.T. The epicentre is under the ocean bed to the north-east of the coast of the

main island of Japan, and is the same as that for the earthquake of November 22, 1h. 14.1m. G.C.T. No effects of this shock have been reported from land.

Commonwealth Fund Fellowships Awards

THE Committee of Award of the Commonwealth Fund fellowships has made the following appointments, among others, to fellowships tenable by British graduates in American universities for the two years beginning September 1939: C. A. U. Craven, Imperial College of Science and Technology, University of London, to Harvard University, in geology; Dr. B. M. Crowther, Clare College, Cambridge, to the Massachusetts Institute of Technology, in physics; G. M. Henderson, University of Edinburgh, to Princeton University, in chemistry; P. B. Hunt, Christ Church, Oxford, to Columbia University, in economics; G. O. Jones, Emmanuel College, Cambridge, to the Massachusetts Institute of Technology, in engineering; J. P. Keane, University of Wales and University of London, to the University of Michigan, in economics; Edward Lee, University of Manchester, and University of Cambridge, to the University of Michigan, in physics; Nicholas Miller, Imperial College of Science and Technology, University of London, to the University of California, in engineering; D. G. Northcott, St. John's College, Cambridge, to Princeton University, in mathematics; G. W. Parnell, University of Bristol, to the University of California, in zoology; J. H. Read, University of St. Andrews, and Emmanuel College, Cambridge, to Columbia University and the American Film Center, New York, in cinematography; J. A. Scott, Trinity College, Oxford, to the University of Pennsylvania, in economics; Dr. E. V. Watson, University of Edinburgh, to Harvard University, in botany; E. R. Winton, University of St. Andrews, to the Massachusetts Institute of Technology, in engineering; N. A. Wylie, Oriel College, Oxford, to Yale University, in forestry.

THE following have been appointed to fellowships tenable by candidates from the British Dominions: H. C. Corben, University of Melbourne, and Trinity College, Cambridge, to the University of California, in physics; Dr. A. P. Guinand, University of Adelaide, New College, Oxford, to Princeton University, in mathematics. The following have been appointed to fellowships tenable by candidates holding appointments in Government service overseas: H. L. Hume, University of New Zealand, of the Public Works Department, Government of New Zealand, to the University of California, in engineering; M. R. Jacobs, University of Adelaide, and St. Catherine's Society, Oxford, of the Department of the Interior, Government of Australia, to Yale University, in forestry; C. S. Kelly, Balliol College, Oxford, of the Indian Civil Service, Government of Burma, to Yale University, in anthropology; S. L. Macindoe, University of Sydney, of the Department of Agriculture, Government of New South Wales, to the University of Minnesota, in agriculture. The following have been appointed to fellowships tenable

by candidates holding appointments in the Home Civil Service: J. G. M. Alcock, Jesus College, Cambridge, of the Board of Education; C. H. W. Murphy, Selwyn College, Cambridge, of the Unemployment Assistance Board; J. B. Williams, McGill University, and University of Cambridge, of the Colonial Office.

The Night Sky in June

THE short nights round about the summer solstice on June 22 are less than $7\frac{1}{2}$ hours in length according to the sun's setting and rising in the latitude of London, and a little more than 3 hours if nautical twilight be reckoned. The moon is full on June 2 and new on June 17. A notable occultation occurring on June 25 is that of the first magnitude star Spica (α Virginis) when the moon is 8.2 days old. At Greenwich the disappearance takes place at 16h. 12.6m. at position angle 142° from the north point and the reappearance at 17h. 14.0m. at 285° . At Edinburgh, the corresponding times and position angles are 16h. 11.3m. (133°) and 17h. 14.5m. (272°). Lunar conjunctions with the planets take place as follows: on June 6 with Mars, on June 11 with Jupiter, on June 13 with Saturn, on June 15 with Venus. In the latter part of the month, Mercury may be seen in the evening twilight, low down in the direction north of west. Venus rises in the dawn, preceded by Saturn some two hours earlier. Mars is growing brighter (-1.2 m. to -2.0 m.) and rises before midnight. Jupiter, also increasing in brightness (-1.8 m. to -2.0 m.), rises after midnight. There are close groupings of the four inner satellites about Jupiter at 2 $\frac{1}{2}$ h. on June 5, 22 and 30. On June 17 at the same hour only two of the satellites (3rd and 4th) are visible, the first two being in transit. At the beginning of June the faint comet Pons-Winnecke is near β Boötis and by mid-June near β Coronae Borealis. Comet Juriol-Ackmarof-Hassel is being lost in the sunset. On June 1 it will be about 5° north of γ Geminorum, and by June 30 about midway between Procyon (α Canis Minoris) and γ Geminorum. In mid-June at 22h., Arcturus has already southed; Antares, low down in the south, is approaching meridian passage; Vega is 3 hours before the meridian. The small beautiful constellation Corona Borealis is on the meridian. At midnight, 24h. U.T. (all times being thus expressed: add 1h. to convert to Summer Time), the star γ Draconis passes within $1\frac{1}{4}'$ of the zenith at Greenwich. Observation of this star in 1725-26, for any sign of annual parallax, led to the discoveries by Bradley of the aberration of light and, later, of the nutation of the earth's axis.

Announcements

PROF. EMMANUEL TEODORESCO, of the University of Bucharest, has been elected *correspondent* of the Section of Botany of the Paris Academy of Sciences.

THE two lectures which were to have been delivered by Dr. A. Hrdlička at University College, London, in April but which were postponed, will be delivered on May 31 and June 1 at 5 p.m. The subject of the first lecture will be "The Present Status of our Views

on Human Evolution", and that of the second "The Racial Fallacies and Realities of European Peoples". The lectures are open to the public.

THE Gresham lectures on astronomy will be delivered on May 30, 31, June 1 and 2 at Gresham College, Basinghall Street, E.C.2, at 6 p.m. by Mr. Arthur R. Hinks. The subject of the course is "Recent Discoveries of Special Interest". The lectures are open to the public.

At the anniversary meeting of the Linnean Society of London held on May 24, the following officers were elected for the year 1939-40: *President*, Dr. John Ramsbottom; *Treasurer*, Mr. Francis Druce; *Secretaries*, Mr. Isaac H. Burkill (botany) and Dr. Malcolm A. Smith (zoology); *New Members of Council*, Prof. T. M. Harris, Mr. H. R. Hewer, Prof. T. G. B. Osborn, Mr. H. W. Parker and Dr. Malcolm A. Smith.

At the annual general meeting of the Institute of Physics held on May 17, the following were elected to take office on October 1, 1939: *President*, Prof. W. L. Bragg; *Vice-President*, Prof. A. Ferguson; *Honorary Treasurer*, Major C. E. S. Phillips; *Honorary Secretary*, Prof. J. A. Crowther; *New Members of the Board*, Dr. H. Lowery and Mr. R. S. Whipple; and Mr. J. H. Awbery (appointed by the Physical Society).

THE Medical Research Council has appointed the following committee to advise and assist in promoting investigations into problems of preventive medicine: Sir W. Wilson Jameson, dean of the London School of Hygiene and Tropical Medicine (chairman); J. H. Brincker; J. Fenton; J. Ferguson; W. M. Fraser; L. H. R. Harries; A. Bradford Hill; W. D. Hood; J. R. Hutchinson; R. A. McCance; A. S. M. MacGregor; R. H. Parry; Prof. R. M. F. Picken; W. M. Scott; J. C. Spence; Prof. W. W. C. Topley; D. K. M. Chalmers, of the National Institute for Medical Research (secretary).

THE thirtieth annual Conference of the Association of Teachers in Technical Institutions will be held at Southport during May 27-30, under the presidency of Dr. E. A. Seeley of the Municipal College, Bournemouth. Further information can be obtained from the Secretary at 29 Gordon Square, London, W.C.1.

UNDER the auspices of the French Zoological Society, the thirteenth International Congress of Zoology will be held in Paris in July 1940, the actual date not having so far been fixed. Further information can be obtained from the Secretary-General, Société Zoologique de France, Institut Océanographique, 195 rue St-Jacques, Paris, V^e.

THE bicentenary of the foundation of the Royal Academy of Sciences of Sweden will be celebrated on September 23-25.

ERRATUM. In NATURE of May 20, p. 844, column 1, under "Prominences through Colour Filters" and under "Movements of Prominences", "for H λ " read "H α ".

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 901.

Reflection of Atmospherics from the Ionosphere

THE details of the structure of the 'oscillatory' portion of the wave-form of an atmospheric have been the subject of several investigations¹. Prof. J. H. Laby and his co-workers of the Australian Radio Research Board have made the remarkable suggestion that the observed complicated structure can be interpreted in terms of a series of reflections from an ionospheric layer of the simpler primary disturbance due to lightning. Their analysis places its height at 59-88 km.

We have worked on this question since November 1937 in conjunction with a direction-finding network which fixes independently the distance from receiver to parent thunderstorm, and arrangements have been made whereby the wave-form oscillogram corresponding to a source at a known distance is automatically marked. The height of the layer is then the only unknown quantity to be determined from the wave-form record. Several thousand oscillograms of atmospherics which have travelled from 50 km. to 2,800 km. have been examined.

A study of these records strongly supports the view of the Australian workers that the structure arises from repeated reflections, but brings to light a new feature which can be interpreted as a pronounced lowering of the effective height of the layer, h , in the neighbourhood of the parent storm. Thus we find: (1) h determined from the singly reflected sky wave is equal to 85 ± 5 km. for all direct distances between 2,800 km. and 600 km., that is, at all points of reflection from 1,400 km. to 300 km. from the source. (2) h determined from multiply-reflected sky waves is also equal to 85 ± 5 km. provided that no component reflection takes place within a distance less than 300 km. from the source. (3) For cases where reflection occurs one or more times within this critical distance of 300 km., h falls from 85 km. at 300 km. distance to 50 km. directly above the source. By examining the multiple reflections at one distance only, a model of the layer can be constructed which satisfactorily accounts for all reflections at all distances examined.

This evidence indicates that there is a real lowering of the effective height of reflection for long waves in the neighbourhood of a thunderstorm. Evidence for abnormal ionization of the layer under these conditions has already been found by many workers on short-wave pulse-sounding.

The accompanying reproduction illustrates how the first pulse of the ground-wave G is related in time and amplitude to the corresponding sky waves 1, 2, 3, 4, 5 after the atmospheric has travelled various distances. At small distances (A, B) the reflected waves are separated from the ground-wave (a single complete period of disturbance) by a quiet interval. Farther away (C to F) they form an apparently continuous damped oscillation. It can

WAVE FORMS OF ATMOSPHERICS. G , FIRST PULSE OF GROUND WAVE; 1, 2, 3, 4, 5, CORRESPONDING PULSES REFLECTED 1, 2, 3, 4, 5 TIMES BY LAYER.

be shown that this continuity is due to an effective increase in 'wave-length' of a single long-period transient on reflection, and arises if the properties of the layer vary appreciably over a distance of the order of a wave-length. The reproduction illustrates how the time-interval between successive reflections decreases with distance and can be used for the conclusions listed under (1), (2) and (3) above. In deriving h from these results, it is necessary to consider the curvature of the earth and the layer.

The relative amplitudes of the first ground-pulse G and its reflections 1, 2, 3, 4 and 5 alter noticeably with distance. At moderate distances, as would be expected, G is the largest (A, B, C). Farther out (D, E), attenuation of the ground-wave reduces its amplitude below that of the first sky wave. Still farther away from the parent storm (F) the first sky wave must graze the earth before reaching the receiver and becomes attenuated from this cause also, so that the second sky wave has the maximum amplitude.

The atmospherics which exhibit the clear evidence of reflection here discussed are all due to flashes to ground. As has been pointed out elsewhere, discharges within the thundercloud produce effects which are weaker in intensity and more complex in form.

We have to thank Mr. I. Kats, Prof. D. B. Hodges and Mr. Phillips of Howard College, Durban, and Mr. R. A. Jubb of the Meteorological Department, Southern Rhodesia, for operating the direction-finders used in locating thunderstorms.

Disintegration of Nitrogen by Fast Neutrons

ACCORDING to researches published up to the present time, bombarding nitrogen with fast neutrons produces the two following nuclear reactions:

- (i) $^{14}\text{N} + {}^1_0\text{n} = {}^{12}\text{B} + {}^2_1\text{H}$
- (ii) $^{14}\text{N} + {}^1_0\text{n} = {}^{14}\text{C} + {}^1_1\text{H}$

The present paper deals with the determination of the cross-sections σ for these two processes and the total energy Q evolved in reaction (i).

An ionization chamber filled with nitrogen was bombarded with fast neutrons obtained by the reaction ${}^2\text{D}({}^2\text{D}, {}^1_0\text{n}){}^3\text{He}$. The products of transformation were detected with the help of a linear amplifier and of an oscillograph. Both neutron source and amplifier have been described in detail in a former paper¹.

In the accompanying figures are plotted two statistics for the process $^{14}\text{N}({}^1_0\text{n}, {}^4_2\text{He}){}^{12}\text{B}$. Curve A corresponds to an angle of observation of 0° (neutronic energy 2.8 Mev.) and Curve B to an angle of 90° (neutronic energy 2.36 Mev.). By 'angle of observation' we understand the angle between the direction of the incident deuterons and the direction of observation of the emitted neutrons. The cross-section σ and the reaction energy Q for the process $^{14}\text{N}({}^1_0\text{n}, {}^4_2\text{He}){}^{12}\text{B}$ can be determined, since the intensity of the neutron source and the energy of the emitted neutrons are known. The study of a thousand of such processes gave the following results:

$$\sigma = 1.63 \times 10^{-28} \text{ cm.}^2. \quad Q = -0.43 \text{ Mev.}$$

From corresponding measurements for the process $^{14}\text{N}({}^1_0\text{n}, {}^1_1\text{H}){}^{14}\text{C}$ we found a cross-section equal to $\sigma = 0.4 \times 10^{-28} \text{ cm.}^2$.

The difference between the neutronic energies corresponding to the two angles 0° and 90° can be

OSCILLOGRAPH DEFLECTIONS AS A FUNCTION OF THE CORRESPONDING ENERGY

calculated by means of the theorems of conservation of energy and momentum. If the deuterons are accelerated by 140 kv., this energy difference is equal to 0.44 Mev. The observed difference, 0.39 Mev., is, within the limits of possible errors, in agreement with the calculated value.

A complete account of the experiments will be published in the *Helv. phys. Acta*.

Crystal Structure of Glucosamine Hydrobromide

PROGRESS in the detailed analysis of carbohydrate crystal structures has hitherto been slow, on account of the lack of guidance from physical (optical and magnetic) properties of the crystals, the wide choice of molecular conformations on which 'trial and error' calculations might be based, the absence of outstandingly strong reflection intensities, and the asymmetry of the compounds concerned. The isomorphism of α -chitosamine hydrochloride and hydrobromide has now enabled us to determine the positions of all the atoms (other than hydrogen) in the crystal lattices of these substances by synthetic methods alone, no stereochemical assumptions being necessary.

α -Chitosamine hydrobromide and hydrochloride are monoclinic sphenoidal, space-group $P2_1$, with two molecules in the unit cell, the dimensions of which are as follows:

Hydrochloride ¹	Hydrobromide
$a = 7.06 \text{ \AA.}$	$a = 7.06 \text{ \AA.}$
$b = 9.18$	$b = 9.20$
$c = 7.11$	$c = 7.18$
$\beta = 115^\circ 25'$	$\beta = 115^\circ 35'$

About 900 reflection intensities (Cu radiation) were measured for each salt, and the structure amplitudes derived from them were employed in three-dimensional Patterson (F^2) syntheses, and two- and three-dimensional Bragg (F) syntheses. The phase angles necessary for the latter were obtained by comparison of corresponding F -values for chloride and bromide. In this way we have arrived at the structure which is shown projected on the (010) plane in the diagram.

and more precisely described by the accompanying table of atomic co-ordinates; these are accurate to about 0.01, that is, about 0.08 $\text{\AA.}$, with the exception of those for the primary alcohol oxygen atom, the position of which has not emerged quite so definitely from the Fourier syntheses, possibly because it is oscillating over an appreciable angle, as appears not improbable from its environment in the lattice. There is no doubt, however, that this atom is attached to the sixth carbon atom. The general accuracy of the analysis is vouched for by the fact that in the numerous F -syntheses performed, there occur no negative electron densities comparable in magnitude with the positive values in the atomic peaks.

Atom	x	y	z	Atom	x	y	z
Br	0.143	0	0.018	O ₁	0.55	0.50	0.48
C ₁	0.56	0.35	0.47	N ₁	0.33	0.47	0.27
C ₂	0.41	0.33	0.27	O ₂	0.30	0.30	-0.06
C ₃	0.49	0.33	0.10	O ₃	0.67	0.17	-0.06
C ₄	0.02	0.20	0.13	O ₄	0.06	0.24	0.50
C ₅	0.76	0.20	0.35	O ₅	-0.91	-0.02	-0.50
C ₆	0.81	0.04	0.40				

We are now engaged in refining this structure by utilizing structure amplitudes the phase angles of which were originally uncertain, together with others obtained with molybdenum radiation, and also by 'trial and error' methods. Meanwhile, it may be of interest to point out that the accuracy of the analysis as it stands is adequate, without the assistance of any stereochemical data, to justify the following statements:

(a) For the first time the configuration of a carbon compound containing several asymmetric centres has been confirmed by direct determination of atomic positions. In this particular case, chitosamine is shown to be a derivative of glucose and not of mannose (cf. the recent work of Haworth, Lake and Peat²).

(b) The pyranose (six atom) ring has a real existence in a crystalline sugar. (It should be observed that the chemical evidence for pyranose structures applies strictly to glucosides and only by inference to sugars.)

(c) In the α -form of a d -glucose derivative (that is, that which possesses the higher [positive] rotation) the oxygen atoms on the first and second carbon atoms are in *cis* positions.

The analysis is not yet sufficiently refined to distinguish between a nitrogen and an oxygen atom, so that we cannot at present confirm that in chitosamine the nitrogen atom is attached to the second carbon atom; this, however, is completely certain from its mode of synthesis. The pyranose ring is definitely not Sachse *cis* (boat-shaped), but is either Sachse *trans* or some partially flattened form of it³.

Absorption Spectra of Proteins

In a recent communication¹, Prof. F. Haurowitz and Dr. T. Astrup describe observations of absorption spectra on solutions of native and digested serum globulin, which are said to be in better accord with the classical theory of the structure of proteins than with the cyclol hypothesis. They reason that because, after digestion of serum globulin with trypsin to a stage at which only a fine opalescence is given with sulphosalicylic acid, there is no increased absorption at λ 240 m μ , there has therefore been no formation of CO groups from $>O(OH) - N <$ groups which are required by the cyclol hypothesis.

Haurowitz and Astrup state that CO groups absorb strongly at λ 240 m μ . This is contrary to observations made here and elsewhere on amino-acids and peptides. For example, at this wave-length the molecular extinction coefficient of glycyl-leucine is only 10. At λ 240 m μ the contribution of CO groups to the absorption of serum globulin is small compared with that of the nuclei of the aromatic amino-acids. The former can be calculated from average amino-acid composition figures for serum globulin and known extinction coefficient values for the aromatic amino-acids at λ 240 m μ to be about 17 per cent of the total.

The change of absorption of the globulin on digestion can be seen to be mainly a shift of the whole band to shorter wave-lengths with a filling up of the trough. That this shift is due to change in absorption of tyrosine and tryptophane has been shown in experiments to be published. This shift in itself causes a fall in absorption at λ 240 m μ large enough to mask a large increase of the kind for which Haurowitz and Astrup were looking. It would be

necessary to distinguish change of absorption of the aromatic amino-acids from appearance of new absorbing centres (CO groups) before such observations could be used as arguments for or against the cyclol hypothesis.

The question will be discussed more fully in a paper to be published shortly.

Protein Stability as Revealed by Ultracentrifugal Analysis

IN the course of sedimentation velocity studies with serum protein mixtures, it has been noted from time to time that the concentrations of the different molecules calculated from the sedimentation diagram differ from those determined analytically¹. The substance sedimenting at the higher rate decreases in amount to form units of a lower apparent sedimentation constant, even though it has appeared to be perfectly stable under the same conditions when it is present alone. It has been concluded that these changes are caused by some medium effect produced by the action of one protein upon the other. It was then reasoned that it should be possible to produce this effect by means of such lower molecular substances as amides, amino-acids, polypeptides, and protamines. The action of such 'dissociating compounds' is found to be highly specific. Thus an amino-acid which acts strongly upon a certain protein may have no effect upon another, and *vice versa*, and the effect may depend upon the presence or absence of salt^{2,3}.

Naturally it is important to understand such effects of proteins upon each other and of smaller molecules upon proteins. In some quarters it is believed the effect is due to a real dissociation of the faster sedimenting unit, but it must be recognized that in some cases the modification of the sedimentation rate may arise from a change in the shape of the molecule or even from hydration effects. It

appears that final answer to this question will have to come from the results of parallel osmotic pressure determinations.

It has now been found that changes in sedimentation behaviour of the type mentioned above can be produced, at least in solutions of the uniform protein now being investigated in this Laboratory (antitox (diphtheria) pseudoglobulin, thyroglobulin⁴, thymus nucleohistone), by the simple expedient of increasing the protein concentration in the solution and reducing the electrolyte content. In other words, the effect is produced without the addition of any reagent. Typical sedimentation diagrams are shown in the accompanying figure. There are many reasons for believing this is a quite general property of protein systems.

The observations can be described by means of the following scheme:

The formation of the labile state, probably due to an unfolding of native protein, appears not to involve any reaction between molecules, but is essentially a slow, intramolecular change involving an equilibrium the rate of establishment of which depends upon protein and hydrogen ion concentration of the solution and temperature. An increase in protein concentration and the removal of electrolyte from the solution favour the formation of the labile form. Any subsequent formation of denatured protein, dissociation or association products depends upon the presence of such reagents as urea, salicylate, hydrogen ion concentration of the solution, heat, ultra-violet light, and other factors.

Inasmuch as the presence of certain proteins, amino-acids or other substances favours the establishment of this equilibrium or may cause complete denaturation or change in molecular size even in the presence of salt, we believe this equilibrium between native and labile protein to form the basis of effects noticed by McFarlane, Pedersen, and others.

X-Rays and the Cyclol Hypothesis

THE purpose of the vector map described by Fankuchen and Riley¹ to which Dr. Wrinch has taken exception in her recent letter² was merely to show that the cyclol C₁ skeleton does not contribute anything to the specific character of the observed X-ray reflections from crystalline insulin. No one imagines that insulin contains only (CON) groups, but these are the only atoms of which the positions have been definitely stated by Dr. Wrinch, and therefore the only ones amenable to exact computation. Dr. Wrinch is, of course, at liberty to place other concentrations of density wherever she likes, but she cannot logically claim in this case that the structure arrived at in this way offers any confirmation of the cyclol hypothesis. Moreover, as has been shown already³, Dr. Wrinch's construction of the vector map from such concentrations⁴ has been incorrectly carried out, and therefore cannot confirm her proposed model of the insulin structure. Finally, the shape and size of the cyclol molecule do not offer particularly convincing fit into the cell of insulin. Any spherical molecule of approximately the right molecular weight would fit the cell equally well. The only positive agreement is in the presence of a trigonal axis of symmetry, which can scarcely be claimed to justify the acceptance of such an elaborate construction.

We feel, therefore, that no case whatever has been made out for the acceptance of the cyclol model on X-ray grounds; indeed so far as it goes, the X-ray evidence is definitely against the model and in favour of one composed not of a cage but of more or less discrete sub-units, although it is admitted⁵ that no model has yet been proposed that will fit existing experimental evidence. The arguments against the cyclol molecule on X-ray grounds have now been fully stated⁶, and it seems to us unprofitable to continue the discussion until fresh evidence or new interpretations are provided.

Rapid Calculation of Relative Humidity from Readings of the Sling Hygrometer

At the recent Institute of Physics Conference at Leeds, I communicated a rule which I have found useful for calculating the relative humidity direct from readings of the ventilated wet- and dry-bulb hygrometer. Expressed so as to facilitate rapid mental calculation, it is as follows: to calculate the percentage relative humidity, express three times the wet-bulb depression ($^{\circ}$ F.) as a percentage of the dry-bulb reading, and subtract from 100; or symbolically:

$$\text{R.H. (\%)} = 100 - 3\left(\frac{t - t'}{t}\right) \times 100,$$
where t = dry-bulb temperature ($^{\circ}$ F.) t' = wet-bulb temperature ($^{\circ}$ F.).

The same formula applies when centigrade thermometers are used, except that the wet-bulb depression must then be expressed as a percentage of the dry-bulb temperature plus 18.

The rule applies only to the readings of a ventilated hygrometer, and breaks down at relative humidities below 30 per cent; but it applies very closely from 30 to 100 per cent relative humidity, and over an air-temperature range of 20° to 140° F. The degree of accuracy of the formula over these ranges can be checked by comparing calculated values with the corresponding values given in "Psychrometric Tables for Obtaining the Vapour Pressure, Relative Humidity, and Temperature of the Dew Point" by C. F. Marvin, U.S. Dept. of Agriculture Weather Bureau, 1937. It will be found that the average difference between the calculated and tabulated values is less than 2 per cent R.H., whilst the maximum difference under extreme conditions within the ranges mentioned is ± 4 per cent R.H. For example, according to the formula, a wet-bulb depression of 5° F. at temperatures of 20° , 40° , 60° and 100° F. corresponds to relative humidities of 25, 63, 75 and 85 per cent respectively, whilst the tabulated values are 28, 60, 73 and 83 per cent R.H.

If the practical interest is confined to the more restricted ranges between 50 and 90 per cent R.H., and 40° F. to 120° F., the calculated relative humidity is in general higher than the tabulated by 2 per cent, and when this correction is made the error does not exceed 1 per cent R.H.

Rapid Graphical Analysis of Circuit Performance by the Use of Logarithmic Charts

In connexion with some recent work, use has been made of charts with $\log (| \text{impedance} |)$ and $\log (\text{frequency})$ as axes, and the properties of this plane have been found to lend themselves to graphical use. The chief properties are:

The impedances of the three circuit elements (resistance, capacity and inductance) are represented by straight lines.

The impedance for all frequencies of any two elements in series is exactly represented by one of two curves the shape of which does not depend upon the value of the elements; these can therefore be made in the form of templates.

Since $\log \frac{1}{|Z|} = -\log |Z|$, operations upon

impedances in series and parallel are equally simple, and the same two curves apply to elements in parallel as in series.

Since the ratio of the voltage (E_2) across one (Z_1) of two impedances (Z_1, Z_2) in series, to the total voltage E is

$$\frac{|Z_1|}{|Z_1 + Z_2|}$$

and

$$\log \frac{|Z_1|}{|Z_1 + Z_2|} = \log |Z_1| - \log |Z_1 + Z_2|,$$

and the attenuation in decibels is $\left[20 \log_{10} \frac{E_1}{E} \right]$, distances in the vertical direction give attenuations directly.

The use of charts of this plane, together with the two elementary curves mentioned above, enable the rapid graphical analysis of the behaviour of many circuits, also the synthesis of networks with desired frequency characteristics and the determination of equivalent circuits.

An accuracy to 5 per cent in frequency or impedance and 0.5 decibel in attenuation can readily be obtained. The method has been found both rapid and convenient in application to various aspects of radio receiver design.

Structural Geology of the Bermuda Islands

IN conjunction with investigations for the development of a technique for deep-sea seismic measurements that will permit the obtaining of positive geological information on the structure of the ocean basins, we have investigated the structural geology of the Bermuda Islands.

Of especial interest is the fact that contours around the Bermuda area based upon recently published sounding data¹ and unpublished soundings secured by the ketch *Atlantis* of the Woods Hole Oceanographic Institute suggest that the islands consist of four main volcanic cones with several minor ones on the flanks of the main structures, and also that the island mass is surrounded by a series of concentric folds which die out in amplitude with distance from the islands. In order to verify this latter indication, we have arranged for several lines of continuous soundings to be made in the near future.

Two seismic refractions depth profiles made in the island area show the top of the volcanics to lie at depths of 273 feet and 243 feet below sea-level. These determinations are in excellent agreement with the depth reported for the top of the volcanics in a deep well in the islands, 245 feet below sea-level. The volcanics were characterized by a velocity of 16,000 ft./sec., whereas the overlying calcareous eolianite composing the visible portion of the islands had a velocity of 8,800 ft./sec.

An examination of existing magnetic data which comprise a fairly complete isogonic survey² and localized studies of the variation in the horizontal component of the earth's field³ show that the islands are characterized by local areas of low magnetic susceptibility. Further, that the depths of the disturbance are all about the same and less than 1,200 feet in depth. To elaborate the magnetic indications further, we have made a series of observations on the vertical component of the earth's field and find very high local disturbances both positive and negative in character. This work is still too incomplete to permit any conclusions to be reached as to the nature of the disturbances. They are near surface, and it is believed cannot be attributed to artificial causes.

Of significance in this connexion is the discovery of a calcareous sandstone heavily impregnated along dark bands with magnetite, ilmenite and andradite garnet. There are no surface exposures of this rock, and it was brought up from twenty feet below water

in constructing a bridge pier. Also believed of significance is a coarse limestone conglomerate cemented in a very dense calcite matrix which occurs at about the same depth in several localities. In the formation we have found a weathered volcanic pebble four inches in diameter, but so fine only one.

From the evidence presented it is seen that various conflicting conclusions might be drawn, but it is hoped by extending the seismic measurements, the magnetic studies, and geological studies of the low dense limestone formation to reach a structural interpretation that will satisfy all the observed conditions. The nature of the exposed surface geology, cross-bedded eolianites, makes orthodox methods of structural geological investigation of little use in the area.

Microphonic Potentials from the Utricle

Stevens and Davis¹ have put forward the view that the generation of potential differences in the cochlea when sound is incident on the ear is due to the 'piezoelectric' properties of the hair-cells themselves.

The principal item of evidence for this view is the similarity of the threshold curves for the microphonic effect determined oscillographically in the guinea pig and for sound perception in man. By implication, therefore, the microphonic effect is an integral part of the receptive process. Their argument is supported by the work of Adrian, Craik and Sturdy², who have demonstrated microphonic potentials in the ears of lower vertebrates (eel, frog, tortoise), which, though they do not possess a cochlea, yet have hair-cells in the maculae of the labyrinth closely resembling those of Corti's organ. These observations were confined to the inferior part of the labyrinth, in particular the sacculus, which in these animals has an auditory function. This evidence therefore tends to confirm the belief that such microphonic potentials might be intimately connected with the reception of sound.

I have obtained similar microphonic potentials from the labyrinth of perch, tench and roach in response both to loud air-borne sounds and to vibrations transmitted through the bench. By exploration with concentric electrodes, it was possible to show that they were derived not only from the sacculus (and perhaps the lagena) but also from the utricle. Indeed they could be obtained equally well from the latter after complete bilateral extirpation of sacculus and lagena, which in these bony fishes are widely separated from the upper non-auditory part of the labyrinth. Von Frisch³ has demonstrated that in fish, as in higher vertebrates the utricle plays no part in hearing. It is clear therefore that the generation of microphonic potentials in a sense organ is not in itself a sufficient

dication of the reception of acoustic or vibratory stimuli. Consequently it is not legitimate to regard the magnitude of the microphonic response as a measure of the sensitivity of an auditory organ.

Microspores in Diatoms

THE occurrence of microspores in centric diatoms and their possible nature have been the objects of great discussion. Recently, Gross¹, on the basis of cultures of *Chaetoceros pseudocrinatus* and *Ch. didymus*, concluded that "there is no evidence whatever that these microspore-like bodies found in the cultures of *Ch. pseudocrinatus* acted as reproductive cells. They are never liberated or at any rate never found outside the parental cells, and flagellate-like cells were never found in the cultures where their formation had taken place". He tentatively put forward the view that "what have been described as microspores are either abnormal products of the diatom cell or alien flagellates, neither participating in the life cycle of the diatoms".

Culture work with plankton diatoms has suggested a different conclusion. In cultures of *Chaetoceros* species obtained by isolation of single cells or chains by means of capillaries and cultivated according to Allen's method², two species formed microspores, namely, *Ch. constrictus* and *Ch. decipiens*. The formation of the spores took place in much the same way: the cell content first divided into two, then into four parts by constrictions parallel to the valves. Each part then divided into two by constrictions perpendicular to the valve, so eight spores were formed in each cell. The spores were not all strictly of the same size; but all contained one or more chromatophores. Being fully developed, the spores had one rather solid cilium, several times as long as the spore, lying coiled around the spore. The liberation of the spores from the cells was observed. They were lively and motile and the culture fluid was crowded with them. Among the free-swimming microspores several were larger than the others and had two cilia. Fusion between two single-ciliate ones was, however, not observed. The formation of microspores took place in cultures without usual signs of crowding.

Transference of *Ch. decipiens* microspores by means of capillaries from a culture to a drop of pasteurized Allen sea-water³ and again to a flask with the same fluid in such a way that no regular *Chaetoceros* cells might by chance be brought along, gave in several cases luxuriant cultures of regular *Ch. decipiens* cells. In some cases two microspores or more were transferred, in other cases only one. Growth occurred in some cultures of both categories, but the number of isolations are yet too small to allow any conclusion as to the possible necessity of two microspores for obtaining ordinary vegetative *Chaetoceros* cells from microspores.

The development of regular *Chaetoceros* cells from microspores seems to give conclusive proof that these spores represent a mode of reproduction in *Chaetoceros*.

Their part in the life-cycle of the plant has to be determined by further studies, also of the cytological features of microspore formation.

Cultivation of Rabies Virus in the Developing Chick Embryo

IN a recent publication we reported that fixed rabies virus can be recovered from an infected chick embryo, that the virus tends to be localized in the brain of the embryo, but that serial passage was irregular and uncertain¹.

The continuation of these studies has led to successful serial passage of the virus in the developing chick embryo. In one series the virus has been carried through nine, and in a second, through six successive passages without loss of virulence of the virus to mice and rabbits when infected intracerebrally. The virus is present both in the allantois and in the embryo brain, but always in higher concentration in the latter. Both series are being continued.

The successful cultivation of the virus in the developing chick embryo depends, apparently, on the age of the embryo at the time of infection, as well as at the time of passage. A large series of experiments showed that embryos of eight days or more are only irregularly infected and that passages are, as a rule, negative. On the other hand, embryos 5-6 days old are readily infected and serial passages can be maintained without any difficulty if they are made 9-10 days after infection. The eggs have been kept at a temperature range of 37.0-38.5° C.

The following experiments are illustrative of this:

(a) Embryos eight days old were infected with 0.1 c.c. of a 1:10 emulsion of infected mouse brain; eggs opened nine days later: the embryo brain infected mice injected intracerebrally with a dilution of 1:10, the allantois failed to infect; in another case the embryo was removed after twelve days and both brain and allantois infected mice in dilutions of 1:100.

(b) Embryos five days old were infected as above; embryos removed nine days later, and both brain and allantois were infective for mice in dilutions of 1:10,000; embryos removed after thirteen days, the brain was infective in a dilution of 1:1,000 and the allantois in a dilution of 1:100.

In all passages thus far, the embryo brain removed 9-10 days after the infection was infective for mice in dilutions of 1:1,000 to 1:10,000. Passages from embryo to embryo can be made with emulsions of either allantois or embryo brain, provided that young embryos are infected and that passages are made not later than 10 days after the infection. Embryos removed more than ten days after infection have shown lower concentration of virus; in one case (passage 4) an embryo tested fifteen days after infection failed to infect mice in any dilution. It is of interest that this specific neuro-virus can be cultivated in the chick embryo provided the infection is made at the earliest possible stage of its development.

The embryo brain of the passage virus of the sixth passage was still virulent for mice when injected intraperitoneally. Studies of the pathogenicity of the virus for chick embryos and on the virulence and immunizing properties of later passages of the embryo culture virus for mammals are being continued.

Oestrous Cycle in the Cat

THE problem of reproduction among cats was studied so far back as 1784 by Spalanzani. Longley¹, van der Stricht², Hill and Tribe³, Courrier and Gros⁴, Greulich⁵, and Foster and Hisaw⁶ have made more recent studies of this question, with somewhat contradictory results.

About seventy cats kept and bred in this Institute have been, during two years, observed and dissected. The results obtained are as follows:

The cat is a dioestrous animal, that is, one in which oestrus appears twice a year. The first cycle occurs in the spring, the second one in early autumn. In this respect, together with the other factors (change of habitation, for example), climate has a great influence. It may happen that these two cycles overlap during the summer months, whereas winter is mostly a period of complete rest from sexual activity. More frequent oestrus than twice a year has sometimes been observed by breeders of Angora cats. That is probably connected with advanced domestication. Normally oestrus lasts 3-5 days. By lack of service it may be prolonged to 10 days or more.

Numerous experiments have proved that ovulation invariably takes place after coitus. That is identical with the rabbit and the ferret. Up to this time, authors differed on this subject. It is interesting to note that a great number of interstitial cells appear in the ovaries of these animals in contrast with other mammals, including women, in which such cells are found either in very small numbers, or not at all. That would be a further confirmation of Ansel's and Bouin's⁷ hypothesis, that the interstitial cells are connected with the above-mentioned symptom and have a restraining influence upon it. An extra nervous stimulus as is given by coitus is thus necessary for its accomplishment. Judging by the numerous interstitial cells which can be found in the ovaries of the above-mentioned three species of mammals, the hare and perhaps the mole ought also to be classified among animals with copulative ovulation.

In the female cat, ovulation occurs about forty to fifty-four hours after copulation. Graafian follicles which do not disrupt undergo an atresia; the granulous cells are partly subject to changes: cells of connective tissue grow out of the theca, interstitial cells undergo strong hypertrophy and grow towards the centre. Only a nucleus of connective tissue remains in the centre of the follicle. At first sight, this formation reminds one of the corpus luteum. Differences consist in their way of staining. The follicles undergo a process of atresia in all stages of development, already beginning at the period

which precedes sexual maturity. As in the rabbit or ferret, a female cat served by a vasectomized male shows the phenomenon of pseudo-pregnancy, which lasts about thirty-six days.

The corpus luteum of pseudo-pregnancy is formed in the first instance of granulosa cells. The blossoming of the corpus luteum takes place after thirteen days and twenty-eight days after copulation it undergoes a reduction simultaneously with the appearance of the growing Graafian follicles of the new cycle.

During the different phases of the oestrous cycle considerable changes occur in the genital tract.

The histological aspect is analogous. During anoestrus, the tube presents a cylindrical epithelium without cilia, whereas on the contrary during oestrus the tube becomes enlarged, it is ciliated and produces a mucus which contains, according to some authors, nourishment for the eggs which traverse the tube after ovulation. Even more prominent changes occur in the uterus. When in anoestrus, we observe flattened, single-layered epithelium and small inactive glands; during oestrus, on the contrary, the epithelium becomes cylindrical, though deprived of cilia, the glands attain a high degree of development and grow deeply into the endometrium. During pseudo-pregnancy, the development of the glands is still stronger and the endometrium grows out into large folds towards the lumen of the uterus. Lastly the vagina also shows marked changes during the cycle: the epithelium thickens many times during oestrus, at the same time the superficial layer flattens considerably, becomes cornified, loses their nuclei and become thrown out of the lumen separately or in flakes.

Further work is in progress.

Synthesis of 5:6-Dihydroxyflavone and the Structure of Primetin

PRIMETIN, $C_{15}H_{10}O_4$, isolated from the leaves of *Primula modesta*¹, has hitherto been regarded as 5:6-dihydroxyflavone (I), and several attempts have been made to prepare this compound². An unambiguous synthesis of 5:6-dimethoxyflavone has now been carried out via the stages 2:6-dihydroxyacetophenone, 2-hydroxy-6-methoxyacetophenone, 2:5-dihydroxy-6-methoxyacetophenone, 2-hydroxy-5:6-dimethoxyacetophenone, 2-benzoyloxy-5:6-dimethoxyacetophenone, and 2-hydroxy-5:6-dimethoxydibenzoylmethane.

Demethylation gave a dihydroxyflavone, which because it regenerated 5:6-dimethoxyflavone or methylation and for other reasons, must be regarded as 5:6-dihydroxyflavone (I), and not the alternative 5:8-dihydroxyflavone (II), which might be produced by opening of the pyrone ring and closure in the alternative direction.³ This substance and its derivatives differ widely from primetin and corresponding derived compounds, and a revision of the structure of primetin is therefore necessary.

It is of interest that Sugawara³ actually succeeded in preparing two derivatives of 5:8-dihydroxyflavone and even a crude specimen of 5:8-dihydroxyflavone itself, but, because the compounds were not identical with primetin and derivatives, he erroneously assumed that they were derived from 5:8-dihydroxyflavone (II).

A review of the available evidence leads to the conclusion that primetin is a dihydroxyflavone derived from hydroxyquinol, and must be regarded

as 5:8-dihydroxyflavone (II). It is probable that another flavone of this type occurs naturally; this is the 4'-methoxy derivative of (II) isolated from the leaves of *Ginkgo biloba* L. by Furukawa⁴. The synthesis of these 5:8-dihydroxyflavones is in progress. A detailed account of this work will shortly be published elsewhere.

Points from Foregoing Letters

B. F. J. Schonland and his associates present evidence supporting the view of Australian workers that the oscillatory structure of atmospheres arises from multiple reflections from the E-layer of the ionosphere. They find that the effective height of reflection is approximately constant (85 km.) except in the neighbourhood of the thunderstorm producing the atmospheric wave, where it decreases from 85 km. at 300 m. distance to 50 km. immediately above the storm.

The cross-sections for the transformation of nitrogen (¹⁴N), when bombarded by fast neutrons, into boron (¹⁰B) or carbon (¹²C) are found by E. Baldinger and P. Huber to have the values 1.63 and 0.4×10^{-28} cm.² respectively. The reaction energy for the nitrogen-neutron transformation is -0.43 Mev.

The crystal structure of α -chitosamine hydrochloride and hydrobromide has been determined by L. G. Cox and G. A. Jeffrey without the assistance of stereochemical data. The authors state that it proves the correctness of the configuration assigned to glucose derivatives, and in particular shows that chitosamine is definitely a derivative of glucose. The results also demonstrate the existence of the pyranose sugar ring and show that in α -glucose derivatives the groups attached to the first and second carbon atoms are in cis positions.

E. Holiday states that deductions from observation of change of absorption at λ 240 m μ as to whether CO groups are formed during enzymic digestion of a protein are not possible until account has been taken of the large masking effect due to accompanying change in absorption of the aromatic amino-acids.

Sedimentation curves for several proteins (thyroglobulin, antitoxic diphtheria pseudoglobulin and thymus nucleohistone) are submitted by H. P. Lundgren, indicating the formation of 'labile' components with lower sedimentation constants; this may be brought about by the simple expedient of increasing the protein concentration and reducing the electrolyte content of the solution.

A. J. Turner communicates a simple formula for calculating the relative humidity directly from readings of a ventilated wet- and dry-bulb hygrometer; the formula gives results accurate to 1 per cent relative humidity between 50 per cent and 90 per cent R.H., from 40° F. to 120° F.

D. N. Truscott reports a graphical method of circuit analysis and synthesis, based on the use of charts with logarithmic scales of impedance and frequency; this has been used in radio receiver design.

A survey of the structure of the Bermuda Islands by means of sound-velocity technique indicates, according to G. P. Woolard and M. Ewing, that the islands consist of four main volcanic cones with several minor ones, and are surrounded by a series of concentric folds which die out in amplitude with distance from the islands. Sound refraction measurements show the tops of two of the volcanoes to be at a depth of about 250 ft.

R. J. Pumphrey has recorded microphonic potentials in response to sound from the non-auditory part of the labyrinth of teleost fish. Such potentials are therefore not an absolute indication of the reception of acoustic or vibratory stimuli.

By isolating single cells of plankton diatoms (*Chaetoceros*) and cultivating them in suitable media, T. Braarud has been able to follow the formation of ciliate microspores and to show that such spores represent a mode of reproduction in *Chaetoceros*.

I. J. Kligler and H. Bernkopf describe experiments showing that it is possible to cultivate fixed rabies virus in the developing chick embryo provided that (a) the allantois of embryos 5 to 6 days old are infected, and (b) passages are made 9 to 10 days after the infection. Passages from embryo to embryo can be made with emulsions of either allantois or embryo brain.

H. Liche confirms the existence of copulative ovulation in the female cat and suggests that it is conditioned by the presence of numerous interstitial cells in the ovary. He describes the pseudo-pregnancy and anatomical as well as the histological changes which occur during the different stages of the oestrous cycle.

Primetin, isolated from *Primula modesta*, has previously been regarded as 5:8-dihydroxyflavone. This substance has now been synthesized by W. Baker, who finds that it is not identical with primetin. There can be little doubt that primetin is 5:8-dihydroxyflavone.

Research Items

Nuer Time-Reckoning

IN a study of Nuer time-reckoning by Dr. E. E. Evans-Pritchard (*Africa*, 12, 2; 1939), it is pointed out that the Nuer have a sense of time different from ours, not merely owing to the fact that a system of time-reckoning in mathematical symbols differs from a verbal system not so reckoned, but also because both European and Nuer alike speak of time in terms of social activities and relationships, which in the two systems differ fundamentally. In Nuer concepts of time we may distinguish between those which reflect their relation to the environment, 'ecological' time, and those relating to the social structure, 'structural' time. The ecological cycle is a year of two main seasons, each divided into six months, one season, broadly, the wet, and the other the dry. The wet season is that of residence in villages, with appropriate occupational activities, and the dry that of residence in camps. The concepts of time are based primarily on the social rhythm, of which the outstanding quality is the movement from village to camp and back again. It is by reference to the changes in the character of their activities that they reckon time, and on them they base their calendar. Years are recalled generally by reference to the places at which their camps were made and the circumstances which arose during their stay there. Hence there is no accurate, or general, system of dating years. Each division of the Nuer has its own system of reference. A habitual method of dating an epoch, or certain events, is by reference to the age of certain persons, and this not by counting years, but by their relation with certain groups of persons. The interval between events is measured by the relation between the persons of one age group and those of another. Time can also be measured by employment of the genealogical method. Events integrate at a certain point in the clan system, and thus each person in the genealogy constitutes a significant point of reference.

Tahimahan Clan Relationships

THE clan relationships of members of nine tribes now resident at Port Simpson, British Columbia, were investigated by Viola E. Garfield in field work carried out in the summers of 1932, 1935 and 1937, with the purpose of defining more clearly the functioning relationships of Tahimahan individuals to each other as determined by their clan and tribal affiliations (*Univ. Washington Pub. in Anthropology*, 7, 3; 1939). In summarizing these relationships, those which are old and still functioning are differentiated from those which are now obsolescent, or those which have grown out of white impact. Closest contacts were with members of the father's and mother's lineages. Children usually lived with the mother in a household composed largely of the father's relatives; but they were taught that their homes were with their maternal uncles, with whom the boys went to live at adolescence. At the present day, however, children grow up under the father's care, and are less influenced by lineage relations. The duties of a father and his lineage towards his child are well formulated. The father's brother and sister are privileged to perform the first services to the child at birth. The father's brother provides the

cradle, while his sister acts as midwife—services now obsolete, owing largely to the provision of hospitals. At the giving of the first name, the maternal uncle gave the name, but it was proclaimed by the father's brother; and in the first power ceremony the father's sister acted as the child's assistant. No power ceremonies now take place. The ear, lip, and nose piercings were performed by a woman of the father's lineage. A paternal aunt assisted in the wedding preparations and the father's sister was the bride's chief attendant. The father's sister cared for the body of the deceased after death, being compensated by the clan relations, while the father's brother provided the coffin.

Metabolism and Castration

M. Sandberg, D. Perla and O. M. Holly (*Endocrinology*, 24, 503; 1939) studied the effect of castration in male and female albino rats on nitrogen sulphur, chloride, sodium and potassium metabolism and on changes in weight and food intake. They found that if the gonads were removed after puberty nitrogen, sulphur, chloride, sodium and potassium metabolism either decreased slightly or remained unchanged. If castration occurred before puberty urinary nitrogen excretion increased considerably urea nitrogen accounting for the increase. Ammonia nitrogen, uric acid, creatine, creatinine and faecal nitrogen excretion remained unchanged. Exogenous as well as endogenous sulphur metabolism was disturbed. Total sulphur excretion rose as well as that of neutral sulphur. After a period of seven months endogenous sulphur metabolism began to return to normal. Chloride, sodium and potassium retention was decreased. The weight curves and food intake of male and female rats which had been castrated before puberty were similar to those of normal animals. The weight curves of male rats which had been castrated after puberty were similar to those of normal animals up to the age of 30 weeks. Then the curves of the castrates flattened out and at 40 weeks of age the controls weighed 10 per cent more. Food intake expressed in gm. per 100 gm. body weight was somewhat higher in normal animals up to a weight of 370 gm. Afterwards it was the same for both groups. The weight curves of female rats which had been castrated after puberty showed a gain in weight over the controls in spite of the fact that their food intake expressed in gm. per 100 gm. body weight was less.

Synthesis of Cystine in Rats

E. F. Beach and A. White (*J. Biol. Chem.*, 127, 87; 1939) placed a group of male rats on a diet of the following composition: cystine-free casein hydrolysate 14.7, tryptophane 0.3, crisco 21, cod liver oil 5 Osborne and Mendel salt mixture 4, and starch 54 per cent. Each rat received in addition a daily supplement of 100 mgm. of ryzamin B and 50 mgm. of liver extract, which provided sufficient water-soluble vitamin to permit a fair rate of growth. This vitamin supplement represented the only possible dietary source of cystine, inasmuch as the casein hydrolysate used in the diet was cystine-free. Moreover, analysis of the animals showed that young rats restricted to this diet for a period of approximately six weeks

usually deposited a quantity of cystine which was considerably in excess of the amount present at the start of the experiment plus the small amount possibly present in the vitamin supplement. The authors include that cystine *per se* is not a dietary essential, but may be synthesized from methionine.

Migrations of Pacific Mackerel

The range of the Pacific mackerel, *Pseudophoxinus*, covers nearly 2,000 miles from Vancouver land to Lower California. Since 1928, the fish has been extensively used for canning, and the opportunity has been taken to mark large numbers so that questions of spawning and other movements may be elucidated (Donald H. Fry, jun., and Phil. M. Roedel *California Fish and Game*, 25, 2; 1939). From 1935, when the marking programme was launched, to 1938, 16,848 had been tagged by metal tags which were either clamped on a gill-cover (an unsuccessful method because the tags do not stay in place), or were inserted through a tiny slit into the body cavity. The tags are recovered by magnets during the processes preparatory to canning, or are sent in by fishermen for a small monetary reward. In order to determine relative movements of different shoals, 403 mackerel were marked at Monterey, 10,184 in southern California, and 1,261 in Lower California. The tag returns seem to be disappointingly few, in all only 412 (out of 16,848), and of these 233 were taken within ten miles of the place of release; 130 were recovered by cannery magnets in the same general area in which they were marked, and 49 were found more than ten miles from the place of release. The recoveries show that there is an interchange of fish between Monterey and southern California and a mingling of fish from different parts of the southern Californian area. The time which has elapsed between tagging and recovery has been as long as two years, and some of the more rapid rates of movement shown by marked fish are 21 miles in twenty hours, and 200 miles in thirty-four days.

Corpuscles in Body Fluids of Invertebrates

SINCE 1924, Toshio Ohno has been conducting a series of investigations into the characteristics of the corpuscles to be found in the body fluids of invertebrates. The findings of eleven of these inquiries have already been published in the Science Reports of the Tôhoku Imperial University. In the issue of the *Journal* for December 1938, the author summarizes the previous work and sets forth his general conclusions. The investigations cover forty-four invertebrate animals belonging to six phyla. The author considers that there is no fundamental hiatus between the erythrocytes of invertebrates and those of vertebrates. Those of invertebrates constantly contain inclusions which are of a substance analogous with that found in the granules included in the leucocytes. Thus the erythrocytes can be regarded as modified leucocytes. Thus the lymphocyte may be regarded as a pluripotential element capable of differentiation along several lines, the particular one followed being dependent upon the individual environmental requirements. The invertebrate blood is characterized by the presence of many and variously pigmented leucocytes.

Sterility in Plums

CONTINUING their studies on incompatibility of fruit trees, M. B. Crane and A. G. Brown (*J. Pom.*, 17, 51-66; 1939) show that self-incompatibility,

cross-incompatibility and partial incompatibility exist in the plums. The existence of self-compatible varieties together with the complex behaviour in respect of intervarietal compatibility is due in large measure to the hexaploid constitution of the plum. The authors show that the old greengage variety exists as a population of different strains which are intercompatible. These strains have several distinct morphological features and they may be either seedlings of one parent or bud sports from one plant. The application of the experimental results to economic practice is discussed.

Earthquake in Chile, January 24, 1939

A SHORT article on this earthquake, written by Julio Bustos Navarrete, director of the Salto Observatory, Santiago, has recently appeared (*Rev. pour l'étude des Calamités*, 2, No. 5, March-April 1939). The author states that the region principally affected was that of Chillan-Concepcion-Cauquenes and that previous occurrences affecting the same area were on May 25, 1751, and February 20, 1835. On January 24, 1939, a series of shocks commenced with light rockings at 23h. 35m., each lasting about three minutes. These gradually became stronger until the climax was reached when a terrific shock occurred, followed by after-shocks. The earthquakes are considered to have been due to an orogenic movement which, being shown by inclinographs, was mentioned in the *Bulletin d'études de l'Observatoire de Salto* in November 1938. It was then stated that the culmination would probably be a series of small shocks or a larger one, though in the present state of the science the exact time and place of these shocks could not be foretold. The anticipated seismotectonic process commenced on January 17 by a shock of intensity V felt at Coquimbo and La Serena and on January 18 by a shock of intensity IV felt at Antofagasta and La Pampa. These were interspersed and followed by minor ones. The shock of January 24 reached a probable intensity XI at Chillan and Cauquenes, and in general the intensity decreased with epicentral distance. There were, however, some exceptions owing to the geological structure of the country, such as at San Carlos and San Gregorio between Chillan and Cauquenes, where the intensity was not above VIII. About the same time as the shock, the volcanoes Quisapu, Antuco and Llaima are reported to have erupted. The author supposes that a 'trigger' action may have been the passage of the centre of a strong anticyclone over the south of Chile at the time, and mentions reports of observations of brilliant lights, thunder, lightning, rain, hail, and peculiar atmospheric conditions accompanying the shock.

Zoned Olivines

AN important investigation of zoned olivines and their petrogenetic significance by S. I. Tomkeieff has recently been recorded (*Min. Mag.*, 229-251, March 1939). The widespread occurrence of zoned olivine in igneous rocks is demonstrated by measurements of the optic axial angle—which varies with the composition in the forsterite-fayalite series—supplemented by determinations of other serial properties such as refractive indexes and birefringence. As a rule, the zoning is found to be continuous, varying from a magnesium-rich centre to an iron-enriched margin. The difference in composition between centre and rim exceptionally reaches 40 per cent fayalite. The olivine in the British Tertiary dolerites

ranges between 18 per cent fayalite in the core to 40 per cent in the outer zone, but in the British carboniferous dolerites the corresponding average range is lower, being 31-39 per cent of fayalite. Data are assembled to show that there is an intimate connexion between the composition of the magma and that of the olivines crystallising out of it at different stages of solidification or differentiation. The recorded observations on natural olivines and the rocks in which they occur are in complete agreement with the results of the recently published study of the forsterite-fayalite binary system by Bowen and Schairer (*Amer. J. Sci.*, 29, 151; 1935).

Origin of the Earth's Magnetic Field

W. M. ELIASBERG (*Phys. Rev.*, 55, 489; 1939) has devised a thermo-electric theory of the origin of the earth's magnetic field. It is known that the electric currents which produce the magnetic field must be located inside the earth, and there is considerable evidence to show that the deep interior core of the earth is fluid and metallic. The continuous production in the core of heat which is lost from the outside leads to up and down convection currents just as in the atmospheric vortices of meteorological theory. The combination of these convection currents and the rotation of the earth leads to Coriolis forces perpendicular to the convective motions. These forces produce an asymmetry in each vortex such that there is an upward motion in the eastern part and a downward motion in the western part. At any horizontal level in any given vortex, the motion leads to an asymmetric temperature distribution. It is probable that this is accompanied by an asymmetric variation of the thermo-electric properties, due to phase changes in the material. A numerical calculation, with temperature variation of the order 10° , leads to currents of the right order of magnitude to account for the earth's magnetism, and the theory accounts indirectly for the rough coincidence of the earth's rotational and magnetic axes. The thermo-electric mechanism does not account for the magnetism of sunspots, which are probably due to currents in the upper layers of the sun's atmosphere.

Isotopic Abundance and Atomic Weight of Europium

THE abundance of the isotopes of europium was determined by Aston in 1934. He found two isotopes of mass numbers 151 and 153 respectively, the former having an abundance of 50.6 per cent and the latter of 49.4 per cent. Using the packing fraction $(4 \pm 2) \times 10^{-4}$, and the correction factor (0.999725) for the conversion of the atomic weight from the physical to the chemical scale, the value of the atomic weight obtained was 151.19 ± 0.03 . Recent determinations of the atomic weight of europium by chemical methods carried out by Baxter and Tummeler give 151.963. Kapfenberger (*Z. anorg. Chem.*, 238, 273; 1938) obtained the value 151.901 by determining the ratios $\text{EuCl}_2 : 2\text{Ag}$, and $\text{EuCl}_2 : 2\text{AgCl}$. H. Lichtblau now reports the results of a reinvestigation of the isotopic abundance of europium (*Naturwiss.*, 27, 260; 1939). Details of the method are given, and the result obtained is $^{151}\text{Eu} : ^{153}\text{Eu} = 96.8 \pm 1.2 : 100$. Other isotopes were not found, and if they exist the upper limit of their abundance is 0.4 per cent. The mean mass number calculated from the abundance is $152.619 \pm 6 \times 10^{-4}$. Using Dempster's value for the packing fraction, $(2 \pm 0.5) \times 10^{-4}$, and the above-mentioned correction factor for converting the

physical to the chemical atomic weight, the atomic weight is calculated to be 151.95 ± 0.01 . Using Aston's value for the packing fraction, the atomic weight is 151.92 ± 0.03 .

Overhead Line Vibration

THE paper on the vibration of overhead line conductors by Messrs. E. W. W. Double and W. I. Tuck, read to the Institution of Electrical Engineers on April 12, is a useful contribution to an important practical problem. When a smooth cylindrical body is placed in a fluid moving with steady velocity at right angles to the axis of the body, it is known that the formation of eddies in the fluid behind the body depends on the velocity of the fluid, the length of the axis of the cylinder and the dynamic viscosity of the fluid. A simple formula derived from the three quantities leads to Reynolds' number, the value of which enables us to find the velocity of the water flow when it changes from steady streamline flow to the turbulent condition when eddies are formed behind the cylinder. The generally accepted theory is that vibrations are set up when the eddy frequency of the vortices coincides with one of the elastic periods of the vibrating line. This cause resonance, which initiates and maintains vibrations. Field observations were made on the vibrating conductors consisting of 100-ft. lengths of stranded steel cored aluminium conductor in air, under given controlled conditions of vibration, to get data on the behaviour of the conductor and clamps and the maximum bending stresses induced in the conductor. It was thought that when these data were found it would be possible to deduce the maximum safe 'stringing' tension of the line, assuming that it depended mainly on the repeated bending stresses. A study of cables broken at the end of the suspension clamp showed that the 'scoring' of the aluminium wires aided by abrasion weakened them so that full use was not made of the fatigue strength of the aluminium. The actual break occurs at points where the wires were 'nicked'.

Energy Production in Stars

THERE have been many attempts to account for the production of energy in stars with the aid of atomic transmutations. A. A. Bethe (*Phys. Rev.*, 55, 434; 1939) has now described in detail a cyclical scheme of reactions in which reactions between protons, carbon, nitrogen and oxygen nuclei result in the combination of four protons and two electrons into an α -particle:

It is shown that the probabilities of these reactions, at a temperature of about 20 million degrees, corresponding to the central temperature of the sun, give about the right rate of energy production for that body. The dynamics of the process are also consistent with the mass luminosity relations which have been observed among the stars. Nuclear reactions other than these are examined and shown to play little part in the energy production—in particular, it is not possible for elements heavier than He^4 to be built up continuously in ordinary stars, and these elements must have existed already when the star was formed. In some faint stars, however, it is possible that energy is produced by the reaction

International Standard of Concert Pitch

By Dr. G. W. C. Kaye, O.B.E., F.R.S.

THE question of the international standardization of concert pitch, to which reference has already been made in NATURE (November 5, 1938), was the subject of an International Conference on May 11 and 12 last, under the auspices of the International Standards Association (I.S.A.). The Conference, which was held at Broadcasting House by the courtesy of the British Broadcasting Corporation, was organized, at somewhat short notice, by the British Standards Institution under its director, Mr. J. Maistre. Five countries (France, Germany, Great Britain, Holland and Italy) sent delegates, while the official views of Switzerland and the United States of America were before the Conference. The International Union for Broadcasting (U.I.B.), and the International Consultative Committee on Telephony (C.C.I.F.) were also represented by delegates. The President of the Conference was Dr. G. W. C. Kaye, Chairman of the British National Committee on Acoustics, and the British delegation consisted of Dr. Kaye, Dr. F. W. Alexander, Captain E. H. T. Broadwood, Mr. L. S. Lloyd and Mr. Henry Willis.

The Conference was formally opened by Sir Cecil Graves, deputy director-general of the B.B.C., who, after welcoming the delegates, pointed out that the fixing of a new concert pitch is a problem for the musician to decide, after which the aid of the technician must be sought to help the musician to make and maintain the pitch he has chosen. Although it is probable that the extreme range of variation in the pitch of orchestras the world over does not exceed a semitone, it was scarcely necessary to stress the increased comfort and assurance of a standardized pitch to singers and to players of concertos for stringed instruments. There is no doubt, too, that the manufacturers of musical instruments, particularly of organs and pianos, would welcome a standardization which would relieve them of the frequent necessity of re-tuning. As regards listeners to music, whether at the concert hall or through the medium of broadcasting, no real comparison on the score of brilliancy of two different performances of the same symphony by different conductors is possible unless the two performances are based on the same pitch. In these days of emotional stress, it is no small achievement for nations to come together to discuss a subject that is very much bound up with the emotional factor. General agreement on principles and practice might well be a promising portent for the future of the world.

In his opening address, the President reminded the delegates of the occasions in the past when agreement had been sought on the present question, but no outstanding measure of international unification had ever resulted. He hoped that before the Conference dispersed, it would have set up a musical milestone of lasting significance. The question of an international standard of concert pitch, while always of commercial importance in the international trading of musical instruments, has assumed new prominence in view of the requirements of international broadcasting and the development of electro-acoustical instruments. It was in fact the

urgent requirements of the International Broadcasting Union which finally led to the decision to endeavour to bring about international agreement.

After suggesting that the Conference should confine itself to the standard convention of expressing concert pitch in terms of the note A in the treble clef, brief reference was made to the historical background of concert pitch—to the early and pronounced meanderings of pitch during the fourteenth to the nineteenth century; to the first attempt at standardization a century ago in Great Britain, namely, the philharmonic pitches of 433 in 1826 and of 455 in 1845; to the value, 440, adopted by the Stuttgart Conference in 1834; to the French Diapason Normal, 435, of 1859, and its endorsement by the International Congress of 1885 in Vienna. In the United States, a figure of 440 is now general after many vagaries, while as regards Great Britain, reference may be made to the standardization at 439 of piano pitch by the piano makers in 1899, and to the lowering in 1927 of the pitch of the British Army bands from 455 to 439. The first question before the Conference was virtually that of reviewing the present general upward departure from the standard adopted in Vienna more than fifty years ago. Incidentally, so far as actual frequency measurements go, the standardization requirements of musical pitch present an easy problem to the physicist who can, if desired, measure frequency to an accuracy of 1 in 100 million.

A survey of the reports submitted by different countries to the Conference indicates that the present position can well be regarded as propitious for international agreement:

	Treble A (cycles per sec.)
French Standards Association, proposes	440
German Standards Association, proposes	440
American Standards Association, proposes	440
British Standards Institution, proposes	440
Dutch Acoustics Committee, agrees	440
Swiss Standards Association, agrees	440
International Union for Broadcasting, suggests	440
Italy has adopted	435 ± 4
Mean of European Concert Broadcasts	443
Electric organs, American	440
Electric organs, British	439

A friendly and vigorous discussion followed, during which it was happily found possible to establish eventual agreement on the main points at issue. Thereupon, taking cognizance of the general lack of observance of the Vienna standard (435) in favour of an appreciably higher though variable figure, which moreover shows a constant and regrettable tendency to increase, and having regard to the aesthetic, technical and economic importance of early international standardization within the limits of existing practice, the Conference unanimously agreed to forward the following recommendations to the parent International Acoustics Committee for submission to, with a view to ratification by, the national standardizing bodies affiliated to the International Standards Association; also to the U.I.B., the

C.I.J.F. and the International Electrotechnical Commission (I.E.C.):

(1) That the international standard of concert pitch shall be based on a frequency of 440 cycles per second for the note A in the treble clef. ("La normale".)

(2) That this value shall be maintained within the closest limits possible, by soloists, orchestras, choirs, etc., throughout all musical performances, and also in recorded music.

(3) That with a view to reducing the necessary tolerances to acceptable values, a set of technical recommendations be drawn up, preferably on the basis of international co-operation.

An appendix to the recommendations relates to a future programme of study designed for early discussion, so as to render effective as soon as possible the practical observance of the new standard concert pitch: for example, the differential influence of temperature on the various orchestral instruments and the consequential tuning adjustments before and during a performance; the feasibility of transmitting the standard pitch by means of broadcasting or telephone; the provision of sub-standards of pitch,

portable or otherwise, and the advisability of the verification by an official laboratory; the production of specifications dealing with the appropriate tolerances in the manufacture of musical instruments and the setting up of supervisory safeguards, both national and international, for verifying the observance of the new standard pitch and so preventing the possibility of its falling into disuse, as has occurred with the Vienna standard.

The success of the Conference was a happy vindication of the decision to go forward with the plans for bringing the delegates of the different countries together, despite the troubled nature of the times. The delegates further consorted in complete and amicable accord on the occasions of visits to the Acoustic Laboratory of the National Physical Laboratory by the kind invitation of the Director, and to Lyn Capel, Surrey, at the invitation of Captain Broadwood, whose beautiful house and estate, in all the glory of the spring foliage, formed a lovely setting for his genial hospitality and the delightful unaccompanied old English melodies of the famous Tudor Singers under the direction of Mr. Cuthbert Bates.

Telephony in the United States

THE annual report by the directors of the American Telephone and Telegraph Co. for the year 1938 is of great interest. The taxes last year were equal to about 80 cents per month per telephone, which is about 14 per cent of the average telephone bill, or about one third of the total pay roll. Notwithstanding the heavy taxation and increased wages, the earned dividends for the last two years were nearly the same.

Until 1927, the longest distance a telephone call could be made was about 3,000 miles; to-day there is no limit. We can talk round the world. The improvement in transmission on a call from New York to San Francisco as compared with twenty years ago when trans-continental service was inaugurated is roughly equivalent to the difference between conversing in an open field at a distance of several hundred feet and conversing with someone in the same room at about one third the cost. Five years ago the time of making a long-distance connection was reduced from 7.5 minutes to 3 minutes. Last year a direct radio telephone circuit from San Francisco to Australia was made, replacing the original route from New York via London. This new circuit is several thousand miles shorter and made possible a substantial reduction in the price of a call.

The ocean liner *Nieuw Amsterdam* has been added to those with which the Bell system operates ship-to-shore radio telephone service. Twelve shore stations of the Bell system and its connecting companies now serve nearly a thousand small vessels on the Atlantic and Pacific coasts and on the Great Lakes.

The damage experienced by the destructive effects of fires, floods, tidal waves and hurricanes in 1938 was the most extensive ever experienced. In September all these destructive forces combined, causing a disaster in the eight north-eastern States affecting the greatest number of telephones and communities since the telephone was invented. More than half a million telephones were silenced, and 240 communities were isolated. The wreckage of telephone plant put

the Bell system to the greatest test it had ever been called on to face—a test of the organization, of its men and women, and of its resources of equipment and supplies. More than 2,300 trained men with 615 motor-vehicles were loaned by fourteen telephone companies. Enormous quantities of materials were rushed in promptly by the Western Electric Co. The Bell companies in the stricken area, assisted by the resources of the entire Bell system, successfully met the challenge of the catastrophe, the telephone men and women, unmindful of hardship, carried on with resourcefulness and courage, and the result was an almost impossible job splendidly done.

Research in the field of radio telephone transmission has been specially pushed in the direction of increasing the efficiency and the steadiness of trans-oceanic circuits in anticipation of the adverse conditions likely to occur in 1940 and 1941 at the time of the expected maximum effect of sunspot disturbance. Highly efficient adjustable directional antennae have been prepared. One of these, two miles long, is now being installed in the trans-Atlantic route. Two noteworthy achievements in civil and military aeronautics were made last year. One was the development of an accurate instantaneous terrain clearance indicator by which a pilot is at all times apprised of his height above the ground. The other was the development of an aeroplane locator for use at ground stations. By dialling the frequency of the aeroplane radio, the airport operator can see on a map the direction of any aeroplane within range. This should be of great value in reducing risks to aeroplanes in bad weather.

The Company has a memorial fund which provides annual awards in recognition of unusual acts of service. This year one (posthumous) gold medal worth £100 and thirty-two bronze medals were awarded to individuals, and four special bronze plaques were awarded to groups of employees in recognition of their skill, courage and devotion to duty along the Ohio River Valley during the flood of January 1937.

Jubilee of Johns Hopkins Hospital

LET us hope," said John Shaw Billings at the opening on May 7, 1889, of the Johns Hopkins Hospital in Baltimore, "that before the last sands have run out from beneath the feet of the years of the nineteenth century, it will have become a model of its kind, and that upon the centennial of its anniversary it will be a hospital which shall still compare favourably, not only in structure and arrangement, but also in results achieved, with any other institution of like character in existence."

Half a century has rolled by since that memorable day, full of pride, tradition, and famous men whose names continue to shine with undiminished brightness in the medical firmaments: Osler, Welch, Talsted, and Kelly. The intellectual child of that healthy Baltimore bachelor and banker John Hopkins, when the hospital opened its doors, it consisted of seventeen buildings with two hundred and thirty beds, seven graduate head nurses, and seventeen probationers. There were but four services: medical, surgical, gynaecological, and pathological. To-day "Hopkins" has developed into a medical centre with 1,024 beds and 690 nurses.

On May 4, 5, and 6 a large number of old Hopkins people, medical men and nurses, and many distinguished visitors gathered together at Baltimore, to celebrate the fiftieth birthday of an institution of which it has been said that it has become more famous than the historic city beyond its walls. At the exercises held on the green lawn of the hospital in the afternoon of May 4, Dr. James B. Herrick,

"dean of American physicians", described Osler's text-book of medicine as Johns Hopkins's greatest single contribution to medicine. A serious note was struck by the Hospital's director, Dr. Winford H. Smith, who suggested that the days of great individual fortunes are passing and with them the days of great philanthropies and benefactions, so that one of the prime problems of the hospital of the future will be increasing dependence upon Government for support. In the evening a historical play, "The Flowering of an Idea", written by Dr. Alan M. Chesney, dean of the Medical School, and dealing with the early development of the Hospital, was performed.

A carefully planned and fascinating programme consisted of exhibits, lectures, demonstrations, and conferences. Among others, Dr. Simon Flexner spoke on "The Nuffield Benefaction and the Full-Time Chairs at Oxford". At a reunion dinner attended by some thousand medical men and nurses, Dr. J. M. T. Finney acted as toastmaster, and the speakers included Dr. Howard A. Kelly, the only surviving member of the "Big Four" immortalized in Sargent's painting, and Dr. Lewellys F. Barker.

The eyes of the scientific world will be focused upon Johns Hopkins Hospital during the next fifty years of its existence. It has had a great past, and its responsibility towards the future is enormous beyond reckoning. "A city that is set on a hill cannot be hid."

WALTER BETT.

Scientific and Industrial Research in Australia

THE twelfth annual report of the Council for Scientific and Industrial Research, Commonwealth of Australia, covers the year ended June 30, 1938.*

The most important development during the year was the decision of the Government to extend the work of the Council for the secondary industries, for which purpose the sum of £250,000 was appropriated for capital expenditure, involving establishment of the Standards Laboratory and an aeronautical and engine testing laboratory and an information section. A site has been offered by the University of Sydney for the Standards Laboratory within its own grounds. It is proposed that the laboratory should be organized in sections for meteorology, electro-technology and physics. The aeronautical laboratory is to be located in Melbourne, for which purpose a site has already been acquired. In addition to providing the information service visualized by the Secondary Industries Testing Research Committee, the proposed information section is intended to initiate research work in co-operation with industry, and the Imperial Agricultural Bureau plan will be extended to include other branches of science and industry than agriculture.

* Parliament of the Commonwealth of Australia. Twelfth Annual Report of the Council for Scientific and Industrial Research for Year 1937-38. Pp. 96. (Canberra: Government Printer, 1939). 4s

In addition to the preparation of bibliographical references, the work of the section will cover the supply of scientific and technical information, the preparation of information relating to recent advances in the application of science to industry, etc., the preparation and publication of articles, Press statements, reports, etc.

The report gives brief reviews of the work carried out by the various departments of the Council. The Division of Plant Industry has continued its work on the breeding of pasture plants, the storage of fruit and on the root rot of wheat. Tobacco investigations have included the control of downy mildew, and a survey is being made of the potato virus diseases of Australia.

The work of the Division of Economic Entomology during the year on the sheep blowfly pest has been concerned with the study of attractiveness, the development of standard methods of testing poisons and investigations of dressings. Further work has been carried out on the control of codling moth with the particular object of finding an efficient alternative to lead arsenate.

The Division of Animal Health and Nutrition occupied the new animal health research laboratory at Melbourne during the year, and work on pleuro-

pneumonia in cattle and mastitis in dairy cattle was continued. The Division has also continued its studies in fleece chemistry, yield and fibre measurement and on the sheep blowfly problem, and an investigation on sheep dips was initiated during the year.

In addition to continuing its various soil surveys, the Division of Soils has been concerned with the use of a spectrograph and the polarograph for the determination of traces of metals in soils and in plant and animal diseases.

The work of the Division of Forest Products has continued to expand during the year and, in addition to the chemistry of wood and pulp and paper investi-

gations, has been concerned with the preservation of timber, the seasoning of timber and various problems in the wood manufacturing industry.

The Division for Food Preservation and Transport occupied its new laboratory at Homebush Bay, Sydney, during the year and has completed its work on the cooling of beef in sides. Other work has dealt with the loss of bloom on chilled beef, the storage of oranges, peaches, plums, pears and grapes as well as on apples and eggs. Further progress has been made during the year by the Council in the provision of staff and facilities for fishery investigation in which aerial reconnaissance has again been used.

The Dutch Congress of Natural Science and Medicine

THE twenty-seventh Dutch Congress of Natural Science and Medicine was held at Nimeguen, Holland, during April 11-13, under the presidency of Prof. G. Holst. Reference was made to the general lectures in the programme in a note in NATURE of April 1, p. 554. At a joint meeting of the physical and chemical sections Prof. Errera, of Brussels, gave a special address to the Congress on his investigations of the absorption of organic compounds in the infra-red part of the spectrum. Besides the well-known absorption bands belonging to special atomic configurations, new absorption bands appear which must be ascribed to multi-molecules (association). In solutions, there appear special bands due to the interaction of an atomic group of the solvent with the molecule in solution.

MATHEMATICAL PHYSICS AND PHYSICS

Among the papers presented to the section on mathematical physics, the following may be mentioned. Methods of approximation of the general wave equation were discussed with special reference to the Schrödinger equation. Prof. de Laer-Kronig treated a new perturbation theory, leading to a difference equation, which can be solved numerically by the application of an extension of the well-known Wentzel-Kramers-Brillouin approximation. It was shown by Prof. Zernike that the intensity of light in the vicinity of a focus can be described, even for the most general boundary conditions, by a special kind of orthogonal functions, introduced by him. Dr. Bremmer demonstrated that the Wentzel-Kramers-Brillouin approximation of the wave equation may be considered as the first of a series of terms, which can all be interpreted physically. Ehrenfest's theorem of the classical motion of the centre of a wave packet describing a particle in quantum-mechanics was extended by Prof. Fokker for a very general type of propagation equation.

In the physical section, Dr. Matthijs gave an account of measurements on the thermo-electric force of superconducting metals in the neighbourhood of the transition point, showing that superconductivity becomes evident at a temperature superior to the transition point.

In a discussion on nuclear physics, Mr. Barendregt reported experiments on pair formation by β -rays, which process appears to take place much more

frequently than theory predicts. Dr. Heyn gave an account of experiments, made in collaboration with Mr. Aten, jun., and Dr. Bakker, on the fission of thorium and the thorium nuclei by neutron bombardment. From experimental evidence it follows that these nuclei can break up in more than one way.

CHEMISTRY

In the chemical section, Mr. van Pelt communicated experiments on the bromination of pyridine and compounds containing a pyridine ring. It was found that, depending on the temperature, either *ortho*- or *meta*-substitution occurs. Dr. Heertje dealt with the measurement of the density of fibres. A gas-volumetric method with helium was used. Evidence was produced for the assumption that water is absorbed by cotton in two different ways. Prof. Aten described an objective colorimeter which can be constructed at very low cost using ordinary laboratory apparatus. Mr. Troelstra discussed the latest improvements in electrodialysis.

BIOLOGY

The programme of the biological section contained a large variety of communications. The main topic was the need of magnesium in plants (O. de Vries) and animals (Sjollema). Further botanical subjects dealt with were the transport of substances (Aris), the relation between yield and the ratio between roots and sprouts (Boonstra), bacterial leaf-symbionts (De Jongh), antagonisms between micro-organisms (Westerdijk), the influence of colchicine on nuclear divisions (Wellensiek) and problems in the rooting of cuttings (Funke, Hubert and Rappeport).

Zoological subjects discussed included: Colorado beetle (Roepke), the life of termites in the Netherlands Indies (Kalsbeek), metabolism in trypanosomes as a basis for control (Krijgsman) and the power of orientation of migratory birds (Van Dobben).

In addition, pollen analysis investigations (Florschütz), vertebrate fauna (van der Vlerk) and botanical investigations (Polak) of the quaternary in the Netherlands were discussed in the geological section, while the general lectures of Ornstein on physics and biology and of Gorter on very thin membranes attracted considerable attention from biologists.

University Events

CAMBRIDGE.—G. Manley of Gonville and Caius College has been appointed University demonstrator in geography.

The Board of Management of the Frank Edward Moore Fund will shortly proceed to the award of two studentships for research in medicine. The studentships are open to male graduates of any University who were born in any country within the British Empire other than Scotland. The students appointed will work in the Department of Medicine of the University of Cambridge under the direction of the regius professor of physics. The commencing salary will be £300 a year, and the appointment will be for two years in the first instance. Further information may be obtained from the regius professor of physics, Department of Medicine.

The following have been elected to fellowships at St. John's College: Dr. W. A. Deer, Strathcona research student (1934), Royal Commission for Exhibition of 1851 senior student (1938), formerly at the University of Manchester. F. Hoyle (Emmanuel College), Part I, Mathematical Tripos, Class I (1934), Part II, Mathematical Tripos, Class II (1935), Part III, Mathematical Tripos, honours with distinction (1936), Mayhew Prize (1936), Goldsmiths' senior student (1937), Smith's Prize (1938).

LEEDS.—The Council has received the following donations: £50 from the Education Committee of the National Association of Local Government Officers to assist in the encouragement of the study of public administration; £110 from the Anglo-Saxon Petroleum Company (Royal Dutch Shell group) for a scholarship tenable in the Mining Department.

LONDON.—Prof. W. E. Le Gros Clark has been appointed as from October 1 to the University chair of anatomy tenable at University College. He has held University chairs of anatomy at St. Bartholomew's Hospital Medical College and at St. Thomas's Hospital Medical School, and since 1934 he has been professor of anatomy in the University of Oxford.

Dr. Samuel Nevin has been appointed to the University chair of the pathology of mental disease tenable at the Maudsley Hospital. He will take up his duties in September next.

Dr. Patrick D. F. Murray has been appointed, as from October 1, to the University readership in biology tenable at St. Bartholomew's Hospital Medical College. He has held a Rockefeller travelling fellowship and a Smithsonian research fellowship; and since 1937 he has held a teaching post in the Department of Zoology at Bedford College.

The title of reader in economic statistics, with special reference to mathematical economics, in the University has been conferred on Mr. Roy G. D. Allen in respect of the post held by him at the London School of Economics.

The title of professor emeritus of medicine in the University has been conferred on Prof. T. R. Elliott on his retirement from the professorship of medicine and the directorship of the Medical Unit at University College Hospital Medical School.

The degree of D.Sc. has been conferred on Mr. C. L. Wilson, an internal student, of University College and on Mr. F. G. Young, an internal student, of University College.

Science News a Century Ago

The Royal Geographical Society

THE eighth anniversary meeting of the Royal Geographical Society was held on May 27, 1839. According to the annual report, sixty-three new members had been elected; and the Society consisted of 651 members, and sixty foreign, honorary and corresponding members. The president, in handing a gold medal to Chevalier Bunsen to be sent to the naturalist and traveller Dr. Wilhelm Ruppell (1794–1884) of Frankfort, said that the medal was awarded in testimony of Dr. Ruppell's services in the advancement of physical geography. Dr. Ruppell had made three journeys into Africa. After the first he had placed himself under the tuition of the learned Baron von Zach. He then returned to Egypt, visited Arabia, the gulf of Akabah (which he was the first to explore geographically), Abyssinia and Kordofan. All the produce of his travels in the department of zoology, which absorbed a large part of the pecuniary means at his disposal, he had generously made over to his native city.

Daniell's Constant Battery

ON May 30, 1839, at a meeting of the Royal Society, the fifth letter of J. F. Daniell to Faraday on voltaic combinations was read. The letter also gave an account of the effects of a large constant battery. The constant battery consisted of seventy cells in a single series, which gave, between charcoal points separated a distance of three-quarters of an inch, a flame of considerable volume, forming a continuous arch, and emitted radiant heat and light of the greatest intensity. The latter, indeed, proved highly injurious to the eyes of the spectators, in which, although they were protected by grey glasses of double thickness, a state of very active inflammation was induced. The arch of the flame between the electrodes was attracted or repelled by the poles of a magnet according as the one or the other pole was held above or below it; and the repulsion was at times so great as to extinguish the flame. When the flame was drawn from the pole of the magnet itself, included in the circuit, it rotated in a beautiful manner. The heating power of the battery was so great as to fuse, with the utmost readiness, a bar of platinum one eighth of an inch square; and the most infusible metals, such as pure rhodium, iridium, titanium, the native alloy of iridium and osmium, and the native alloy of platinum.

Lyell's "Elements of Geology"

ON June 1, 1839, in its column headed "Our Library Table", the *Athenaeum* included this note about Lyell's "Elements". "The author states that the present treatise was originally intended to appear as a supplement to his 'Principles' but that he was subsequently induced to enlarge it, and bring it out in the form of a distinct work. It is an attempt—and we think a very successful one—to put forward in a simple and clear manner, those facts which are indispensable to a knowledge of the science, and to place the student in possession of the data by which geologists of the existing school explain the more palpable and widely spread geological phenomena. The bold and ingenious speculations, so ably developed by Mr. Lyell in his larger work, and to which his present fame is mainly to be attributed, are here, in a great measure, kept out of the field."

Societies and Academies

Paris

Academy of Sciences (*C.R.*, 208, 1125-1178,
April 12, 1939).

H. VALLÉE: The adjuvant factors of vaccination. The acidity of anthrax vaccine and its various insoluble sediments are essential factors in determining immunizing power.

O. C. DE BRAUBERGARD: The problem of the exact measurement of a long line.

J. VILLEY and R. LEDUC: Auto-propulsion of a projectile-source.

L. MALAVARD: Prandtl's correction in a 'mixed' [partly directed, as opposed to free] channel: electrical method and calculation.

R. GRANDMONTAGNE: Evaluation of the brightness of the mean night sky by means of a cesium photo-electric cell.

MILLE. P. FAVRIER: Objective character of indiscernibility.

G. REBAUD: Formulae for the convection of heat for a fluid flowing normal to the axis of a cylinder.

MILLE. E. MONTEL: Determination of the mobilities of gaseous ions.

M. CHÈNE: Preparation of two phosphides of vanadium by fusion electrolysis [of vanadium anhydride dissolved in alkaline phosphates].

P. ROUARD: Study of very thin platinum films. The metal was deposited on glass by cathodic sputtering. Films less than 7 mμ in thickness are different in properties from the massive metal.

P. LAMBERT and J. LECOMTE: Infra-red absorption spectra of hydrocarbons of high molecular weight and of some heterocyclic compounds.

A. PIKARA: Variation with heat of the magnetic birefringence of polar liquids.

MME. Z. SOUBAREW-CHATELAIN: Hydrated neutral sodium dimolybdate.

J. VAUTHIER: Action of nitric acid on iron carbide.

MILLE. G. CAUQUIL: Action of selenium oxide on 1-methyl-4-isopropylidenecyclohexanone-3.

MILLE. Y. GARREAU: New addition products of diphenols.

B. BRAJNIKOV: Geology of Vérala Planina (Bulgaria).

E. DE MARTONNE: Formation of 'sugar-loaves' [rocky peaks with precipitous sides, several hundred metres high] in Brazil.

R. BERNARD: Possible presence of cyanogen bands in the spectra of the red auroras of type B.

MME. O. THELLIER: Diurnal variation of the electric conductance of the atmosphere and the number of ions and condensation nuclei at the Observatory of Chambon-la-Forêt.

MILLE. A.-M. DE LA BERNARDIE: Existence of antagonism between thyroxine and the vitamins.

B. S. LEVIN and L. OLIZKI: Total loss of pathogenic action of *B. typhi murium* given orally, after prolonged culture in lecithin media.

Budapest

Hungarian Academy of Sciences, April 17.

G. RADOS: Semi-definite Hermitian forms.

G. ZEMPLÉN: Synthesis of α-1-xyloido-6-glycose, the isomer and derivative of the primverose.

P. FRÖHLICH and I. MISCHUNG: Emission of phosphorus.

J. FINKEV: Flotation of grey slate from Recek.

A. BUZÁGH and E. ERNYEI: Permeability and absorption of liquids by sediments.

F. PAPP: Several minerals from Szarvaskő.

G. ZILAHY SEBES: Sexual organs of the Heleides.

L. GOMBAY: Electric conductivity of phosphorus.

P. KOLLER: Development of the mechanism of sex determination.

Geneva

Physical and Natural History Society (Feb. 2, 1939).

E. PAREJAS: Transversal tectonic of Anatolia (preliminary note). The Alpine folding runs mainly from south-east to north-west. The most important transversals are those of the Dardanelles, Marmora, Antalya, Istanbul-Chypre, Tüz Golu-Odessa, Kizilirmak-Crimea, Kertch and the Caucasus.

MME. R. DOVAZ: Vaginal mucification in the pregnant guinea pig. During gestation, the ovaries sometimes contain big follicles; in such cases, there are excessive vaginal mucus and intense leucocytosis. The condition depends on the food conditions or the temperature.

A. MIRIMANOFF: Is sterilization in the cool possible in microbiology? Attempts to generalize the sterilization of culture media, at ordinary temperature, by volatile anaesthetics, which would conserve thermolabile factors, have been unsuccessful.

G. TIERCY: Solution of the equation of transfer of energy and the function $B(\tau)$ in astrophysics. Investigation of the form of $B(\tau)$ necessary to give a finite value at the surface of a star, and also to the intensity of radiation, while the derivative of the function would become infinite.

March 2, 1939.

E. BRINER and E. PERROTET: Determination of the solubility of ozone in water.

T. POSTERNAK: Pigments of *Penicillium rubrum* and *P. citreoroseum*. The red pigment of the former is the phenolic of *P. phanicum* (2,2'-dioxo-4,4'-dimethyl-diquinone). The pigment of *P. citreoroseum* has the properties of a poly-oxyquinone.

J.-L. PERROT: Fertilization in *Arion empiricorum* Fer. (preliminary note). The possibility of direct self-fertilization by ripe autochthonous sperms in the ovo-testis cannot be excluded; but there seem to be varieties of different physiological character.

M. PERROT: Systematic position of *Euparypha pisana* Muller, from a study of the chromosomes. Conchological, anatomical and zoogeographical characters and cytological observations separate the genus *Euparypha* clearly from *Helix*, *Archelix* and *Cepaea*. It is proposed to put *Helix pisana* in a new sub-family, the Euparyphinae.

E. A. H. FRIEDHEIM: Negative effect of sources of mitogenetic rays on growth of tissue cultures. Hanging-drop cultures of chick fibroblasts submitted to the action of various 'inductors' (root and juice of onion, cultures of *B. tumefaciens*, tadpoles and tadpole extract, chick embryo, embryo extract, normal and cancerous human blood, monochromatic ultra-violet light from 2,000 to 3,600 Å.) have not shown more abundant mitoses than untreated cultures.

March 16.

P. BALAVOINE: (1) Variation of composition of the water of Lake Geneva. Analyses during 1936

1937 and 1938 show that the surface water is impoverished in calcium carbonate during the warm months by 7-10 per cent in relation to the total dissolved matter. This seems to be a physico-chemical effect, rise of temperature playing the chief part in this precipitation. (2) Observations on snow. Snow is able to condense strongly traces of ammonia in the atmosphere. The ammonia content of snow is ways very small (0.01-0.05 mgm. per litre of water fusion, exceptionally 2.0 mgm. per litre); but this explains the presence of ammonia in tanks not receiving faecal water.

M. GYSIN: A soda orthose in the syenitic rocks of Divrik (Turkey).

Moscow

Academy of Sciences (C.R., 21, No. 5; 1938).

N. GUNTHER: Theory of integrals of Stieltjes-adon and integral equations.

K. WULFSON: Sensitivity threshold of a gas radiometer.

M. L. VINGEROV: K. Wulfson's article "The sensitivity Threshold of a Gas Radiometer".

R. I. GARBER: Formation of elastic twins during the twinning of calcite crystals.

N. MIHAL: Determination of gravity anomalies from the astronomical-geodetical deflection of a plumb-line.

V. I. NIKOLAEV and B. I. STEPANOV: A method of producing pure common salt through bihydrate of sodium chloride, $\text{NaCl} \cdot 2\text{H}_2\text{O}$.

V. I. NIKOLAEV and E. I. RUDNENKO: Adsorptive properties of clay (kaolin).

G. B. BOKY: The number of physically simple crystal forms.

A. E. FERSMAN: Geochemistry of Kislovodsk environs.

A. K. GERGENEGIU: A new valuable bearer of vitamins and its commercial use.

D. S. BELIANKIN: Contribution to characteristics of the breccia-like and banded lavas of the volcano Elbrus.

G. L. KAMENSKI: Movement of ground waters in water-riverine tracts.

E. N. SHMARGON: Analysis of the chromomere structure of mitotic chromosomes in rye.

P. A. POVOLOCHKO: Causes of constancy in the chromosome number of the autotetraploid *Nicotiana glauca* var. *eghisi*.

V. L. RISCHKOV and K. S. SOUKHOV: Virus of the tobacco mosaic tested for its power of fermentative activity.

C.R., 21, No. 6; 1938.

S. BACHVALOFF: Couples of stratifiable congruences.

N. DOBROTIN, N. IWANOWA and B. ISAJEV: Recoil-ray showers.

N. MALKIN: Helmholtz's formula and the isostasy hypothesis.

A. S. MOROZOV: Effect of sodium chloride and sodium sulphate salts on sugar content of melons.

S. W. BRUJEWICZ, R. M. PRYZENLAK, V. L. PONTIKOVSKAJA and M. A. SUBIRJAKOV: Accumulation of biogenic elements (nutrient salts) in mud water of freshwater basins.

A. L. BERNING: (1) Caspian relicts in the fauna of the Uzbek lakes. (2) Elements of subtropical fauna in rice fields of Uzbekistan.

T. K. ENIN: Intervarietal crossing in peas.

E. G. MININA: Phenotypical modification of sexual characters in higher plants under the influence of the conditions of nutrition and other external factors.

V. A. RYBIN: Colchicine-induced tetraploidy on flax.

SHEGHIUS LYOFF and G. M. TOUPKINA: Effect of sodium fluorine on the formation of citric and gluconic acids of the fungus *Aspergillus niger*.

A. G. EBERZIN: The Azov horizon of Kuban.

Vienna

Academy of Sciences, February 2.

K. GRAFF: Variation of the brightness of the satellites Titan and Iapetus of Saturn during 1922. The author's measurements during 1922 are in agreement with the hypothesis that the eastern and western hemispheres of Iapetus have an albedo in the ratio 1:6.3. The same hypothesis is in agreement with the observations of Wendell from 1896 to 1900.

February 9.

W. JENTSCHKE and F. PRANKL: Confirmation of the formation of heavy nuclei by the disintegration of uranium bombarded by neutrons. The energy of the particles emitted by uranium under neutron bombardment is found, by measurement of the ionization they produce, to be not less than 6×10^7 ev, while their range is only about 2 cm.; they are, therefore, almost certainly heavy nuclei having a high charge.

L. SCHMID and W. HOSSE: Amber (5). The constituents soluble in alcohol are examined chemically.

F. KERNER v. MARILAU: Temperature of springs on a slope of the Alps.

O. AMPFERER: Forms of mountain tectonics.

February 23.

L. SCHMID: Acids occurring in amber.

F. KOCCY: Determination of helium in rock-salt and sylvine. Rock-salt contains about 10^{-4} c.c. per gm. and sylvine about 10^{-4} c.c. per gm. of helium. The coloration of rock-salt is not connected systematically with the helium content; on the other hand, the magnitude of the latter indicates that the irradiation of the rock-salt must have been ample to produce the coloration.

G. ORTNER and G. PROTIWINSKY: Reaction of fast neutrons with neon nuclei. The neon was contained in an ionization chamber and the sum of the energies of the ^{10}O and ^4He nuclei into which it disintegrates on bombardment with neutrons was measured by the magnitude of the bursts of ionization produced. The results are in partial agreement with other work on the energy-levels of the ^{10}O nucleus when formed by other reactions.

W. CZULIUS and J. SCHINDLER: Method for separating the radioactive nuclei formed from uranium bombarded by neutrons. The nuclei arising from the explosion of the uranium nucleus are collected on a cylinder of celluloid wrapped around the uranium; by this means they are obtained free from any contamination by natural decay products of uranium.

K. W. F. KOHLRAUSCH and R. SABATHY: Studies of the Raman effect (99). Esters of mono- and polybasic carboxylic acids.

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

LECTURER IN MECHANICAL ENGINEERING in the Haddon Mining and Technical School—Director of Education, County Education Office, Derby (May 27).

LECTURER IN PRODUCTION ENGINEERING in the Birmingham Central Technical College—The Chief Education Officer (May 31).

LECTURER IN MECHANICAL ENGINEERING in the Rugby College of Technology and Arts—The Principal, 61 Clifton Road, Rugby (May 31).

LECTURER IN ENGINEERING in the County Technical College, Wednesbury—The Director of Education, County Education Office, Stafford (May 31).

TEACHER OF MATHEMATICS, PHYSICS AND CHEMISTRY in the Smethwick Technical College—The Chief Education Officer, Education Office, 215 High Street, Smethwick (May 31).

LECTURER IN PHYSICS AND LECTURER IN TELECOMMUNICATION in the Woolwich Polytechnic, London, S.E.18—The Secretary (May 31).

LECTURER IN PHYSICS in the School of Science, Khartoum—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (May 31).

LECTURER IN THE DEPARTMENT OF PHYSICS AND APPLIED PHYSICS in the Technical College, Cardiff—The Director of Education, City Hall, Cardiff (June 2).

LECTURER IN MECHANICAL ENGINEERING in King's College, Newcastle-upon-Tyne—The Registrar (June 3).

LECTURER IN MECHANICAL ENGINEERING in the Shrewsbury Technical College—The Clerk to the Governors, County Buildings, Shrewsbury (June 3).

ASSISTANT LECTURER IN PHARMACOLOGY in the University of Sheffield—The Registrar (June 5).

LECTURERS IN CIVIL ENGINEERING, MATHEMATICS AND PHYSICS in the Northampton Polytechnic, St. John Street, N.C.1—The Principal (June 5).

HEAD OF THE DEPARTMENT OF MECHANICAL ENGINEERING in the Northampton Polytechnic, St. John Street, N.C.1—The Principal (June 5).

CHIEF ENGINEER at the Royal Ordnance Factory, Irvine, Ayrshire—The Under-Secretary of State (O.S.), The War Office, London, S.W.1 (June 5. Quote 141 A).

TECHNICAL ASSISTANTS (grade II—engineering) in the Munitions Technical Planning Establishment—The Under-Secretary of State (O.S.), The War Office, London, S.W. (June 6).

LECTURER IN PHYSICS AND MATHEMATICS AND LECTURER IN MATHEMATICS AND ENGINEERING DRAWING in the Sir John Cass Technical Institute, Jewry Street, Aldgate, E.C.3—The Principal (June 7).

THREE ASSISTANTS (grade III—coal-mining explosives) at the Safety in Mines Research Board Station, Harpur Hill, Buxton—The Establishment Officer (June 10).

ASSISTANT LECTURER IN GEOGRAPHY in University College, Hull—The Registrar (June 10).

LECTURER IN CHEMISTRY AND LECTURER IN MECHANICAL ENGINEERING in the Midway Technical College (Senior Department), Gillingham, Kent—The District Education Officer, Fort Pitt House, New Road, Rochester (June 10).

ASSISTANTS (grade III—metalurgy) in the Admiralty Technical Pool—The Secretary of the Admiralty (O.E. Branch. Ref. O.E. 5834/39. June 10).

ASSISTANT LECTURER IN GEOGRAPHY in the University of Sheffield—The Registrar (June 12).

ASSISTANT INSTRUCTOR IN AGRICULTURE in Nottinghamshire—The Director of Education, Shire Hall, Nottingham (June 14).

RESEARCH ASSISTANT IN VETERINARY PARASITOLOGY in King's College, Newcastle-upon-Tyne—The Secretary, Duke of Northumberland Memorial Fund (June 10).

RESEARCH OFFICER at the Farnham House Laboratory—The Secretary, Agricultural Research Council, 6A Dean's Yard, Westminster, S.W.1 (June 15).

UNIVERSITY LECTURER AND TWO UNIVERSITY DEMONSTRATORS IN ANATOMY in the University of Cambridge—Dr. F. J. W. Broughton, Department of Physiology, Cambridge (June 17).

TWO SENIOR METEOROLOGICAL OFFICERS in Hire—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (June 20).

BIOCHEMIST at the Long Ashton Research Station—The Secretary, University of Bristol.

SENIOR LECTURER IN MECHANICAL ENGINEERING in the County Technical College, Mansfield—The Principal.

Whither the Gas Industry?

THE "independent non-party group" concerning itself with "Political and Economic Planning" under the suggestively abbreviated title P E P, has added to its publications a "Report on the Gas Industry in Great Britain"*. This report has been produced by the Gas Group of P E P and will be followed, we are told, by a more comprehensive P E P report on fuel policy in Great Britain, for the purposes of which the findings of the coal, gas and electricity groups will be re-examined. The work has been well done and presents a picture of the gas industry as it exists to-day of a kind that, for interesting and revealing detail, has no rival. The development of the industry through various phases is also indicated with clarity, which is very desirable for a full understanding of the present situation and future possibilities.

For a long period after Murdoch and Winsor came forward a century ago with their processes for making coal-gas and using its luminous flame for lighting, improving technique simply served that purpose, important but limited, and under conditions of virtual monopoly. The introduction of the Bunsen burner and the Welsbach mantle, and the development of electrical supply, then played their part in gradually broadening the basis of the gas industry as a purveyor of heat as well as light, and in creating its competitive aspect. This has brought about the condition of to-day, in which the gas industry is no longer one for the heating of coal in retorts for making lighting-gas, but one for the systematic treatment of coal by carbonization and gasification in such a manner as to secure thereby products of

maximum thermal, chemical and monetary values. The realization of these values has also demanded agencies for their proper utilization and, brought into the scope of the industry, schemes for the distribution of gas (the primary product) and the provision of efficient appliances for its combustion, as well as a new-found solicitude for the yields, quality and fate of coke, tar, and such chemical products as benzole, with its practically unlimited market as a liquid fuel.

With this increasing complication there has arisen the paramount necessity for scientific and efficient management, and for wise and far-seeing administration, if the industry is to deal adequately with the problems it has to face. There are such matters to settle as the degree of linking-up in production and management which may with advantage be effected, partly with a view to better supply and partly so as to bring first-class men into more effective use than is possible with the very numerous scattered works now in being and working independently. It may be pointed out that the small gas-works is not at all necessarily an uneconomical unit if well designed, constructed and run. Similarly, the best method of utilizing the spare gas from coke-oven plants well repays careful study. The possibilities in that direction have been demonstrated already in such districts as Sheffield, where the cheap supply obtainable by the gas company from neighbouring coke-oven plants has been largely responsible for the wide and extending use of coal-gas in metallurgical and other industrial furnaces.

Such utilization of coke-oven gas seems an obvious and desirable economy; but it raises questions which require careful consideration when one remembers, for example, that the coke oven

* Report on the Gas Industry in Great Britain: a Survey of the Current Trends and Problems of the Industry, with Proposals for its Future Development. Pp. vii + 213. (London: P E P, 1939.) 10s. 6d. net.

cannot with advantage continue to make unwanted metallurgical coke in order that the gas supply may be maintained. There is, again, the vexed question of tariffs in the gas industry, the allotment of charges on a rational basis to small and large consumers, where the gas industry has inherited statutory limitations imposed in the old days, which tell against it in competition with the newer electrical undertakings, the successful working of which is indeed largely conditioned by their greater freedom in this respect.

The discussion of these matters, even in brief, is not possible here; but they are gone into thoroughly in the P E P report, which is, in effect, a call to the industry to organize itself in a manner befitting its responsibilities and opportunities. The acknowledgment is rightly made of much that has already been done. It has to be admitted that contact has already been made with the universities (particularly Leeds), and some recruiting of young men, although not nearly enough, has been so effected with great advantage to the industry. Co-operation with the Board of Education has meant a considerable extension of such training as can be given by evening teaching in technical schools to the coming non-commissioned ranks, both for gas-manufacture and for supply.

Discussion and reports on technical and other matters are very full and frequent, partly because the various gas companies and municipal gas departments are not in direct competition with one another and can pool information more freely on that account. This is more particularly the province of the central Institution of Gas Engineers (and the branch associations), which in the past have rather tended to regard gas-engineering and gas-manufacture as the same thing, but are, slowly it is true, broadening their views and basis of membership so as to recognize the essential unity of the whole gas-engineering profession. The Society of British Gas Industries has served as a meeting-ground for the many industries concerned with the manufacture of gas plants and appliances for both domestic and industrial use; the British Commercial Gas Association has made itself responsible for publicity work, while the National Gas Council and, more recently, the Gas Federation, have effected co-ordination on matters of common interest, particularly on the financial, legal and political sides. Co-operative research work has been so far mainly the concern of the Institution of Gas Engineers through its Executive Research Committee and the Joint Research Committee of

the Institution and the University of Leeds pioneering effort which has met with much success over a long term of years. There has, however, also been instituted a considerable research organization in the larger gas companies (particularly in London) contracting firms and appliance manufacturers.

The report is appreciative up to a point of that the gas industry has done in organizing itself but calls for a greater effort, and particularly form of organization which shall include a central authority within the industry for the co-ordination of its many activities. It would also be at giving full opportunities for the personnel of the industry to exercise its talents for the mutual general good and for the recruiting and training of first-class men. It would seek to effect improvement, which is indeed needed in most of the industries of Great Britain, by not only securing an adequate supply of research workers but also ensuring that the results of their work are understood and utilized by the executive management. It would aid schemes of development and amalgamation which it approved, and would claim a right to prohibit what it believed to be ill-advised.

Such extensive powers would plainly only be given after full consideration of their implication and under such conditions as would not allow vested interests or bureaucratic self-confidence to impede travel along new paths. The long view is essential in such matters, and the future possibilities in the treatment of coal by the gas and cognate industries were perhaps never so alluring as at the present time. The use of high temperatures and pressures in combination for the gasification of coal is bringing into prominence new reactions for the controlled transformation of 'fixed carbon' into methane and other hydrocarbons, and the various technical potentialities of the gasification process, chemical and thermal, are awaiting more complete investigation. Moreover, perhaps the most striking feature of recent progress in the technical world has been the new chemical engineering which is emerging from a vastly increased knowledge of materials of construction, particularly in the metallurgical field and this is going to facilitate enormously not only the laboratory investigation of determining conditions but also the translation of the results into large-scale processes. The gas industry has splendid opportunities, but only a well-founded and well-manned vessel can hope to sail these uncharted seas.

What We Know About Flow

Second Report on Viscosity and Plasticity
 Prepared by the Committee for the Study of
 Viscosity of the Academy of Sciences at Amster-
 dam. (Verhandelingen der Koninklijke Neder-
 landsche Akademie van Wetenschappen, Afdeling
 Natuurkunde, Eerste Sectie, Deel 16, No. 4.) Pp.
 i+287+2 plates. (Amsterdam: N. V. Noord-
 Nederlandsche Uitgeversmaatschappij, 1938.) n.p.

THE subject of viscosity and plasticity is one
 of peculiar difficulty. The two states of
 matter of which we have a moderately satisfactory
 knowledge are the gaseous and the perfect solid.
 The flow of a gas is easily understood, but it is
 remarkably clear that the mechanism of gaseous
 flow has little bearing on that of liquid viscosity,
 since none of the basic assumptions is valid for
 the liquid state. The perfect crystal is incapable
 of plastic deformation, at any rate under forces
 anything like as small as those which produce
 formation in real solids. We know extremely
 little about the liquid state, and there is practically
 no direct evidence for the internal flaws which we
 are forced to postulate in order to account for the
 fitness of, in particular, metals, and even the
 conception of these flaws which the theories offer
 lacks definiteness.

The problem of flow is, however, fundamental
 to any understanding of the structure of real
 solids and liquids, and is, further, of the greatest
 importance for the industrialist who is concerned
 with metals, glasses, emulsions such as asphalt or
 clay, or plastic polymers, to mention only a few
 materials. The literature is so extensive, and the
 work has been carried out from so many different
 points of view, that one of the great needs of
 workers in this field is a reliable survey, of the
 present position, and our Dutch colleagues have
 undertaken the task of supplying this need. The
 first volume of the "Report on Viscosity and
 Plasticity" prepared by a Committee of the
 Academy of Sciences at Amsterdam appeared in
 1935, and received notice in NATURE (Nov. 2,
 1935, p. 697). The second volume is now before
 us. In the interim, Dr. Houwink, who contributes
 a chapter on "The Yield Value" to this latter
 volume, has written a valuable book on "Elasticity
 and Plasticity" (see NATURE, May 7, 1938, p. 810)
 which in many ways supplements the "Reports".
 The viscosity of simple liquids is the main
 subject of the first two chapters of this second
 Report, due respectively to Dr. J. M. Burgers,
 who has played so prominent a part in the work

of the Committee, of which he is the secretary,
 and to Prof. F. M. Jaeger. Certain generalities
 are first discussed, such as the statistical view of
 liquids with which the names of Prins and Bernal
 are connected, and the Prandtl model; interesting
 as these are, it cannot be said that they have yet
 come into any very close contact with experiment.
 A survey is then given of various theories of liquid
 viscosity that have been put forward, starting
 with that of van der Waals junior. Some of these
 are based on the assumption that the viscosity is
 primarily a function of the specific volume, a view
 which offers grave difficulties, since Bridgman's
 work on viscosity at high pressures has shown
 clearly that widely different viscosities can attach
 to the same volume; for example, for mercury,
 with which molecular distortions or associations
 cannot be invoked, the viscosity at equal volume
 is 0.0140 at 75° as against 0.0152 at 30°. The
 data on carbon dioxide, summarized in Fig. 11 of
 this "Report", are equally unambiguous on this
 point. Michels and Gibson found that, with high-
 pressure nitrogen at constant volume, the viscosity
 always increased with temperature. The obstacles
 in the way of the assumption might have been
 more strongly emphasized.

Generally speaking, the treatment of the
 various points of view is clear and critical, and
 the present writer has been gratified to find that
 difficulties which he has himself experienced have
 been felt by the author, with regard, for example,
 to the interesting calculations applied by Herzog
 and Kudar, where the exposition of the basic
 principles "is not such as to give a clear picture of
 what is actually intended", and, again, with
 regard to the obscurities of Lederer's theory. In
 general, there is a tendency on the part of many
 theorists to lose sight of the experimental facts,
 and, especially, of the need of showing how the
 absolute magnitude of the viscosity can be pre-
 dicted. The theory of Eyring and Ewell is not
 reviewed at all, which is to be regretted, since a
 critical analysis of its assumptions and achieve-
 ments would have been interesting. The account
 includes a welcome review of the extraordinary
 properties of the so-called 'liquid crystals' or
 liquids possessing mesomorphic states, and also
 deals with mixtures and solutions. Considering
 how little is known of simple liquids, it is not
 surprising that this part of the subject is not in a
 very satisfactory state.

A very valuable section, by Dr. J. M. Burgers,
 is devoted to the influence of suspended particles

on the viscosity of a liquid, a subject which is of topical interest in view of the importance attached to the experiments of Staudinger and his school. Here, as in so many fields, the pioneer paper is due to Einstein, who worked out the influence of spherical particles, and a further stage is represented by G. B. Jeffery's work on the behaviour of ellipsoidal particles in a viscous liquid. The problem is a particularly complicated one, in view of the conflict between the Brownian motion and the hydrodynamic forces in orienting elongated particles, a point on which experimental evidence is furnished by the double refraction of the flowing liquid.

Further difficulties are furnished by the possible deformation of long molecules, such as those of the polystyrenes, and the influence of the particles on one another. Dr. J. M. Burgers shows his usual skill in exposing, in a clear and critical manner, the essence of the large body of mathematical work which has been done on the problem, and in correlating it with experiment. His account is not overburdened with detail, but at the same time it is far from being a mere list of results. It supplies a clear and balanced picture, such as only one thoroughly conversant with the difficulties could give, of the present state of research on the subject. The general impression that it leaves is that, while much has been done, the conception of uniform, isolated rigid ellipsoids of revolution, immersed in a viscous fluid, is not altogether adequate to describe the behaviour of, for example, polystyrenes in solution.

The remainder of the "Report" is devoted to the discussion of 'yield value', to which reference has already been made, and to chapters on plastometers by Dr. C. J. van Nieuwenburg and on

technical viscometers by Dr. R. N. J. Saal. The chapter on yield value contains an extension of Dr. J. M. Burgers of the treatment of the plastic flow of metal single crystals which he put forward in the first "Report". This development of the Becker-Orowan theory is extremely interesting and leads to expressions giving the dependence of the yield value on temperature and rate of deformation; unfortunately, there is the usual difficulty in throwing them into a form capable of critical experimental confirmation and in finding relevant experimental data. The attempt is, however, stimulating and suggestive. The introductory remarks of Dr. van Nieuwenburg should be read by all who attempt to design plastometers, since they present clearly the weaknesses that attend most of the attempts to measure plasticity, a quantity which we cannot yet satisfactorily define. This lack of certainty as to what is really being measured finds its expression in the somewhat capricious design of the instruments.

A very valuable feature of this "Report" is its critical, but not carping, point of view. The authors have maintained their strong individuality but they have not abused their position as reporters to push unduly any particular point of view. They have clearly pointed out the great gaps in our knowledge, but have not been too severe on those who have attempted to fill them, even if their efforts have been inadequate. The general impression left by the "Report" is how little we know for certain about the fundamental features of flow phenomena. One of the best ways of emphasizing our needs, and of stimulating workers to supply them, is a report like this.

E. N. DA C. A.

Origins of Hindu Customs

Hindu Customs and their Origins

By Stanley Rice. Pp. 220. (London: George Allen and Unwin, Ltd., 1937.) 7s. 6d. net.

MR. STANLEY RICE, both as a member of the Indian Civil Service stationed in Madras, and after his retirement, as a member of the State Council of Baroda, has been in intimate relation with the problems of caste, which is the principal, though not the only, topic of this volume. Nowhere is the caste system so rigid as in Madras; while in Baroda he was an eye-witness of the difficulties which confronted the attempts to alleviate its more seriously obstructive characteristics, to which the Maharaja refers here in his

foreword. It is not surprising, therefore, that although the author's interest in caste in this volume is that of the anthropologist and the student of origins, it is inevitable that he should from time to time take a side glance at its place in the present and future social and political situation in India.

Of the various theories which have been put forward from time to time to account for the existence of caste in India, Mr. Rice counts none as acceptable. The view that it arose out of the Aryan conquest involves, he shows, a number of inconsistencies and leaves much unexplained—no least, perhaps, that the caste system is more rigid in the south than in the north, where it is natur-

expect that an Aryan system would manifest itself most strongly. At the same time, he holds, is no less difficult to accept occupation as the root of caste. This cause is not adequate to the effect, nor is the effect such as would naturally flow from such a cause.

The theory which Mr. Rice himself advocates is not entirely new; but it has not previously been worked out in detail. Shortly, it is that the system indigenous to India, and was of aboriginal origin. It grew out of aboriginal elements simulated by the conquering Dravidians, and by whom it was transmitted to the Aryans at some time considerably later than the Aryan invasion. The central features of caste, he points out, are the regulation of marriage and the fear of pollution by taking food or drink from, or by consorting with, a member of another forbidden or inferior caste. These two elements he traces to primitive roots connected with on one hand totemism, and on the other with the conception of uncleanness or pollution. Such an aboriginal origin alone, he maintains, would explain the existence of outcasts or untouchables. As Hinduized aboriginals, and the theory of caste as originating from an Aryan conquest, they would automatically enter the ranks of the inferior castes and would not require a special category.

The solution which Mr. Rice offers is perhaps the best that so far has been suggested. At the same time it is not free from objection. The argument for totemism is by no means so strong as is claimed, and the association of animal forms with members of the Hindu pantheon is susceptible

of explanation as a mode of Hindu thought which is not necessarily totemic. Further, is it true to say that in the matter of caste India is unique? Is it possible to set aside, as does Mr. Rice, the contention that it was characteristic of the group of Nordic peoples, of which the Arya were members? The obvious discrimination between caste and class distinction, to which he refers, rests on a comparison with modern conditions; and while they are perhaps stronger than he admits, historically they grew out of something far more rigid. Among the early Teutonic peoples breach of the marriage regulation was sometimes punishable by death. It would seem, therefore, as if the Aryan conquerors may have contributed more than a little to the system as a regulation of marriage, even though reference to it may be much later than their first appearance in India.

The influence of aboriginal culture in religious belief is traced further in discussion of the origin of reverence for the cow; while in the essay on the Brahman in Indian society, he glances incidentally, but with illuminating understanding, at the character, influence, and aims of this class in relation to the political situation.

Chapters dealing with Mahratta customs and the esoteric meaning of Hinduism complete a series of studies which is not only of interest to the anthropologist and student of Hindu culture, but also brings home to the lay reader the inner meaning of the day-to-day problems with which the administration and the statesman have been, and still are, confronted in dealing with the assemblage of races and beliefs which make up "India".

Farmland Grass

Grassland Management for the Practical Farmer by W. R. Peel. Pp. xv + 191 + 8 plates. (London: Macmillan and Co., Ltd., 1938.) 7s. 6d. net.

THIS book deals with the subject and with the results of scientific investigations in a very practical way from start to finish, and it contains nothing which a farmer can fail to understand.

The author introduces his subject well by describing the general factors which determine the productivity of grasses, such as leaf to stem ratio and palatability. The differences in habit between indigenous and commercial strains are pointed out and the importance of the indigenous strains is stressed.

The characteristic habits of those grasses and clovers most commonly met with are well described,

but, very wisely in a practical book on management, no morphology has been introduced. The factors to which certain grasses owe their importance agriculturally, such as palatability, early growth and winter greenness, are clearly set out, for the encouragement of desirable species to the exclusion of the less productive species is the underlying principle of good management.

The renown of the Romney Marsh pastures and the Leicestershire fattening pastures is familiar to all farmers; but few can have any clear idea how these famous pastures became established or why their productivity has persisted. The author shows how these and other well-known types of pastures, both good and bad, have been produced by the type of farming practised, and by management. He also shows how alterations in the type of

pasture are speedily brought about by a change from the traditional method of farming. The lesson to be learnt is that all pasture consists of associations of different species of grasses and clovers, and that any particular association is the result of a particular system of farming and management.

There follows, quite logically, a description of the various methods by which grassland can be improved, from the ploughing up and reseeded of the poorer types, to the harrowing and manuring of the types which have deteriorated least. Full practical details of the various methods of improvement are given, and the management of young grass in its early years receives the attention it merits. The various methods of conserving the extra grass at flush periods are described, and some valuable notes on silage-making and on the nutritive values of the conserved products are given in the appendixes.

Once the grassland is back to good productivity, careful management is required to maintain this productivity. The principles of good management

are clearly set out, the need for controlled grazing and the periodic rest, the provision of the ear bite and winter keep, and the manuring for pasture and hay are all fully described, as are the many other practical details of grassland management.

The last chapter deals effectively with the use of temporary pastures, and gives full details of sowing land down to grass, and of seeds mixture. However, there is no bewildering list of seed mixtures to confuse the farmer; but a few typical mixtures for various purposes are given. There are also useful notes on the most suitable arable crops to grow on freshly ploughed grass.

Farmers and others who have read this book will cease to look upon grass as such, but will see it as an association of many different species and strains of plants which require careful management to ensure full productivity; but which if left alone or not managed to maintain an association of the most productive species, will rapidly degenerate into an unproductive piece of land inhabited by a few species of grasses which have little or no feeding value.

The Life-Work of a Palaeontologist

Published Papers and Addresses of John Campbell Merriam

Vol. 1. Pp. viii + 666. Vol. 2. Pp. vi + 667-1288. Vol. 3. Pp. viii + 1289-1944. Vol. 4. Pp. viii + 1945-2672. (Publication No. 500.) (Washington, D.C.: Carnegie Institution, 1938.)

BEFORE Dr. John C. Merriam became president of the Carnegie Institution, Washington, in 1920, he was for many years professor of paleontology and historical geology in the University of California at Berkeley. During that period he devoted special attention to the fossil vertebrates occurring in the coastal region of the western United States, and made many notable discoveries, which he described chiefly in the publications of the University and of the California Academy of Sciences. His scattered papers have now been collected and reprinted, with some addresses and more popular writings, in four handsome volumes, which are issued by the Carnegie Institution. They are admirably edited, with references to the source and original pagination of each paper; and when they are reduced from the quarto form many of the plates are subdivided to maintain the size of the figures. The reprints are arranged under several subject headings, and a bibliographical list in chronological order is appended to the fourth volume just before the index.

Dr. Merriam studied at Munich under Prof. K. A. von Zittel, and the first reprinted paper in his inaugural dissertation on some Pythonomorph reptiles from the Chalk of Kansas published in 1894. Then follow several papers on remains of new fossil reptiles which he collected from the Triassic formations of California and Nevada. His important discovery of the marine Rhynchocephalians which he named *Thalattosauria* is described and discussed in a memoir which was published in 1905. His valuable contributions to our knowledge of the Triassic *Ichthyosauria* form the subject of a still larger memoir which appeared in 1908.

Most of Dr. Merriam's papers are on fossil mammals, which were collected with special care to determine their relative ages. He began by examining the John Day region of Oregon, where he found mammalian remains of all periods from the Oligocene onwards. He then studied other western coast areas, and finally co-operated with the Los Angeles Museum in collecting and describing the skeletons of Pleistocene mammals found embedded in the asphalt lake of Rancho La Brea, which now forms a public park in the outskirts of Los Angeles. Rancho La Brea has yielded the most remarkable series of Pleistocene carnivores and birds of prey hitherto discovered. They were attracted to the spot by easy prey—peccaries,

reese, camels, elephants, ground sloths, and other animals which were accidentally trapped in the phalt. Unfortunately, the detailed description of the collection is little more than begun.

Other papers discuss the discoveries of fossil man in association with extinct mammals in North America, and Dr. Merriam summarizes the results in an address which was delivered to the International Geological Congress at Washington in 1933. There seems to be no doubt that typically modern man lived in North America with some of the large mammals which became extinct before historic times.

The technical papers are followed by reprints of some popular articles on the same subjects; and the final volume is devoted chiefly to miscellaneous addresses and to papers on the educational use of the national parks. Dr. Merriam has done great service in providing guides and exhibits to help the public to appreciate the scientific interest of the vast open spaces which the United States Government has preserved for their enjoyment. His activities have indeed been numerous and varied, and the volumes before us form an imposing record of the life-work of a leading man of science.

A. S. W.

Popular Astronomy

1) Everyman's Astronomy

by Mary Proctor. Pp. viii+246+23 plates. London: The Scientific Book Club, 1939.) 2s. 6d.

2) Starcraft

by William H. Barton, Jr., and Joseph Maron Joseph. Pp. vii+228. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 10s. 6d.

1) THE title of Miss Proctor's book is rather misleading, as it suggests a general elementary treatise. Actually, it is a collection of seventeen disconnected essays on astronomical subjects, written in a popular style. In its general scope it is somewhat reminiscent of the many similar volumes of essays published, sixty or seventy years ago, by the author's distinguished father, the late R. A. Proctor.

There is some internal evidence to suggest that the various chapters were written at different times. This has resulted in some repetitions and contradictions, and the attempt to bring the details up to date has not always been very successful. Perhaps the most interesting part of the book is to be found in the last seven essays, all of which deal with the subject of meteoric astronomy. Here the author has collected a considerable number of facts and numerical data relating to the more famous falls of meteorites, and these notes may be found useful for reference by other popular writers and lecturers.

The chief objection to the book is that it has throughout such a strong nineteenth-century flavour. The author appears only partly to have digested the results of modern research, and often quotes the necessarily tentative ideas of out-of-date authorities on matters which have long since ceased to be subjects for mere speculation.

There is also a tendency to dwell at great length on trivial points, while more important matters

are either passed over or put in a way that can only mislead or mystify the reader. A few misprints occur in the book, but they are mostly too obviously such to be of serious consequence. There are some fine illustrations, though one is wrongly described in its legend.

(2) Messrs. Barton and Joseph have written their book for American schoolchildren. It is, in a sense, a field-book of elementary practical astronomy. The principal constellations are taken separately. A diagram of each is given, with instructions for finding it at various seasons of the year; and some short notes on the chief objects contained in it are added. There are also photographs of some of these objects, obtained with the large American telescopes.

Simple instructions are given for the making of a sundial and other astronomical instruments, including a reflecting telescope. With regard to the latter, we are inclined to think that any young person capable of following successfully the very abbreviated directions supplied would scarcely be satisfied with so scrappy a treatment of the subject.

There are some inaccuracies of statement in the book; for example, it is alleged that the companion of Polaris is visible in a field-glass, and that Saturn's rings are invisible to the naked eye because of their "faintness". The derivation of geocentric is given as "*geus*, the earth, and *centric*, the centre", while heliocentric is said to be derived from "*helio*, the sun, and *centric*, to circle about"!

The tone of the book is rather condescending, and the authors' attempts to be colloquial are often quite pathetic. Of course, American children may prefer "squinting" through a telescope to merely "looking" through it, like other people. All we can say is that those we have met have not seemed "that dumb".

W. H. STEVENSON.

An Approach to a Philosophy of Education
By Dr. Theodore H. Eaton. Pp. ix+278. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 12s. 6d. net.

THIS book is in two parts. Part 1 (longer and more important) attempts the establishment of systems of values from the points of view of the biologist, the psychologist, and the student of social sciences. Part 2 deals with the application of those systems to education.

The book is a good example of that essentially American stream of pragmatic thought of which Dewey and Thorndike are representatives. Like them, the author eschews metaphysics and attempts to found a system of values out of the stuff of common experience; and like them he draws inspiration from the ever-changing phenomena of American society in the twentieth century.

Dr. Eaton finds the highest biological values in parenthood and self-preservation; the highest psychological values in the achievement of integrated personality; and the highest social values in a critical attitude of mind based on standards of general human welfare. Difficulties at some points seem too easily brushed aside. Summary treatment, for example, is accorded to such questions as the meaning of 'biologically fit', and the nature of those 'satisfactions' which are the basis of personality. Freedom is scarcely discussed at all, and too little is said in explanation of the power which ideals involving self-sacrifice have held. But the title of the book does not allow us to demand full treatment of all these.

The Málers of the Rajmahal Hills
By Sasanka Sekher Sarkar. Pp. xiv+135+11 plates. (Calcutta: The Book Co., Ltd., 1938.) 4 rupees; 6s.

THE author of this monograph, a recruit to anthropological research, to whom Sarat Chandra Roy extends a cordial welcome in a commendatory preface, has now spent some years in the investigation of the Málers of the Rajmahal Hills, and has already contributed a number of papers on specific points to scientific literature. In this work, which is of a more generally descriptive character, he is especially interested in the problem of their relation to the Oraons. He is unable to accept the view that they are a branch of the Oraons, a relic from the time of the migration of that people, presumably as a result of Moalem pressure. In support of his contention he points, *inter alia*, to the absence of totemism and exogamic clans among the Málers; while he stresses the fact that as a hill people, they never have occupied the plains, nor could they be persuaded by the Government to do so.

Only two accounts of this interesting people have appeared in print previously—some thirty years ago. A point of interest in the present account is the change which has taken, and is still taking place in their culture. Dormitories, for example, for bachelors and spinsters are now decaying institutions, while the ancient custom of interment, under Hindu influence, has given place to cremation.

A Textbook of Inorganic Chemistry for Colleges
By Prof. James F. Norris and Prof. Ralph C. Young. (International Chemical Series.) Second edition. Pp. x+803. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 21s.

IN the preparation of the second edition of this book Prof. Norris has been assisted by a co-author whose interests lie in the field of inorganic chemistry. A special feature of the book is the careful development of the fundamental ideas of atomic structure, isotopes, electronic valency, radioactivity, modern dissociation theory, etc., in such a way that they fit naturally into the course, and so much is presented at each step as can readily be understood by the student. The modern theory of acids and bases is used.

The pedagogic aspect of the subject has been kept constantly in mind, and for this reason the book will be of special interest to teachers. A useful feature is the numbered bibliography at the end, providing a wide range of suitable material from which both students and teachers can extend their knowledge of particular topics in which they are specially interested.

L'Antenne Rayonnante
Par Pierre Baudoux. (Institut Belge de Recherches Radioscientifiques, vol. 7.) Pp. 255. (Paris: Gauthier-Villars et Cie., 1938.) 40 francs.

THIS publication is a monograph describing a mathematical analysis of the current distribution in antennae of various forms and of the resulting radiation therefrom. The classical theory of the problem is outlined, and the author then obtains solutions and an analysis of the appropriate coefficients to a closer degree of approximation than hitherto. After considering the vertical antenna of uniform cross-section, he deals with the spindle (or cigar-shape) and pyramidal forms of antennae that are now in such common use at radio transmitting stations. The dipole antenna is also dealt with. The final chapter describes experiments carried out with model antennae of various shapes of about 1.5 metres in height using oscillations of wave-length 2-5 metres. The current distribution in these models was measured and the resulting radiation deduced for comparison with the theoretical analysis. R. L. S. R.

Fortschritte der Biochemie
Teil 3 (1931-1938). Von Prof. Dr. Felix Haurowitz. (Wissenschaftliche Forschungsberichte: Naturwissenschaftliche Reihe, herausgegeben von Dr. Raphael Ed. Liesegang, Band 49.) Pp. xi+167. (Dresden und Leipzig: Theodor Steinkopff, 1938.) 9 gold marks.

THIS is the third volume of a series in which Prof. Haurowitz has presented reviews of the progress of biochemical research over a period of years. The present work covers the period 1931 to the beginning of 1938. It is comprehensive, concise and accurate, but it is unlikely to appeal to British or American men of science, who are accustomed to rely on reviews which appear annually and usually treat subjects in greater detail. J. O. D.

The Last Thousand Feet on Everest

Physiological Aspects

By Prof. Yandell Henderson, Yale University

A MOUNTAINEER at rest on the North Col of Mount Everest (bar. 335 mm.) probably consumes nearly the same amount of oxygen as at sea-level. This amount, 250–350 c.c. S.T.P. per minute, is required for the maintenance metabolism of muscle tonus, the resting heat production and the work of breathing and the heart beat. If a mountaineer ever rests on the summit of Everest (bar. 240 mm.), even there he will probably consume nearly the same amount. On any less, anywhere, he would die.

When he climbs, a man consumes far more oxygen; but at every altitude the amount is limited by the barometer. He cannot do more work climbing, nor climb faster, than the oxygen that he can absorb from the air will permit. No amount of muscular strength can escape this limitation. The advantage of the athlete over the ordinary man, and the superiority of the acclimatized mountaineer over the unacclimatized, consist less in their strength than in their ability to obtain larger amounts of oxygen.

During steady vigorous exertion for an hour or more at sea-level, or up to 5,000 feet, a man may absorb and consume ten or twelve times the resting amount of oxygen, with a corresponding expenditure of energy. For shorter periods the rate of consumption may be much more, but not so long. As he ascends and the air grows thinner, the amount of oxygen that he can obtain, even by the greatest possible volume of breathing, decreases; and his decreased capacity for work results in a directly proportional decrease in the number of feet, or metres, that he can climb upward in each hour. Up to the greatest altitude and lowest barometer for which a man's oxygen consumption and capacity for work in climbing have been reported—by Christensen in the Andes—the ratios of oxygen to work are nearly uniform with those at sea level.

From measurements on Marathon runners by Benedict and Cathcart, and others, we know that a vigorous young man can consume 3,300 cubic centimetres of oxygen per minute for two hours or more. Such men do an amount of work equivalent to climbing 3,000 feet, or even a thousand metres, an hour; and men have done this, although the ordinary rate of climbing in the Alps and Rockies is only 1,200–1,800 feet an hour. As an extreme case Dr. D. B. Dill informs me of

a man of 80 kilos who, on a treadmill in the Harvard Fatigue Laboratory, 'climbed' the equivalent of 1,400–1,500 metres in an hour, linear distance 5,000 metres, with an oxygen consumption of 4.0–4.4 litres per minute. Last summer in a contest on Mount Washington (altitude 6,288 feet), the best of sixteen contestants starting at Pinkham Notch, 4,800 feet below the summit, ran up the eight miles of motor road to the top in 1 hour 17 minutes, and the slowest in a little more than 2 hours (Foster).

At 10,000 feet (bar. 525 mm.) the measurements of Dill and Edwards, Margaria, Schneider and others, indicate that, on an oxygen consumption of 2,800 c.c. per minute, an amount of work may be performed equivalent to that of a man weighing 150 lb. and climbing about 2,500 feet an hour. At 14,000 feet on Pike's Peak, Schneider and I repeatedly ascended 1,000 feet in half an hour, and we were both well past the age of greatest vigour. The manager of the Summit House, whose weight was 156 lb., climbed from Manitou (altitude 6,600 feet) to the summit up the cog railroad, a rise of 7,500 feet in 8.9 miles, in two hours and thirty-one minutes. He probably climbed more rapidly at first than toward the end of the ascent. But very few men could make such a climb, at such a rate, at such an altitude. The oxygen consumption found by Christensen in the Andes at 17,500 feet (5,340 metres) was 1,800 c.c. per minute, and the work done on a bicycle ergometer was equivalent to that of a man of 70 kilos (154 lb.) climbing 600 metres an hour. The periods of exertion were less than an hour. But the natives, as Dr. Dill informs me, commonly climb from their homes at 17,500 feet up to the sulphur mine where they work at 18,800 feet in about an hour.

For greater altitudes there are no measurements of oxygen consumption on acclimatized, or partially acclimatized men. But the rates at which men can climb at the great altitudes of the upper slopes of Mount Everest and other peaks in the Himalaya are significant. There the rates of climbing decrease progressively as the altitude increases; and we may fairly infer that the amounts of oxygen that the men can obtain from the air decrease correspondingly. As they go higher and higher their rate of ascent becomes slower and slower, until at 27,000 feet Somervell

had to "take 8 or 10 respirations for each step, and stop to rest for a minute or two every 20 or 30 yards. At 28,000 feet Norton, in an hour's climb, ascended only about 80 feet."

If from such data we may extrapolate (as in the figure) to obtain estimates of the rate at which a mountaineer might climb the last few hundred of the last thousand feet of Everest and the corresponding oxygen consumption, we see that the rate of ascent must approach zero: in other words, a minimum of progress in an unlimited amount of time. The corresponding oxygen consumption would approximate that of bodily rest as a limit. Men have come near to the summit of Everest in distance; but they have still been far from it in terms of time. As I have recently

APPROXIMATE AMOUNT OF OXYGEN THAT A MAN CAN OBTAIN AND UTILIZE DURING STEADY CLIMBING AT ALL ALTITUDES BETWEEN SEA-LEVEL AND THE SUMMIT OF MOUNT EVEREST, AND THE MAXIMUM RATES IN FEET PER HOUR AT WHICH HE CAN ASCEND.

pointed out elsewhere, inhalation of oxygen from an 'open circuit' inhalator, although helpful during rest, is of no value during climbing; for all the oxygen is blown away by the tremendous volume of breathing. Only by the use of a 'closed circuit' respirator, such as that used in mine rescue operations, can men obtain sufficient oxygen and climb sufficiently rapidly to ascend and descend the last one or two thousand feet of Everest within the period of a day.

THE HEART AT GREAT ALTITUDES

The mountaineer is generally inclined to consider his heart as the organ that limits his exertions. But the above considerations tend to indicate that such is not the case. During the Oxford-Yale expedition, which spent five weeks on the summit of Pike's Peak, altitude 14,100 feet, during the

summer of 1911, we found both in ourselves and others that during mountain sickness the stroke volumes of the heart were diminished; arterial pressure was lowered; and the pulse rate was increased even during bodily rest, and greatly accelerated under even moderate exertion. But as acclimatization developed, arterial pressure, the stroke volume of the heart, and the pulse rate returned to the same values as at the foot of the Peak, essentially as Christensen and Forbes have found during the recent expedition to the Andes.

For comparison of the stroke volume on Pike Peak and in Colorado Springs (altitude 6,000 feet) we used a 'recoil board'—a light wooden plank supported on a number of soft rubber stoppers. A man lying upon it illustrates the Newtonian

principle that "every action has an equal and opposite reaction" for with each heart beat, as blood is propelled alternately headward and feetward, the man's body and the plank recoil in the opposite direction. This movement of about 0.1 mm. was magnified sixty times by a system of levers and recorded on a smoked drum. As the amplitudes of these curves and the arterial pressures were the same in acclimatized men at 14,100 feet as at 6,000 feet, the strokes of the heart must also have been of the same volume and force.

From these observations it appears that readjustment of the circulation plays no considerable part in acclimatization. During intense muscular exertion at sea-level, the volume of blood that

the heart can pump is probably one of the factors that limit exertion. At great altitudes the limiting factor appears to be chiefly the volume of air that a man can respire, or rather the amount of oxygen that he can absorb from it. As he obtains less oxygen his muscles can do less work; and as his muscles contract less often the volume of the venous return to the heart, which limits the volume that the heart has to pump, is probably much less than during vigorous exertion at sea-level.

Above altitudes of 20,000 feet, according to Argyll Campbell, acclimatization becomes increasingly incomplete. As he has shown also, after a prolonged stay under a low pressure of oxygen, the heart suffers along with other organs and functions. But any ill-effects after mountaineering at great altitudes are assignable rather to prolonged slight asphyxia than to any strain from overwork.

READJUSTMENTS IN ACCLIMATIZATION

Acclimatization to any altitude above or below sea-level, or to sea-level, is wholly a response to the pressure of oxygen, and not to that of the barometer otherwise. It is an adjustment which enables the acclimatized man to obtain sufficient oxygen to live normally, or nearly normally, at altitudes at which, if wholly unacclimatized, he would become unconscious or even die. The readjustment is not in the heart or lungs, but consists chiefly in alterations in the composition of the blood. The red corpuscles are increased and—even more helpful—the bicarbonates (BHCO_3) of the plasma are decreased. Until the bicarbonates are decreased the mountaineer cannot breathe any very much larger volume of air without disturbing the relation of the carbonic acid (H_2CO_3) and bicarbonates, and thus the hydrogen ion concentration, of his blood.

The decrease of bicarbonates is not effected through any process of an acidotic type. It develops through an entirely different process in three stages: (1) The sensitivity or excitability of the respiratory centre (E_H) varies inversely with the pressure of oxygen (O_2), or, more precisely, with the ratio of the pressure of oxygen to the bicarbonates of the blood, that is, $E_H \propto (\text{BHCO}_3) : (\text{O}_2)$; and the initial increase in the volume of respiration is due to this increase of sensitivity. (2) The increase of pulmonary ventilation decreases the partial pressure of carbon dioxide in the air of the lungs, and the amount of carbonic acid in the arterial blood. The relation $(\text{H}_2\text{CO}_3) : (\text{BHCO}_3)$ and the pH of the blood are thereby temporarily disturbed; and (3) this disturbance in turn induces a compensatory decrease of bicarbonates which restores both the relations $(\text{O}_2) : (\text{BHCO}_3)$ and $(\text{H}_2\text{CO}_3) : (\text{BHCO}_3)$ to normal levels. On descent to a lower altitude these processes are reversed.

The decrease of the bicarbonates in the blood affords two advantages to the acclimatized man. It causes him to breathe a larger volume of air

than at sea-level on the same production of carbon dioxide, and thereby raises the pressure of oxygen in his lungs and arterial blood. Less well recognized, but equally important, is the effect of the lowered bicarbonates upon the interchange of gases as the blood passes through the tissues. As the amount of carbon dioxide produced in the tissues is the same under the same exertion at all altitudes, any decrease of the bicarbonates allows the carbon dioxide to exert a much greater effect upon the ratio $(\text{H}_2\text{CO}_3) : (\text{BHCO}_3)$ and the hydrogen ion concentration than it would if the bicarbonates were at sea-level value. This increase of hydrogen ions promotes the unloading of oxygen from haemoglobin.

Yet acclimatization to a great altitude also imposes a handicap. It has been supposed that men or horses—particularly in the Andes—that have come from a higher to a lower level shortly before a race should have an advantage. Exactly the opposite is, however, the case; for Edwards has recently reported that a man acclimatized to an altitude can there do less work on a bicycle ergometer than at sea-level, even if the oxygen in the air that he breathes is artificially increased to the sea-level amount (150 mm. partial pressure). The probable reason is that, owing to the lowering of the bicarbonates in the blood, the man must breathe a correspondingly increased volume of air in order to exhale the increased amount of carbon dioxide.

Shape of Tobacco Mosaic Virus Particles in Solution

By Dr. J. R. Robinson

THE ease with which solutions of the tobacco mosaic virus protein show a strong double refraction of flow suggests that the particles present are extremely elongated. It was reported by Bawden and Pirie¹, who described the general properties of the virus. Bernal and Fankuchen² studied the virus by means of X-rays, and pointed

out that the long tapering structures which have been called crystals are more strictly paracrystals. There is regularity of arrangement in the cross-section, but not in the direction of the long axis. The paracrystals are believed to consist of long, rigid rods, packed closely side by side, but without order, in the direction of their length. These rods

are supposed to exist free in solutions of the virus. By their orientation they give rise to the double refraction of flow.

It has now been shown clearly^{3,4} that the double refraction of flow does in fact arise from the orientation of rigid rods, and not from the deformation of flexible particles. Kuhn⁵ gives a method of determining, from measurements of double refraction of flow and of the angle of isocline, the amount of double refraction to be ascribed to any individual particle with its immediate fluid environment. Calculations such as Kuhn describes have been applied to the results of measurements upon virus solutions supplied by Dr. N. W. Pirie. They show that a tenfold increase in the double refraction of flow with increasing rate of shear is not accompanied by a corresponding increase in the birefringence of the individual particles.

From the fact that spontaneous birefringence first appears in the solutions at a concentration of 1.6 per cent, Bawden and Pirie suggest, on the assumption that this represents Staudinger's limiting concentration, an axial ratio of the order of 90. But they point out that the particles are highly charged, so that the interpretation of the critical concentration is complicated. Moreover, the observed critical concentration almost certainly does not correspond to Staudinger's limiting concentration. For this is calculated from an effective volume which requires that the particles be free to rotate in the solution about central axes perpendicular to their lengths, so that each may trace out a disk^{6,7} (Staudinger, 1931, and 1932, p. 129), whereas spontaneous birefringence implies that the particles are not free to move (whether through mechanical interference or by reason of their charges). If they were free to move, they would attain random orientation, and the solution would become isotropic.

Attempts to determine precisely the shape of the virus particles have usually been based upon measurements of viscosity. Unfortunately, the theory of the viscosity of suspensions is in its present state insufficiently developed to permit of a completely satisfactory solution of the problem. Certain general principles have, however, emerged, and as these are passed over or violated in much of the published work, it may be worth while to review the situation.

Interpretation of the experimental results has generally been sought through the aid of an equation due to Kuhn⁸, which may be stated in the form

$$\eta_{sp.} = 2.5\phi + \frac{\phi^2 f^3}{16} \quad (1)$$

Here $\eta_{sp.}$ is the specific viscosity, defined as $\eta_{rel.} - 1$, where $\eta_{rel.}$ is the relative viscosity. Since $\eta_{rel.}$ is the ratio of the viscosity, η^1 , of a suspension or

solution to that of the pure solvent, η_0 , the definition may be formally stated as

$$\eta_{sp.} = \eta_{rel.} - 1 = \frac{\eta^1 - \eta_0}{\eta_0} \quad (2)$$

If the total volume of the particles is v , and that of the solvent is V , where v is very small compared with V , then ϕ is defined as $\phi = v/V$. f is the axial ratio of any particle, the ratio of its length to its diameter.

From its derivation, equation (1) is applicable only to suspensions so dilute that there is no interaction between a given particle and any other particle, but only between the particles severally and the liquid immediately surrounding them.

It is also only applicable when Brownian agitation is overwhelming, so that there is random orientation. The extent to which this condition is not fulfilled in practice does not seem to be realized, though Lauffer⁹, who used a high precision quartz viscometer, admits that the particles may be "somewhat" orientated. This condition is important because the orientation of the particles, which becomes more marked as higher rates of shear are applied, is accompanied by a decrease in the measured viscosity. This has been shown experimentally by simultaneous measurements of the viscosity and of the optical properties of a 0.02 per cent solution of the virus in a rotating cylinder viscometer. A beam of plane polarized sodium light was passed through the annulus of a Couette viscometer, parallel to the common axis of the cylinders. The angle of isocline, which gives the direction of orientation of the particles, was found by rotating the polarizer and the analyser together and crossed. The strength of the double refraction, which gives the intensity of the orientation, was determined by inserting a quarter-wave plate orthogonally to the polarizer, and rotating the analyser alone as in the method of compensation due to de Sénarmont. It was also found possible to develop a theoretical explanation which yields successful quantitative predictions of the variation of the viscosity with the rate of shear. This is further confirmed by the agreement of experiments and predictions upon the sign and magnitude of the temperature coefficient of relative viscosity.

Briefly, the orientation is the statistical aspect of precessional motions imposed upon the suspended particles by the velocity gradient in the flowing liquid. That direction of the particles for which the precessional motions have their minimum angular velocity is their most probable direction, and therefore the direction of orientation. Theory and experiment agree that as the velocity gradient increases, the direction of orientation approaches that of the streamlines (the angle of

isocline increases from 45° towards 90° ; and the intensity of the orientation increases (the strength of the double refraction of flow increases). To maintain the precessional motions of the particles, work must be done continually. As the velocity gradient is increased, the theory shows that, on account of the increasing orientation, the amount of work so used becomes less compared with that required to maintain the flow of the solvent alone. Since the viscosity coefficient of a liquid is a measure of the rate at which energy is dissipated in its flow, this is reflected experimentally in a reduction in the measured viscosity. Dilute suspensions of the virus exhibit a distinct viscous anomaly.

Because of this anomaly and the extensive orientation which is its basis, measurements made at high rates of shear cannot be interpreted satisfactorily by means of Kuhn's equation. It has already been mentioned that Kuhn gives a method for determining the birefringence to be associated with each particle, and with it, of the maximum possible double refraction of flow which would correspond to a complete orientation of the particles. With the 0.02 per cent virus solution, one half of this value is reached at a velocity gradient of 5.6 cm. per sec. per cm. in the Couette apparatus. The rates of shear in capillary viscometers are generally hundreds or thousands of times greater than this, so that the assumption of random orientation is unjustified.

Yet most workers seem to have used capillary viscometers, and to have published no data from which the rate of shear might be computed. Lauffer states that his results were obtained with such an instrument. Frampton and Neurath¹⁰ do not state how they obtained their results. That they are in good agreement with those of Lauffer suggests that they too used a capillary viscometer.

It is instructive to compare the results of Lauffer¹¹ with those obtained in the Couette instrument. Lauffer states that the specific viscosity of a 0.0296 per cent solution of the virus is 0.0165. The following figures were obtained with a 0.02 per cent solution in the Couette apparatus.

Mean rate of shear (sec. ⁻¹) ...	0.36	0.72	1.44	2.16	2.88	3.60	4.32	5.04
Specific viscosity ...	0.291	0.279	0.260	0.243	0.230	0.219	0.205	0.199

Short extrapolation gives the value 0.30 for zero shear, and this is confirmed by the theory. If Kuhn's equation can be applied to any of these results, it is to that for zero shear, where alone the orientation is random. This would give $f = 176$, approximately, instead of Lauffer's value of 35.

The theoretical treatment, the general description

of which has been given, replaces Kuhn's equation by the more complicated one,

$$\eta_{sp.} = \frac{\eta f^2}{4} \left[1 - \frac{\Delta}{\Delta_m} (1 - 2 \cos^2 \Psi) \right], \quad (3)$$

where Δ is the observed double refraction of flow at any rate of shear, Δ_m is the maximum value corresponding to complete orientation, Ψ is the observed angle of isocline at the given rate of shear, and the remaining symbols have the meanings already allotted to them.

This equation does not assume that the orientation is random, but takes account of its progressive increase as the rate of shear is raised, and so predicts the viscous anomaly. Applied to the experimental results obtained with the 0.02 per cent virus solution, it suggests that f is of the order of 87. (The actual figure is not stressed, for the virus preparation was not fresh. What is important is the anomaly, and the caution which it demands in interpreting measurements made with flow viscometers.)

It must be emphasized that this is not the axial ratio of the virus particle, but only that of the model particle, conceived as a rigid string of beads, which leads to a predicted viscosity equal to that observed for the virus. It does not seem to have been realized that precisely the same difficulty is inherent in Kuhn's equation.

It should also be noted that the equations (1) and (3) are extremely approximate in their derivation, so that they can only indicate the order of magnitude of f . More strict hydrodynamical treatment would have given a less rapid rise in specific viscosity than that proportional to f^2 which the approximate theories indicate.

Neurath and Saum¹² have recently approached the problem by comparing measurements of molecular weight by diffusion and in the ultracentrifuge. They suggest a shape factor which would correspond to a value of f between 52 and 56. It is impossible to assess this result in the absence of more details as to its derivation, but it is interesting to note that it falls between 87 and Lauffer's obviously too low figure of 35.

Whether or no it is justifiable to assume random orientation depends mainly upon the absolute size of the suspended particles. For the existing orientation represents a dynamic equilibrium between a hydrodynamic orientating tendency and the disorientating Brownian agitation. As the size of the particles increases, the former effect becomes more, the latter less, important. The diffusion coefficient for angular rotation, which measures the intensity of the Brownian agitation, is roughly inversely proportional to the cube of the length of the particle. The degree of orientation depends

upon the relation of this quantity to the value of the velocity gradient. In a recent theoretical paper, Peterlin shows that random orientation can only be asserted if the suspended particles are shorter than 10^{-6} cm. Lauffer¹¹ suggests that the length of the virus particle is of the order of 10^{-4} cm., which would exclude the assumption of random orientation involved in his use of Kuhn's equation. Since Kuhn's equation can only be applied when the particles are smaller than 10^{-6} cm., it is clear that its use in interpreting measurements of the viscosity of virus solutions should be discontinued.

Only measurements made in a cylinder apparatus, where simultaneous control and determination of the state of orientation are possible, can be expected to be significant when the particles are so large as to be considerably orientated at low rates of shear.

Quite apart from the high rate of shear which inevitably obtains in them, capillary viscometers are quite unsuited for the study of anomalous systems. In these systems the viscosity depends upon the rate of shear. In a capillary viscometer the rate of shear, and with it the viscosity of an anomalous liquid, varies across the lumen from a high value near the walls to zero on the axis of the flow tube. No precise significance can be attached to a measured 'viscosity'.

G. I. Taylor¹² reported that in his model experiments some time was required for the establishment in a steady state of the motions of precession of the particles. Peterlin¹⁴ points out that even when the particles are so small as those of the virus, this process may require some seconds. All theoretical formulae which are not concerned with a variation of viscosity with time must assume that this steady state is reached. In a cylinder apparatus, unlimited time may be allowed for its attainment. But in a capillary viscometer, a given element of volume

of the liquid remains in the flow tube only for a fraction of a second, and time may not be allowed for the steady state to be established.

Since the variation of the velocity gradient across the lumen of the capillary is accompanied by a variation in the state of orientation, capillary methods are also unsuited for the measurement of double refraction of flow. The double refraction of flow of the suspension as a whole can only be referred to the birefringence of the individual particles if an independent measurement of the state of orientation is also possible. Comparisons between different systems are only valuable if they can be made in corresponding states of orientation. When a cylinder instrument is used, the angle of isocline may be measured as well as the double refraction, and provides the necessary control.

The methodological problem is summed up in the statement that the viscosity of a suspension is most emphatically not a simple physical property of that suspension, as it would be of a Newtonian liquid. The energy dissipated depends upon the type and upon the rate of flow; so the recorded viscosity depends upon the method of measurement, and especially upon the rate of shear which is employed. A statement of the 'viscosity' of an anomalous system which does not include reference to these controlling factors has little meaning.

Lazzaro Spallanzani

Celebration at Pavia

ON April 11-15, the University of Pavia honoured the memory of one of its greatest sons, Lazzaro Spallanzani (1729-1799). The celebrations took the form of a special meeting of the Italian Society of Experimental Biologists, to which a number of representative foreign men of science were invited, with closely associated and contemporaneous meetings of the Italian Botanical and Geographical Societies, as well as a congress of veterinarians.

On the morning of April 11, in the Great Hall of the University, with a Duke of the Royal House presiding, there assembled a most colourful company to listen to the oration given by Prof. Botazzi of Naples, and to receive the greetings and congratulations conveyed from scientific bodies and institutions in foreign countries by their official delegates. Thereafter the company passed along cool cloisters bedecked by fine statues and plaques to the Pavian worthies—Volta, Golgi, among

hers—to the quadrangle where the shrouded marble figure of Spallanzani waited. The unveiling itself was a simple act, and then it seemed that relative merit had at last been recognized, for the fine new monument dominated its environment; then to lunch, given by the Mayor of Pavia in the splendid and attractive Almo Collegio Borromeo. Then, somewhat reluctantly, for the entertainment was rich and satisfying, on to the aula, Spallanzani in the Zoological Institute, formerly a palace and, so far as university department buildings go, still most palatial. If the place where work is done affects its quality, then no wonder great discoveries have been made in Pavia.

All through the afternoon, specialists in different fields of biology, each acknowledged in his turn the indebtedness of his particular branch of science to Spallanzani. It was an inspiring experience to stand and speak where he had stood and taught. His mantle seemed to brush one's shoulder. As speaker followed speaker, it seemed that the history of science in the eighteenth century was a record of Spallanzani's own work: 1754–60, a teacher of logic, metaphysics and Greek in the University of Reggio; 1760, lecturer in the Natural History Department of the University of Modena; 1769, invited to the chair of natural history in Pavia, a post which he adorned until his death. Whilst at Modena he had been active in experimentation designed to test the reality of spontaneous generation, and his contributions concerning the anatomy and physiology of the circulatory system were of such quality as to justify Haller's dedication to him of one of the volumes of his "Treatise of Physiology". With the greater opportunities that Pavia offered, his interests passed rapidly from problems of regeneration to the origin of springs, to the systematics of the Protozoa, to the functions of chlorophyll, to tissue respiration, to the role of the sperm in fertilization, to the chemical aspects of digestion,

whilst at the same time work carried out on journeys along the Mediterranean coast earned for him the title of the founder of volcanology. He augmented the content of each and every subject that he touched, and many of his discoveries, being made before their quality could be assessed, had long to lie dormant until men's minds were later turned in their direction.

It was not surprising, therefore, to listen, during the afternoon and the following three days, to a series of papers dealing with the most diverse of subjects, every one of them nevertheless testifying

to the fact that Spallanzani had made notable contributions to each and all. Abderhalden (Halle) on digestion; Federley (Helsingfors) on the chromosome and gene; Ruggles Gates (London) on the nature of genic differences; Camara (Lisbon) on the branched chromosome; von Muralt (Bern) on the relationship of Spallanzani and Albrecht von Haller; Pupilli (Bologna) on the physiology of the circulatory system; Crew (Edinburgh) on artificial insemination and its uses in the experimental study of the species problem; Timoféeff-Ressovsky (Berlin) on genetics and evolution; Jucoi (Pavia) on physiological genetics; Montalenti (Bologna) on tissue respiration; Brunetti (Pavia) on

animal electricity; Baltzer (Bern) on hybrid grafts and partial homology of nuclei from different species, were among those who contributed to the homage that was so gladly paid. Meanwhile the botanists, geologists and veterinarians were similarly occupied, so that the air of Pavia must have been heavily laden with well-merited eulogy of Spallanzani.

The veterinarians in their meetings dealt entirely with the techniques and possible uses of artificial insemination. It will be remembered that Spallanzani, being greatly impressed by the results of the artificial insemination of trout eggs by Waltheim, succeeded in 1779 in artificially inseminating a bitch. It is a great pity that at

STATUE OF SPALLANZANI AT THE UNIVERSITY OF PAVIA

this meeting there was no one from the U.S.S.R. Had there been, they could have been reminded that they, who have exploited this technique more than any other people, are greatly indebted to the Italian Spallanzani, and their hosts could have been given further reason for their rejoicings by the knowledge that Spallanzani's early sowings had produced so abundant a harvest.

The foreign delegates were housed in the Collegio Ghislieri and in the Almo Collegio Borromeo. 'Housed' is certainly the wrong word, for the hospitality they received was so warm and so friendly, and the accommodation itself so welcoming, that they who had come as strangers, left as friends.

During the days of the congress when for brief intervals the clamour of discussion died down, there were pleasant excursions to the Certosa di Pavia, a Carthusian monastery crowded with works of art; to the town of Pavia itself; and to the

Spallanzani Museum at Reggio. In addition there were evening concerts, exquisite yet informal, such as could only be enjoyed in Italy, in the rooms of the Circolo del Littorio. The foreign delegates came away full of admiration and gratitude, entertaining the wish that all congresses, if a meeting in Italy where they do these things well, should at least be constructed on the Italian model.

This celebration was notable also for the appearance of the first number of a new journal *Scientifica Genetica* (see NATURE of April 22, p. 676). This is a matter of some considerable interest for it truly marks a stage in the development of the science in Italy. A rapidly growing school exists and the stage of its development is indicated by the recognition of the need for the publication of a specialist scientific journal which will cater primarily for the geneticists of the Latin-speaking countries.

F. A. E. CREW.

Obituary Notices

Sir Frank Dyson, K.B.E., F.R.S.

IT is with much regret that we record the death at sea on May 25 of Sir Frank Dyson, Astronomer Royal from 1910 until 1933, whilst on the voyage home after a visit to Australia.

Frank Watson Dyson was born on January 8, 1868, and was educated at Bradford Grammar School and Trinity College, Cambridge. He was second wrangler in the Mathematical Tripos in 1889, and was placed in Class I, Division 2, in Part II of the Tripos in the following year. He was awarded a Smith's Prize and elected to a fellowship at Trinity College. In 1892 he was appointed to an Isaac Newton Studentship, being the second holder of the studentship, which had shortly before been endowed by Mr. Frank McClean for research in astronomy or physical optics.

In 1894 there occurred a vacancy in the post of chief assistant at the Royal Observatory, Greenwich, through the election of H. H. Turner to the Savilian professorship at Oxford, and Dyson was selected by the Astronomer Royal, W. H. M. Christie, to fill the vacancy. The choice proved to be a singularly happy one, and Dyson threw himself with characteristic energy and enthusiasm into the various branches of the work at Greenwich.

Dyson's first important work, undertaken in collaboration with W. G. Thackeray, one of the assistants, was a new edition of Groombridge's Circumpolar Catalogue. Stephen Groombridge, a retired West Indian merchant, had made at Blackheath between the years 1806 and 1819 some 27,000 observations of more than 4,000 circumpolar stars, using a 3½-inch aperture transit circle of 5 feet focal length. The observations had been well made, with

careful attention to the instrumental adjustments but the reductions were not in accordance with modern ideas of accuracy. A complete new reduction was made, starting from the original observing books. The Groombridge stars were re-observed at Greenwich, and from the comparison of the two series of observations, supplemented by such other observations as were available, the proper-motions of the stars were derived. These proper-motions were discussed for the derivation of the constant of precession and the solar motion. The work was completed in 1906 and provided a valuable addition to the available data on the proper-motions of the stars. The publication came at an opportune time. In the previous year Kapteyn had announced his important discovery of star-streaming from the analysis of the proper-motions of the bright stars observed by Bradley in the years 1750-62. The Groombridge proper-motions were used by A. S. Eddington, who succeeded Dyson as chief assistant at Greenwich on the appointment of Dyson in 1906 as Astronomer Royal for Scotland, to confirm the existence of star-streaming amongst these fainter stars, which extended to a greater distance from the sun than the stars used by Kapteyn.

The work on the Groombridge Catalogue directed Dyson's attention to the problems of stellar motions, in relation to the distances and luminosities of the stars and to their distribution in space. Both whilst at Edinburgh and after his return to Greenwich in 1910 as Astronomer Royal, on the retirement of Sir William Christie, he published a number of papers on these subjects.

As chief assistant, Dyson had also taken a considerable part in the Greenwich share in the international co-operative plan for photographing the

heavens and preparing an astrographic catalogue: the zone of the sky allotted to Greenwich was from declination 65° N. to the pole. On his return to Greenwich as Astronomer Royal, many of the programmes of work were directed to making the information about this zone of the sky as complete as possible. Measurement of the parallaxes of stars of large proper-motion, determinations of photographic magnitudes and of effective wave-lengths were undertaken. The whole zone was photographed again, the photographs being obtained through the glass; by placing corresponding early and late photographs film to film, the proper-motions of the stars were conveniently and rapidly derived from differential measures.

The problems to be solved at total eclipses of the sun claimed much of Dyson's attention. He took part in several himself and was fortunate in never having cloudy weather. In the total eclipse of 1927, which was visible in England, he selected Giggleswick as the station for the Greenwich party, and this proved to be almost the one place where the eclipse was observed under favourable conditions. His own work on the spectra of the chromosphere and of the corona made important contributions to the subject. It was in large measure as the result of his initiative and energy that two expeditions went from England to observe the total eclipse of May 1919. Dyson had pointed out in 1917 that this eclipse would afford a particularly favourable opportunity for testing whether there was a deflection of rays of light passing near the sun of the amount predicted by Einstein from his theory of relativity. Preparations were made for the two expeditions in the hope that the Great War would end in time to make it possible for them to set out. How the expeditions set out, obtained their observations and vindicated Einstein's prediction is well known. This successful confirmation, coming at so crucial a time, undoubtedly did much to bring about a general acceptance of Einstein's theory. After his retirement in 1933, Dyson wrote, in conjunction with Dr. R. v. d. R. Woolley, "Eclipses of the Sun and Moon", published in 1937, which is the best book that has been written on this subject.

Dyson took a great interest in problems of time-keeping and in the craft of clock-making. He was responsible for the distribution through the B.B.C. of the 'six-pipe' time signals, the signals being sent direct from Greenwich and making accurate time more readily available than it had hitherto been. He was for many years president of the British Horological Institute, which awarded him its Gold Medal in 1928, and he was a member of the Court of Assistants of the Clockmakers Company, of which he was twice master.

After the Great War, when international co-operation in science had lapsed to a considerable extent, Dyson played a prominent part in the reconstitution of international scientific co-operation with the International Research Council and in the formation of the International Astronomical Union. The success that this Union has achieved in securing international co-operation in different branches of astronomy is in no small degree due to Dyson's wise

guidance. His election as president for the period 1928-32 was a fitting recognition of his services to the Union.

Dyson received many honours. He was president of the Royal Astronomical Society, 1911-13; president of the British Astronomical Association, 1916-18; vice-president of the Royal Society, 1913-17. He was awarded a Royal Medal of the Royal Society in 1921, the Bruce Gold Medal of the Astronomical Society of the Pacific in 1922 and the Gold Medal of the Royal Astronomical Society in 1925. He received honorary degrees from the universities of Oxford, Cambridge, Edinburgh, Durham, Leeds, Toronto, Perth and Melbourne, and was foreign or corresponding member of various national academies. He was created a Knight Bachelor in 1915 and a K.B.E. in 1926.

Dyson was a man of engaging personality and of singular charm. To all of his staff he was not merely a chief but also a friend. He married Caroline Best, daughter of Mr. Palemon Best; she died in March, 1937. They had two sons and six daughters. Foreign astronomers from all parts of the world and many other visitors to Greenwich were sure of a warm welcome and of friendly hospitality in their home. Dyson had a keen sense of public duty, and much of his leisure time was spent in work for the various schools, hospitals, charities and other good causes in which he was interested. Of no man might it more appropriately be said:

"His life was gentle, and the elements
So mix'd in him that Nature might stand up
And say to all the world 'This was a man!'"

H. S. J.

Engineer Vice-Admiral Sir Henry John Oram,
K.C.B., F.R.S.

Of the many engineers who held high positions during the Great War, none had a more onerous and responsible task than Engineer Vice-Admiral Sir Henry Oram, who died at Cranleigh on May 5 at the age of eighty years. From October 1907 until June 1917 he was engineer-in-chief of the Fleet, and as such was responsible for the design, construction and maintenance of the machinery of hundreds of warships from battleships to armed trawlers, and for a personnel of something like 70,000-80,000 officers and men. He had served in various grades at the Admiralty from 1884 until 1907, when he succeeded Engineer Vice-Admiral Sir John Durston and "under him", as *The Times* said, "was created the post-Dreadnought Fleet, which formed the backbone of the Navy in the conflict with Germany, and the very high standard of efficiency obtained under the stress of war in the engine rooms of ships of all types and classes reflected the highest credit upon his professional skill, sound judgment and administrative ability".

Though, unfortunately, little has been published on the work of the engineering branch of the Navy during the Great War, both Admiral Jellicoe and

Admiral Beatty paid tribute to the high standard of efficiency maintained in the engine rooms of His Majesty's ships under difficult conditions.

Oram was a product of the eminently successful system of training introduced by the Admiralty about a century ago, whereby a boy with no other advantages than those of character and physique could climb to the top of the ladder. He was born on June 19, 1858, and at the age of fifteen years entered Devonport Dockyard as an engineer student; during the next six years he passed through the engine and boiler shops, the foundry, the smithery, the drawing office and so forth, meanwhile attending the Dockyard School. In 1879 he passed for an assistant engineer R.N. and then entered upon three further years' training at the Royal Naval College, Greenwich, where at that time the staff included Hirst, Cotterill, Reinold, Hearson, Waghorn, White and W. E. Smith, while among Oram's fellow students were Rear-Admiral F. T. Bowles, U.S.N., and Rear-Admiral Miyabara, afterwards the engineer-in-chief of the Japanese Navy. From Greenwich Oram passed out with the highest distinction, and for the next two years, 1882-84, served afloat in the Indian troopships *Crocodile* and *Malabar*, the running of these and their sister ships being looked upon as the best experience for junior engineers. This proved to be Oram's only sea service, for in 1884 he was appointed to the staff of Sir James Wright at the Admiralty and never again left Whitehall.

To detail the many developments with which Oram was associated would be to trace the progress of naval engineering during the course of forty years. When he entered the Navy there were plenty of ships with horizontal simple-expansion engines working with steam at 30 lb. pressure; when he retired the standard type of machinery was the geared steam turbine working with steam at about 250 lb. pressure generated in oil-fired water-tube boilers. He was associated with all the troubles over forced draught, and by his invention of the "Admiralty" boiler-tube ferrule helped to mitigate some of them; he saw the introduction and development of the splendid triple expansion engines of last century; he was already in a responsible position when the various types of water-tube boiler—Thornycroft, Yarrow, Normand, Babcock and Wilcox, Dürr, Nielsens, Belleville, etc., were being installed, and he attended the trials of the historic *Turbinia*, and saw the turbine supersede the reciprocating engine for all warships.

There was nothing meteoric in Oram's rise to the top of his profession. He passed through all the grades of assistant engineer, engineer, chief engineer, etc., and in 1903 when the new titles were introduced he became an engineer-rear-admiral. He was made a C.B. in 1906, a K.C.B. in 1910, and his scientific attainments were fully recognized by his election in 1912 as a fellow of the Royal Society. He was the first naval engineer to be so honoured. In 1915 he was elected a member of the Athenaeum under Rule II.

Besides his work at the Admiralty, Oram lectured on marine engineering at the Royal Naval College, Greenwich, and he practically rewrote the admirable text-book on the marine steam engine, first published by

Richard Sennett, the engineer-in-chief from 1887 until 1889. In 1908-9 he served as president of the Junior Institution of Engineers and in 1914 of the Institute of Metals, giving to both societies very valuable addresses. At the jubilee meeting of the Institution of Naval Architects he contributed a paper entitled "Fifty Years' Changes in British Warship Machinery." Though not like his predecessor Sir John Durston or his immediate successors Sir George Goodwin and Sir Robert Dixon, a president of the Institute of Marine Engineers, his name appears among the honorary members. From the United States he received the Distinguished Service Medal.

Since his retirement Admiral Oram had lived at Rudgwick and he was buried in the churchyard there on May 8.

EDGAR C. SMITH.

Mr. Daya Ram Sahni, C.I.E.

We regret to record the death of Rai Bahadur Daya Ram Sahni, the distinguished Indian archaeologist, formerly director-general of the Archaeological Survey of India, which took place at Jaipur in March at the age of sixty years.

Sahni was educated at the University of the Panjab, and was one of the first to hold a Government of India scholarship in archaeology. He was also a gold medallist of his university. He joined the Archaeological Survey as scholar and assistant in 1904, reaching the grade of superintendent in 1917. He was a regular contributor to the records of the Survey, dealing more particularly with the decipherment of inscriptions and describing Buddhist sites. He is the author of two well-known and authoritative works on the Buddhist remains at Sarnath; and he contributed two chapters to Sir John Marshall's great work on Mohenjo-daro and the Indus civilization. Sahni was appointed deputy-director of the Archaeological Survey in 1925, and director-general in 1930, retiring in 1935, when he received the honour of C.I.E. On his retirement he accepted the offer of the appointment of director of archaeology from the Jaipur Government and was responsible for excavations at Bairat, one of the most important sites in Jaipur, publishing a report on his results.

We regret to announce the following deaths:

Sir George Kendrick, who was actively associated with the development of the University of Birmingham, where he endowed the Poynting chair of physics, on May 28, aged eighty-nine years.

Sir William Lobjoit, O.B.E., during 1920-27 controller of horticulture at the Ministry of Agriculture, on May 28, aged seventy-nine years.

Dr. C. H. Mayo, founder with his brother of the Mayo Clinic, Rochester, Minnesota, for surgical research, and regent of the American College of Surgeons in 1913-36, on May 26, aged seventy-three years.

News and Views

of W. E. Le Gros Clark, F.R.S.

PROF. WILFRED E. LE GROS CLARK, whose appointment to the chair of anatomy at University College, London, vacant since the sudden death of Prof. H. H. Collard in January last, will take effect as from October 1 next, has been professor of anatomy in the University of Oxford since 1934. Born on June 5, 1895, he was educated at Blundell's School, Tiverton, and passed through the Medical School of St. Thomas's Hospital, London, where he was a pupil in anatomy of Prof. F. C. Parsons, well known as an anthropologist, and an authority on the physical characters of the peoples of Britain. During the Great War, Prof. Clark served in the R.A.M.C. with the rank of captain, and after demobilization was for two years principal medical officer of Sarawak, Borneo. He returned to England in 1923 and in 1924 became reader in anatomy in the University of London. Three years later, in 1927, he was appointed to the chair of anatomy at St. Bartholomew's Hospital, London, transferring to the chair of anatomy at St. Thomas's Hospital in 1930 on the retirement of Prof. Parsons. Apart from his contributions to anatomical and medical journals, Prof. Le Gros Clark is the author of a number of authoritative studies on anthropological topics, including more particularly the physical characters of the Eskimo and the comparative morphology of early man and the apes, his most considerable contribution to discussion of the latter being his "Early Forerunners of Man", which appeared in 1934.

Dutch Congress of Natural Science and Medicine

IN NATURE of May 27, p. 908, reference was made to the Dutch Congress of Natural Science and Medicine held at Nijmegen on April 11-13. A correspondent has sent the following notes on some of the medical papers. On the first day of this Congress the main medical paper was read before a very large audience by Prof. B. Brouwer, of Amsterdam. Prof. Brouwer spoke on the hydrodynamic intra-cranial and intra-vertebral conditions in connexion with the development of modern neuro-surgical diagnostic and operative technique. He showed very clearly the great importance which is attached to very simple physical examinations of the cerebral fluid and the ventricular system for the localization of intra-cranial and intra-vertebral space-occupying lesions. Prof. Brouwer stressed the point that ventricular estimation and ventriculography—when in safe hands—are of the greatest value for the early diagnosis of many intra-cranial space-occupying lesions. Dr. A. Biemond, of Amsterdam, spoke on the diagnosis of mid-line brain-tumours. Going over a list of the ante- and post-mortem findings of twenty mid-brain tumour cases, Dr. Biemond tried to divide this material into three groups, according to their clinical picture and their operability. The prognosis, how-

ever, of mid-brain tumours, even in the light of modern neuro-surgery, is not very hopeful, according to Dr. Biemond's experience. Very much in contrast with this paper was the contribution of Dr. F. Verbeek, of Groningen. Dr. Verbeek described the tremendous advances which have been made during the last twenty years in the neuro-surgical field. A review of his neuro-surgical patients gave much more hope that even the mid-brain tumours will be accessible for operative treatment. Dr. A. Brouwer (Eindhoven) spoke on the technique of X-ray photography. Dr. C. E. Burger (Eindhoven) dealt with X-ray photography as a method for mass examination in the attack on tubercular infection. Dr. J. H. van der Tuuk (Eindhoven) spoke on deep X-ray treatment and its measurement, with reference to apparatus operating up to one million volts.

Teachers in Technical Institutions

IN his presidential address at the annual conference of the Association of Teachers in Technical Institutions on May 29, Dr. E. A. Seeley commended the Spens Report as establishing the parity in status and value of the education given in junior technical schools with that given in 'grammar' and other post-primary schools, but blamed it for disparaging the cultural potentialities of junior commercial and household science schools. These should be given the opportunity of showing that they are capable of developing "on a broad scientific and realistic basis" an education equal in cultural as well as vocational value to that of the schools associated with engineering and building. Referring to the report presented to the Board of Education six months ago, without apparent result, on scholarships for students in technical colleges, Dr. Seeley urged that the nation cannot afford to let willing and competent students be kept from attendance at these colleges by lack of means, while allowing the places that should be occupied by them to be filled by anyone whose parents happen to be able to pay his fees. As regards relations with other associations of teachers, the hopes entertained last year of a workable scheme of federation are for the time being in abeyance. The address closes on the note "education for service"—the sense of responsibility of teachers to the community and the necessity of realizing the social implications of their work: they must train in citizenship as well as in technology.

Indian Education, Past and Present

THREE lectures on "Some Aspects of Indian Education, Past and Present" by Sir Philip Hartog, sometime vice-chancellor of the University of Dacca and president of the Auxiliary Committee of the Indian Statutory Commission on the Growth of Education of 1928-29, have recently been published

in the "Studies and Reports" series of the University of London Institute of Education (London: Oxford University Press. Pp. 110. 2s. 6d.). The lectures, originally delivered in 1935, have been revised and brought up to date and supplemented with memoranda designed to remove, if possible, the imaginary bases for the accusation made by Mr. Gandhi and others that the British Government systematically destroyed an indigenous system of elementary schools and with it a literacy which the schools are presumed to have created. Among the many factors which have militated against the success of Indian educational policies, Sir Philip stresses the extreme lengths to which the policy of devolution was carried with a blind faith that local bodies would learn by making mistakes, the amenability of the Government to pressure exercised by the vocal middle classes in favour of diverting to secondary and higher education funds which ought to have gone to primary education, the extent to which universities have been financially dependent on examination fees and the overcrowding of universities with students who ought never to have been admitted. It has been said that the nineteenth century Liberal thought he knew the final truths about education and failed to recognize that it must serve the community as well as the individual. Sir Philip mentions several hopeful indications, including the work of the social service leagues which he helped to establish at Dacca, of the springing up in Indian educational circles of a new spirit of service to the community.

The Carnegie Corporation of New York

THE report of the president of the Carnegie Corporation of New York, Frederick P. Keppel, for the year ended September 30 records the distribution of grants amounting to nearly four million dollars (including nearly half a million from the Corporation's British Dominions and Colonies Fund) in the following proportions: endowment and support of universities, colleges and schools 22, the arts 17, library interests 15, research studies and publications 14, adult education 5, miscellaneous 27 per cent. It is a document of outstanding interest to trustees and administrators of funds for educational, scientific and cultural purposes and to prospective benefactors and beneficiaries. Highly important questions of principle and policy are lucidly and briefly discussed under the headings "The Public and Foundations", "Funds for Philanthropy" and "Board Procedure". It appears that whilst the volume of large gifts and bequests, derived as they are from fortunes made under conditions which are unlikely to recur, tends to diminish, the funds of the various community trusts made up of relatively small individual contributions have grown steadily in the past ten years from sixteen to fifty million dollars, and the president believes that "current contributions from public funds, from industry and commerce, plus the cumulative contributions of private endowments, are together taking over a steadily increasing share of the total load" of the finance of educational, scientific and cultural enterprises.

Training for Citizenship

A REVIEW of the Corporation's experience in the field of general education leads to some interesting reflections on the present status and influence of the Graduate School (that "sacred cow in American education, to be worshipped rather than studied, understood, and improved") and the extent to which students destined for the professions are trained. Their education must, it is contended, "give far more consideration than it does at present to the place of the professionally trained men and women in modern community, the place that such men and women might take as a *united group*, not divided and weakened in their influence as at present by an *over-emphasis on the spirit and traditions of separate professional guilds*". While education cannot alone create an aristocracy of trained intelligence, it can have regard to such an ideal and foster attitudes that would lead professional men and women to work together rather than separately in contributing to the solution of our political and social problems.

Lines of Magnetic Force

PROF. C. COLBRIDGE FARR, of Canterbury College, Christchurch, New Zealand, has sent a communication in which he advocates the preparation of accurate charts showing the lines of magnetic force running from the south magnetic pole to the north magnetic pole. Prof. Farr points out that the secular change in declination at any observing station is the parallactic angle subtended by the movement of either pole as viewed along a line of magnetic force, and he considers that the comparison of charts, showing the lines of force at different epochs, would lead to a better understanding of the nature of secular variation. The lines of force could be sketched in on existing declination charts, but there would be obvious difficulties in drawing the lines all the way from pole to pole. In forwarding Prof. Farr's letter H. F. Skay, director of the Magnetic Observatory, Christchurch, N.Z., directs attention to the smoothed charts of such lines given by A. G. McNish in *Terrestrial Magnetism*, 41, 87 (1936). The question is whether unsmoothed charts on a large scale would be sufficiently reliable and sufficiently useful to justify the cost of publication.

National Museum of Wales

AT a Court of Governors of the National Museum of Wales held at Aberystwyth on May 23, Lord Harlech from the chair reported on the result of his recent visit to the United States of America, when he was accompanied by Sir Cyril Fox, the director, to appeal to Welshmen in the States on behalf of the National Museum. The sum of £10,000 has already been received in response to the appeal. Lord Harlech stated that the attitude of Welsh Americans towards the Museum was such that the response would have been much greater had it not been for the international tension in Europe at the present time. The variety and range of the recent accessions to the collections of the Museum,

which were reported to the governors by Sir Cyril Fox on this occasion, are an indication of the activities of the Museum in the preservation and display of objects illustrating the history and culture of the Welsh people. Among these were a collection of prehistoric finds from Breconshire, a thirteenth-fifteenth century stone fireplace from the Vale of Glamorgan, and a turned chair of mid-sixteenth century date; while among objects deposited were an important collection of carved stones dated at about A.D. 1230-40 from Castell-y-Bere, and the extremely interesting Iron age fire-dog found in 1852 at Carreg Coodog Farm, Denbighshire. It was also reported that the services of the Museum had been called upon by the Office of Works to report on the antiquities of Pembrokeshire, which are threatened by a tank school.

Inland Water Survey Report

THE third annual report of the Inland Water Survey Committee, issued by the Ministry of Health and the Scottish Office (H.M. Stationary Office, 4d. net), while recording a year of useful activity in various directions, chiefly with the aid of external agencies, finds occasion to express disappointment at the results achieved and to state the conviction of the Committee that action should be taken by the Government, financially or otherwise, for ensuring the extension of the work in both England and Wales and Scotland. The Committee points out that it has no staff at its disposal for taking actual measurements, and that it has to rely in England and Wales (and to some extent in Scotland) on voluntary action by catchment boards and others for the execution of this part of the work of the Survey. It finds, moreover, that relatively very few suitable records of river flow are being kept, and that neither the information available from water undertakers, nor that from catchment boards, is sufficient in scope or adequate in quality to enable a comprehensive survey to be made. It is convinced that in order to be of real use, such a survey should be carried out on similar lines to the Ordnance Survey or the Geological Survey in their respective fields. It may be pointed out that this was precisely the view taken by the British Association Committee four years ago, when the Government reluctantly agreed at its instance to institute a survey.

As regards the actual progress made with the Survey, the examination of river basins, begun in the first and second reports, has been continued, and the results of the investigation of the river basins of the Earn (Perthshire), Eden (Fife), Tyne (East Lothian), Trent, Great Ouse, Wye and Nith (Dumfriesshire) are described in the report. During the year, the Department of Agriculture for Scotland was authorized to spend £500 on the equipment and maintenance of river discharge measurement stations. The existing level-indicating and recording stations on the Clyde, Kelvin, Irvine and Tay have been maintained and stations established on the Earn, Eden, Tyne and Nith. The Tweed basin has also been reconnoitered. In the sphere of underground water, the field work carried out by the Geological

Survey in the Nene basin has been continued, and work is proceeding on a memoir dealing with the underground water resources of an area which includes Northampton and Oxford. The results of measurements for twenty-eight gauging stations in fourteen river basins, collected by various authorities, have been published as "The Surface Water Year Book of Great Britain, 1935/6". The report also deals with several technical difficulties which have been met with during the process of collecting these statistics, and recommendations are made about recording charts and arrangements for securing accuracy of measurement.

Scientific and Industrial Research in New Zealand

AN admirable survey of the work carried out under the Council of Scientific and Industrial Research, New Zealand, during 1927-28 has been issued by the Department as Bulletin No. 69. It includes accounts of work carried out by the Dairy Research Institute, the Plant Research Bureau and the Wheat Research Institute, as well as of the activities of the Department in soil survey, fruit research, animal research, tobacco research and the work of the research associations. The work of the Dairy Research Institute on the cause and control of openness in cheese is described in some detail, as well as further work on discoloration in cheese, and on cheese manufacture. Reference is made to the work of the Plant Diseases Division on chemical sprays and the spray certification system which has been introduced, as well as on virus diseases of tobacco, tomato and of potato, and the importance of the methods introduced for the control of smut of barley. The contribution of the Wheat Research Institute to the improvement of the technique of wheat growing and harvesting, the growing of varieties most suitable for special districts, and cheapening the cost of production is emphasized, as well as the selection and distribution of a new wheat, Cross 7, which yields as well as standard varieties, and has by itself a baking quality equal to that of the old varieties plus the proportion of Canadian wheat formerly used. Fruit research has covered manurial experiments on fruit tree nutrition, boron as a cure for internal cork of apples, orchard sprays, wrappers for fruit; and the soil survey studies have included reference to the physiological diseases of plants. An important discovery in the field of animal research relates to the wasting diseases caused by deficiencies in the diet of cobalt, to which the bush sickness in the North Island, Morton mounds disease in the South Island, and Glenhope ailment in Nelson are due.

Commercial Applications of Blended Light

IN practical work, the term 'blended light' is used to describe the mixture of the light from the ordinary tungsten gas-filled lamps with that from mercury discharge lamps. A. H. Olsen contributes a paper to the *Electrical Review* for May 26 in which he discusses the blending of the light from these lamps. A gas-filled lamp depends on the light emitted by a tungsten

filament; it therefore produces a continuous spectrum, red being prominent, but lacking in blue. The resultant colour is yellowish. A mercury lamp depends on the excitation of vapour and consequently emits a light with a broken spectrum, red rays being almost completely absent and blue being very pronounced. If the two light sources are mixed in the proper proportions, we get an approximation to white light. The effective application of this to shop lighting depends on the type of goods displayed; so no definite ratios of the two lights can be fixed and each installation is examined experimentally. In the case of drapers, furnisiers and outfitters, where fabrics are displayed, the proportion of tungsten lumens to mercury lamp lumens is generally in the proportion of three to one. In practice, this means utilizing one 80-watt mercury lamp with two 200-watt tungsten lamps. When this is done, the colours of the fabrics appear much the same as with daylight. Black appears of a richer lustre, and red shades do not appear mauve as they do under mercury light. Although the consumption of electricity might have been expected to be less than if only tungsten lamps were used, it is found that owing to the amount of tungsten light required to blend with the mercury light, the consumption is much the same. In most of the main town shopping centres, blended light installations present a striking contrast to competitive windows in the same area, being much more prominent and displaying the goods more effectively.

Bureau of American Ethnology, 1937-38

ALTHOUGH the normal activities of the Smithsonian Institution have been curtailed of recent years owing to economic conditions in the United States, the Bureau of American Ethnology has been able to maintain its operations in the field, and even to extend them in archaeology, owing to the provision of Federal finance and the supply of labour made available by measures for relief. A summary statement of the research carried out by members of the staff in the period 1937-38 is given in the fifty-fifth annual report (Washington, D.C., 1939. Pp. 8) covering that statistical year—an exiguous document in comparison with the more elaborate accounts familiar to anthropologists in earlier years. A major work of archaeological excavation was that of the Lindenmeier site in Colorado, where Dr. F. H. H. Roberts, jun., has continued the work of exploration of the habitation site of Folsom man which he initiated in 1934. His operations in the summer of 1937 uncovered an area of 2,300 sq. ft., and 735 specimens were obtained, including a number of new types of stone implement. Early in the season 1938 evidence of the artistic effort of Folsom man, "one of the earliest known of New World inhabitants", came to light in the form of pieces of bone with attempts at engraved design. An interesting investigation approaching completion is Dr. John R. Swanton's research on behalf of the United States De Soto Expedition Commission, of which he is chairman. It involved one field expedition in the year, when Dr. Swanton visited Alabama for the purpose of examining old Indian town sites which might possibly be

identified with those mentioned by De Soto. An extended ethnological exploration of western South America has been planned, which was initiated when in April last Dr. J. H. Steward left Washington for Ecuador, where he has since been at work among the highland Indians.

Britain in the Dark Ages

THE northern sheet of "The Map of Britain in the Dark Ages" (Ordnance Survey Office, Southampton, 1939. Pp. 48. Price 5s. net) is, if possible, of even greater interest than the southern sheet issued by the Ordnance Survey in 1935. This is not least, perhaps, because it serves to emphasize the imperfections in the material, while affording suggestion of the more urgent provinces to which further research should be directed, if any substantial advance in knowledge is to be made. Thus, for example, brochs and earth-houses do not appear here, being reserved for future separate treatment, owing to the difficulty of determining their chronological relation to the period covered by the map. This period, roughly, is from A.D. 440 to 840, an approximation to the date of the union of the kingdom of Picts and Scots under Kenneth, son of Alpin. In regard to technical details, the scale of the map is 1:1,000,000. The practice in the use of symbols of archaeological maps previously issued by the Survey is maintained, the form of the symbols suggesting the objects, additions being made to the symbols already in use as required, as, for example, in indicating the distribution of Pictish symbols. An expository introduction deals with certain broad questions—the extent and location of the British, Scottish, Pictish and Anglian regions, the distribution of tribes, the lines of early roads, and the like. The section in which the roads are traced is a particularly instructive synthesis of geographical and archaeological argument, although the editor modestly disclaims any attempt at original research and professes to do no more than record existing knowledge. The discussion of the range of distribution of the ethnic groups brings out very markedly the need for both a systematic survey of Scottish place names and of systematic excavation, directed to specific ends, mainly chronological.

Tribute to the Memory of Sir Victor Horsley

SIR VICTOR HORSLEY was far from being merely a great surgeon. His death while still in the full plenitude of his powers deprived the world of a remarkable personality which expressed itself effectively in many fields, and his old friend and fellow-worker, Mr. C. J. Bond, has done well to place on record personal notes ("Recollections of Student Life and Later Days". 1939. H. K. Lewis and Co. Pp. 48) of an association lasting forty years. Neuro-psychical phenomena held an irresistible attraction for both men, and in elucidating Horsley's share in some of their conjoint work, Mr. Bond outlines some of the conclusions to which he was led by these and other independent researches the scope of which is indicated by his query: How has it come about that the neural machinery exists for the carrying out of neuro-psychical activities in a dual manner while on the psychical side the more

ghly organized, later evolved responses are perceived and executed by a unified consciousness and single will? Of Huxley's activities in the political and sociological sphere he observes, "He clearly realized that what the world sorely needs is a deeper and wider recognition of the fact that selfishness and the aggressive spirit, although they no doubt had some survival value among primitive peoples and savage tribes, yet under modern conditions of so-called civilization they act as brakes on the wheels of human progress".

School Natural History

PERSONS who lament the alleged lack of interest shown by the modern schoolboy in natural history could read the current annual reports of two famous school natural history societies—the reports for 1938 of the Marlborough College Natural History Society and of the Rugby School Natural History Society. Each of these societies has existed long enough for its usefulness to be thoroughly tested, and the Marlborough report is the eighty-seventh, the Rugby one the seventy-second, and the internal evidence is that enthusiasm abounds and observations are made over a wide range of natural history subjects. The two societies seem to be run on quite different lines. At Rugby, activities centre in thirteen specialist sections, which arrange their own discussions and excursions, and meet in common only at the general lectures given by outside speakers. At Marlborough, there appear to be no lectures by outsiders, the members themselves are the lecturers, and there are but two sections, archaeological and natural science. This arrangement, while encouraging more general distribution of interests, has not affected the specialist labours of the members, for it is a remarkable record that from the pages of successive reports of fewer than seven hand-lists have been published, giving a wonderfully complete conspectus of the fauna and flora of the Marlborough district.

The Science Library

THE first part of a fifth edition of the "Hand List of Short Titles of Current Periodicals in the Science Library" (H.M. Stationery Office. 9s. net) has recently been issued. The new edition contains about one thousand main entries with about four thousand cross references from alternative headings, as against over thousand titles in the fourth edition, issued in 1926. Publications of learned societies and institutions are entered under the names of their permanent seats, and publications of Government departments and other bodies under the name of the countries from which they derive their denominations, or, for want of such denominations, under the places whence their acts are issued. The Hand List is not intended as a bibliographical catalogue; it gives merely brief titles of the publications with details of the Library holdings. The List is being issued in two parts, of which the first is arranged alphabetically. It is hoped later to publish a second part with a subject arrangement. The preface to the List gives a very brief but lucid description of the Science Library and its development.

New Medical Journals

THE first numbers of two new scientific journals have been received. (1) *Anais da Faculdade de Medicina de Porto Alegre*, Universidade de Porto Alegre, Brazil, Fasc. 1, pp. 1-303. This is handsomely produced and well illustrated, and the papers, in Portuguese, Spanish, Italian, French, German or English, have summaries in French, German and/or English. It opens with an account of the medical centre of the University, and contains papers, among others, on detachment of the retina (Arruga), hereditary ophthalmic diseases (Meyer), and feminine types (Gomes). (2) *Anales de la Escuela Nacional de Ciencias Biológicas*, Mexico, vol. 1, No. 1, pp. 1-178. This also is well produced and illustrated, and contains articles in Spanish on the cultivation of *Rickettsia* of typhus fever (Siegfried), histology of the poison gland of a spider, *Cryptidromus* (Ancona), calcium chloride in the treatment of scorpion poisoning (Varela), a new species of *Phlebotomus* (Dampf) and some Mexican textile fibres (Huerta and Ancona) and others. Summaries in English and German are provided. In both journals, the printed matter on a page measures about 8 in. × 5 in.

Journal of the Royal Agricultural Society

THE ninety-ninth volume of the *Journal of the Royal Agricultural Society of England* has now been published (price 15s.). It includes, as in the previous volume, "The Farmer's Guide to Agricultural Research", which this year contains an additional section on pests and parasites. As usual, the subjects of the special articles cover a wide field of interest. Agricultural long-term credit facilities in Great Britain are discussed, and farm organization on the silt soils of Holland, Lincolnshire, described. A detailed account is also given of the life-history, distribution and control of bracken, from which there can be no doubt as to the need for urgency in undertaking means for its eradication. The starling is the subject of a further article, and at present it seems uncertain whether it should be regarded as a friend or enemy of the farmer. The Warnford Farm Estate, where pig breeding and bacon production are carried out on a vast scale, has been selected as this year's "Notable Farming Enterprise".

Durban Museum and Art Gallery

UNDER the directorship of E. C. Chubb this combined institution continues to make steady progress, reflected in an increase of visitors, who in the year ending July 31, 1938, numbered 123,771. The educational value of the collections is increased by the lectures to the public and to school children delivered by the staff, and modern developments are shown in the appointment of a guide-lecturer, through the generosity of the Carnegie Corporation of New York, the extended use of cinematograph films to illustrate museum lectures, and the scheme which enables assistants to visit other South African museums for the purpose of gaining experience in museum technique, a scheme sponsored by the South African Museums Association.

Applied Psychology in Italy

A PERMANENT Commission for the Application of Psychology has recently been appointed by the Italian National Board of Researches. It aims at promoting among State institutions, labour organisations and private persons the application of psychology in any field, with regard to selection and orientation, as well as to the organization of work. At present, applications in the scholastic field, where professional orientation has become a function of the school, are being studied in the first place; applications in industries, aviation and public transport will follow. The president of the Commission is Prof. P. Agostino Gemelli.

Appointments for Research in Tropical Medicine

THE Medical Research Council is offering up to three junior fellowships to qualified medical men or women wishing to receive training with a view to careers in research work in tropical medicine. The fellowships will be tenable for three years. The stipend will be at the rates of £300, £400 and £500 per annum in the successive years, with an additional allowance during service abroad and necessary expenses. In three years' time, at least one senior fellowship will be available for candidates who have held the junior fellowships mentioned above. This will be awarded for a further period of three years, carrying stipend at the rate of £600-£750 per annum, with an additional allowance during service abroad and expenses. The Council is also prepared to consider immediate applications for senior fellowships from candidates who have had adequate experience in research work, whether already specially trained in tropical medicine or not. The Council further intends to establish in due course, as suitable investigators become available as the result of the fellowships scheme, permanent and pensionable appointments for research work in tropical medicine, including senior posts. Further information can be obtained from the Secretary, Tropical Medical Research Committee, 88 Old Queen Street, London, S.W.1, with whom applications should be lodged not later than June 19, 1939.

Announcements

SIR EDWARD MELLANBY, secretary of the Medical Research Council, will deliver the annual Stephen Paget Memorial Lecture of the Research Defence Society on the occasion of the Society's annual general meeting, to be held at the London School of Hygiene and Tropical Medicine on June 13. The title of Sir Edward's lecture will be "The Experimental Method in the Conquest of Disease".

THE seventy-sixth annual general meeting (Murdoch Centenary) of the Institution of Gas Engineers will be held on June 6-9 at the Institution of Civil Engineers. The Murdoch Centenary Lecture will be delivered on June 6 by Dr. E. F. Armstrong.

THE Council of the Institution of Naval Architects has accepted an invitation of the Gesellschaft der Freunde u. Förderer der Hamburgischen Schiffbau-

Versuchsanstalt to participate in an International Meeting of Shipbuilders, Marine Engineers and Nautical Experts to be held in Hamburg in June. A visit will be paid to Kiel at the invitation of the German Navy, and two days will also be spent in Berlin under the auspices of the Lillenthal-Gesellschaft für Luftfahrtforschung and of the Schiffbautechnische Gesellschaft.

THE Cambridge University Press has in active preparation, and will publish early in the autumn the authorized biography of the late "Lord Rutherford", by Prof. A. S. Eve, a personal friend for many years and formerly Macdonald professor of physics at McGill University. The author has enjoyed the fullest co-operation of Rutherford's closest colleagues and friends, and of Lady Rutherford, who has allowed use to be made of the collection of his husband's letters and papers. Earl Baldwin has written a foreword.

THE Institute of Ethnography attached to the Academy of Sciences of the U.S.S.R. is preparing an ethnographical work on the different peoples of the U.S.S.R. which will run into many volumes. The first three volumes are to be ready this year and will be devoted to a description of the people of Central Asia and Kazakhstan, Siberia and the Far East, and the European section of the Soviet Union. The Institute for Soil Study of the Academy has just published the first three volumes of a monograph on "Soils of the U.S.S.R.". These volumes contain a geographical description of the soil of the European part of the U.S.S.R. from the far north to the Caucasus. A fourth volume, dealing entirely with the soils of the Caucasus, will be issued this year.

THE German Society of the History of Medicine, Natural Science and Technique will be held this year at Jena on September 21-24, when the chief subjects for discussion will be the eye in the history of medicine, natural science and technique. There will also be an exhibition of historical collections in Jena and Weimar.

ELEVEN thousand fewer persons were killed in accidents of all kinds in the United States during 1938 than in 1937—a decline of more than 10 per cent. Motor-vehicle fatalities declined from about 40,000 in 1937 to between 31,000 and 32,000 in 1938.

PRELIMINARY figures from the census taken in Soviet Russia last January give the U.S.S.R. a population of 170,126,000. The increase since 1926 is 23,100,000, which is approximately equal to the population of Spain. In Moscow the birth-rate was 69 per cent higher in 1938 than in 1936: the death-rate for the entire country has dropped by more than 40 per cent compared with 1913. The census shows that the total number of industrial workers employed in the U.S.S.R. rose from 11,600,000 in 1928 to 27,800,000 in 1938. The entire population has more than doubled since 1926.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 944

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS

Mechanical Device for Smoothing Data

As is well known, the application of any reasonably satisfactory formula for the smoothing of a lengthy series of data involves a considerable amount of time and labour. In a recent article¹, I indicated the possibility of constructing a mechanical device whereby all mathematical computation would be eliminated. Such a machine has now been constructed.

The model (Fig. 1), capable of dealing with 18 datum points, consists of a mounted wooden board to which are attached 18 movable glass cylinders, each about 50 cm. in length, half-filled with mercury. A cylindrical iron rod with a hole near its upper end floats in each cylinder. The floating rod acts as a perfect spring, since the force it exerts is directly proportional to its vertical displacement from its position of equilibrium.

A suitable scale is pasted along the top portion of the wooden board, and the process of obtaining a smooth curve, which can be read off from the scale, is extremely simple. For purposes of illustration, the Central Cape annual rainfall figures during the years 1881-98 were employed. Starting from the left, the first cylinder is adjusted so that the hole in the freely floating iron rod corresponds to the 1881 rainfall, which was 136 per cent of the normal. If all the other cylinders are similarly adjusted to correspond with the rainfall figures of their respective years, and if a string be passed through the 18 holes in succession,

Fig. 2.

the string will in effect be an unsmoothed graph of the rainfall for the period under consideration (Fig. 1).

The string is attached to a movable hook on the left, and at the right it passes over a pulley, which can also be moved up and down. Tension is now applied to the string by suspending a predetermined weight (depending upon the degree of smoothness desired) to its free end, the hook on the left and the pulley on the right being adjusted so that the first and last portions of the string are horizontal. Evidently the effect of the tension on the string will be to displace the iron rods in such a way that a smoothed curve results (Fig. 2). (This photograph was taken at an angle so as to reduce the apparent width of the board.)

The points on the smooth curve may now be read off from the scale, thus reducing many hours of laborious calculations to a few minutes. Moreover, once the cylinders have been adjusted to fit the original data, curves of varying degree of smoothness may be obtained in a minimum of time simply by attaching different weights to the free end of the string.

With reference to the theory underlying this mechanical process, the machine automatically applies a very interesting type of graduation formula to the crude data. In any smoothing process some departure from the observed facts is essential, and in general a compromise must be struck between departure from the observed facts and the smoothness of the resulting curve. If $y_1, \dots, y_n$ be the crude data, and u_1

Fig. 1.

. . . u_n the corresponding smoothed values, then $\sum_1^n (y_r - u_r)^2$ may be regarded as a measure of the departure from the observed facts, and the sum of the squares of the first differences, that is, $\sum_1^{n-1} (u_{r+1} - u_r)^2$ may be regarded as a measure of the lack of smoothness or the roughness of the resulting curve. If these definitions be accepted, then the logical way to carry out the smoothing process would be to make k times the sum of the squares of the deviations of the data from the graduated curve plus the squares of the first differences of the graduated curve a minimum, where k is an arbitrary constant. This means that:

$$k \sum_1^n (y_r - u_r)^2 + \sum_1^{n-1} (u_{r+1} - u_r)^2 = \text{minimum.}$$

Application of this minimum principle leads to the result (*loc. cit.*)

$$u_r = \frac{2p-1}{p^n - (1-p)^n} \left\{ \varphi_{n-r+1} \sum_1^r \alpha^{r-s} \varphi_s y_s + \varphi_r \sum_{r+1}^n \alpha^{r-s} \varphi_{n-s+1} y_s \right\}, \quad (1)$$

which is the formula by which the u 's are expressed in terms of the crude data, α , p and φ being defined as follows:

$$\alpha = \frac{1}{2+k}; \quad p-p^2 = \alpha^2; \quad \varphi_r = \frac{1}{\alpha+p} \left\{ p^r + \frac{p}{\alpha} (1-p)^r \right\}.$$

Provided the slope of the smoothed curve is nowhere too great, the smoothed data $u_1, \dots, u_n$ as read off from the machine correspond to the values as given by the formula above. The constant k , and accordingly also α and p , can be simply expressed in terms of the physical characteristics of the machine; thus

$$k = \frac{abpl}{m(b-a)},$$

where a is cross-sectional area of any of the iron rods; b is internal cross-sectional area of any of the glass tubes; ρ is density of mercury; l is distance between two adjacent cylinders; m is the mass attached to the free end of the string.

It is felt that the machine should find a very wide field of practical application wherever investigators are concerned with the study of trends of statistical data, not only in scientific work but also in the economic and industrial world.

A more detailed description of the machine, together with a discussion of experimental results and of possible modifications in design, will appear elsewhere in due course.

Splitting of Protein Molecules by Ultra-violet Light and α -Rays

In a previous communication¹, we have reported on a well-defined splitting of the molecule of *Helix* haemocyanin by ultra-violet light. The idea that we have to deal with a primary photochemical process was put forward.

If this really is the case, one would expect temperature to have very little effect on the reaction. To test this assumption we have irradiated frozen haemocyanin solutions at the temperature of liquid air. The reaction took place with practically the same velocity as at room temperature, giving rise to half-molecules.

For purposes of comparison we also studied the action of ultra-violet light on haemoglobin and serum albumin. The latter reaction has recently been subjected to a very thorough study by a group of American investigators². Irradiation at room temperature and at 0° C. causes the formation of low-molecular substances and also a general inhomogenization of the protein. Our experiments confirmed this result. For haemoglobin, the ultra-centrifugal test also revealed a very pronounced inhomogenization of the protein, a continuous series of molecules of both lower and higher weight than the normal being formed.

When irradiated at the temperature of liquid air, haemoglobin showed no change whatever even after an exposure five times as long as that required to give noticeable effect at room temperature. Serum albumin was just slightly affected. It is obvious, therefore, that the effects observed in haemoglobin and serum albumin, when irradiated at room temperature, are due mainly to secondary reactions.

A more concentrated kind of energy might have a different effect. As a first example of this type we have tried the action of α -rays on *Helix* haemocyanin, haemoglobin and serum albumin, both at room temperature and at the temperature of liquid air. Radon was dissolved in a solution of the protein and the sample left to the action of the radiation from Rn, RaA, RaC and RaC' for different lengths of time. Under these conditions there is added to the effect of α -rays also that of the β - and γ -rays. The ionization due to the latter, however, is only 1-2 per cent of the former and their action is therefore negligible. All the proteins showed qualitatively the same behaviour towards α -rays as towards ultra-violet light. Haemocyanin was split into half-molecules regardless of temperature, while haemoglobin and serum albumin were made inhomogeneous when acted upon at room temperature but not at liquid air temperature.

An attempt has been made to calculate the reaction velocity in the case of *Helix* haemocyanin irradiated by α -rays. The density of the ions along the path of an α -particle is so high that one might assume that every haemocyanin molecule situated on the path is caused to split into halves. If v is the average number of hits that a molecule receives, the probability of no hit is e^{-v} and, therefore, the relative concentration of unchanged molecules

$$c/c_0 = e^{-v}. \quad (1)$$

A consideration of the geometrical conditions shows that in our experiments where a low protein concentration was used (number of molecules per c.c. around 10^{14}) we have as first approximation

$$v = \alpha \tau a, \quad (2)$$

where α is the number of rays per c.c. during the whole period of irradiation, τ is the average range in the solution of the α -particles from Rn, RaA, RaC, and RaC' (4.23×10^{-3} cm.) and a the effective cross-section of the haemocyanin molecule taken as an ellipsoid of rotation (approximately 1.81×10^{-11} cm.²).

A series of experiments with varying number of rays per c.o. gave the following figures.

Time of radiation in days	α	γ from equation (2)	α/γ	
			Experimental determination	Theoretical values from equation (1)
0.8	0.9×10^{12}	0.07	0.91	0.93
2.0	1.9 "	0.14	0.85	0.87
4.1	3.3 "	0.25	0.82	0.77
11.8	5.6 "	0.43	0.77	0.66

In view of the approximations made and the experimental difficulties involved, the agreement between the experimentally determined and the calculated relative concentrations of unchanged molecules is quite satisfactory and supports the assumption that every haemocyanin molecule hit by an α -particle is split. This means that, out of the energy received in any part of the molecule, a portion large enough to cause splitting is transferred to the bond holding the two halves together.

As yet we have not carried out measurements of the absolute number of ultra-violet light quanta active in this splitting, but the independence of temperature points to a quantum yield of unity. It is of interest to note that from studies of the action of various rays on the mutation rate, it has been inferred that the production of a single ion pair within a sensitive spot of the cell, probably the gene, produces mutation*. There seems to be a certain analogy between this finding and our results.

The different behaviour of haemocyanin on one hand and haemoglobin and serum albumin on the other seems to us to be of considerable importance. It shows that the former molecule is easily dissociated by absorption of energy while the latter ones are very stable against a raising of the energy-levels so long as secondary chemical reactions are excluded.

Energy of Neutrons liberated in the Nuclear Fission of Uranium induced by Thermal Neutrons

It has been shown that fast neutrons are liberated in the process of nuclear fission induced in uranium by primary thermal neutrons. Two different methods of detection have been used: in the first method¹, the primary and (if any) secondary neutrons are absorbed in a medium in which an endo-energetic reaction can take place, leading to the formation of an easily detectable radioactive nucleus. If the energy threshold is situated above the maximum energy of the primary neutrons, any positive results observed must be ascribed to the secondary neutrons. In the second method², elastic collisions of fast neutrons with heavier nuclei are observed by means of an ionization chamber filled with a gas at atmospheric pressure and connected to a linear amplifier. In order to study separately the effect due to the primary thermal neutrons, the experiment is performed with, and without, a cadmium shield between the source and the uranium mass.

The first method having shown us that fast secondary neutrons are produced with energies of at least 2 Mev. (sufficient to transform ³²S into radioactive ³²P in detectable quantities), we sought to ascertain, by the second method, whether neutrons of energy notably higher than 2 Mev. are also present in the secondary radiation. In our experiment, the oxygen-filled ionization chamber was placed in a nearly cubical box (9 cm. $\times$ 9 cm. $\times$ 8 cm.) containing uranium oxide and surrounded by a thick layer of paraffin wax. The source (300 mgm. Ray + Be), surrounded by a lead shield (5 cm. in the direction of the chamber) was buried in the wax. In order to absorb thermal neutrons, the uranium box could be screened on all sides with a cadmium foil. The pulses were recorded either in the presence or in the absence of this foil and the part of the effect (projection of oxygen nuclei by fast neutrons liberated in the uranium) due to thermal neutrons could thus be evaluated.

In view of the large number of accidental pulses due to the strong γ -radiation emitted by the source, only nuclei recoiling with at least 1.5 Mev. could be taken into consideration. The distribution curve shows that the frequency of pulses observed falls off rapidly between 1.5 Mev. and 2.5 Mev.; between 2.5 Mev. and 3.7 Mev. the frequency decreases much more slowly, pulses observed in this second region being, however, very rare. The total number of pulses recorded is small (with cadmium: 84 pulses in 90 minutes; without cadmium: 161 pulses in 90 minutes); but it appears clearly that recoils with energy of about 2.5 Mev. are notably more frequent in the absence of cadmium and, therefore, that neutrons possessing an energy of at least 11 Mev. are liberated in uranium irradiated with thermal neutrons.

The high energy of these fast neutrons shows that their parent nuclei are in a highly excited state at the moment of their liberation, which is probably simultaneous with the fission. In this way a non-negligible fraction of the fission energy is disposed of; a further fraction is carried off by the β - and γ -rays afterwards emitted by the nuclei produced in the fission. The remainder available as kinetic energy for these recoiling nuclei is therefore considerably smaller than the total amount of energy liberated in the fission process (about 200 Mev.).

Homometric Structures

In connexion with a recent discussion¹ of the question of the uniqueness of an X-ray crystal analysis, Prof. Linus Pauling has directed my attention to a curious property of the point position $T_1' - 1a3 - 24(d)$. Pauling and Shappell² have shown that this point position, which involves a single parameter u , has a structure factor which is even in u , while parameter values $+u$ and $-u$ correspond to the structures which are not identical

nor are they mirror-images of one another. An examination of this point position shows that these structures give identical sets of interatomic distances.

For the sake of brevity, we shall make use of the term 'homometric' to describe the relation between two structures which possess the same interatomic distances. For the present, we shall restrict the use of the term to those structures which give the same X-ray diffraction pattern; that is, for two interatomic distances to be considered the same, they must both be terminated by a similar pair of like or different atoms. It follows immediately that identical structures and structures that are mirror-images of one another are homometric to one another. In the discussion which follows, we generalize the term identical to include those structures which are mirror-images of one another as well as those which are identical in the usual sense.

An examination shows that the special point position $O_h^{18} - Ia3d - 24(f)$ also leads to two non-identical homometric structures for positive and negative values of the single parameter; and it becomes important to discuss the frequency of occurrence of this phenomenon. An examination of the subgroups of T_h^{18} and O_h^{18} on the same lattice indicates that there are no homometric pairs of structures, among the special points of one parameter, which can be obtained by a simple change of sign.

No direct method seems to offer itself for the enumeration of the number of possible sets of non-identical homometric structures. For this reason the following brief account of a cursory examination of the problem is presented in the hope that other workers in the field may make further progress. It is obvious that such an enumeration is essential for the complete discussion of the uniqueness of an X-ray crystal analysis, since it is well known that this method can at best determine the interatomic distances.

An examination of the genesis of the homometric property in T_h^{18} and O_h^{18} indicates that it is associated in these groups with the trigonal and the cubic symmetry of these groups. This fact is confirmed by the absence of the property among the subgroups of these space groups. An examination of the special points of the cubic, hexagonal and trigonal system, involving one or two parameters, seems to show that there are no non-identical homometric pairs obtained by a simple change of sign.

A few space groups can be directly eliminated by considering the homogeneity of any point position. In any space group which contains an operation of the second kind, the equivalent points fall into two classes. The set of vectors (A) drawn from any point of the first class to all other points in the cell are enantiomorphous with the set of vectors (A') drawn from any point of the second class. An examination of the two known non-identical homometric pairs shows that in going from one structure to the other the following process is carried out. Each of the two sets of interatomic vectors belonging to the first member of the pair can be split into two halves: A_1 and A_2 , and A'_1 and A'_2 . To construct the second member of the pair, we then combine A_1 with A'_1 , and A'_1 with A_2 , thus arriving at a different structure with the same interatomic distances. It is obvious that such an operation cannot be performed on a group which does not contain an operation of the

second kind, and that the 65 Sohncke groups, therefore be eliminated from consideration. It seems possible to eliminate those space groups which permit only 2, 4 or 6 equivalent points, since at least 4 points are required to establish the presence of enantiomorphism in three dimensions, and does not seem possible to carry out the operation described above on a set of 6 equivalent points. This results in the elimination of a further 44 space groups but it has not proved possible to carry this line of argument further.

Atomic Energy States of an Unusual Type

WHEN examining the vacuum spark spectra of light elements, some rather unexpected lines have been observed, which indicate optical energy states extremely high above the ionization limit, having character approaching that of X-ray levels.

The observations concern the elements from No. (boron) to No. 9 (fluorine), and extend over the wave-length region from 60 Å. to 15 Å. The spectrum in this region should be very simple, only consisting of two series of lines $1s^2S - np^2P$ and $1s^2S_0 - 1s^2P_1^0$. On well-exposed spectrograms we find, however, besides these normal series and a strong intercombination line $1s^2S_0 - 1s^2P_1^0$, a considerable number of additional lines appearing in distinct groups as shown in the accompanying illustration which the groups are marked A, A' and B.

VACUUM SPARK SPECTRUM OF CARBON.

Though at first sight these new lines seem difficult to account for, it is not impossible to find an explanation for them. Beginning with group A, which contains the strongest lines, its position near $1s^2S_0 - 1s2p^2P_1^0$ indicates transitions of essentially the type $1s^2 - 1s2p$. In the first place, one has to consider $1s^2.2s - 1s2p.2s$ and $1s^2.2p - 1s2p.2p$, but the number of observed lines is greater than can be accounted for in this way, one must also include $1s^2.3s - 1s2p.3s$, $1s^2.3p - 1s2p.3p$ or other similar transitions in a three-electron spectrum, possibly also combinations in a four-electron configuration such as $1s^2.2s^2 - 1s2p.2s^2$. The deep terms in the above three-electron transitions are known from the ordinary Li I-like spectra (C IV, etc.); and the

ies limits of the high terms, being normal terms the He I-like spectra, one can predict the location higher series members such as $1s^2.2s-1s\ 3p.2s$ $1s^2.2p-1s\ 3p.2p$. Confirming the explanation of the group A' falls at the position for second ies members to lines of group A. The original spectrogram even shows traces of the third group of same series.

As a consequence of the above explanation, one ist assume the existence of discrete energy levels ng above the ionization limits by amounts up to s times the ionization potential of the same spectrum, in the case of F VII nearly 800 volts ove the ionization limit of F VII. A previously own analogy to these terms are those found by utler¹ in the absorption spectra of metal vapours, igh in certain cases surpassed the ionization limit almost 17 volts.

The lines of group B, approaching the line $1s\ ^2S-^2P$ from the long wave-length side, are undoubtedly analogous to the lines in He I found by mpton and Boyce² and interpreted by them as nsitions of the type $1s.2s-2p.2s$ and $1s.2p-^2.2p$, an explanation which has later been comed by several theoretical calculations³.

We may recall that the X-ray line K α of a free rbon atom may be written as $1s^2.2s^2\ 2p-1s\ 2p.^2.2p$, being essentially the same transition as the sonance line of C V, $1s^2\ ^1S_0-1s\ 2p\ ^1P_1$, at 40.3 Å. he presence of additional outer electrons will duce the field in which the transition takes place, id consequently cause a shift towards longer wave-ngths. The K α of carbon, as observed in various ystal lattices⁴, extends with several maxima from 1.5 to 48 Å. It is then obvious that the lines of roup A with respect to both configuration and wave-ngth take a place intermediate between a true ptical line and the corresponding X-ray line.

Aurora and Geomagnetic Disturbance

In the course of analysis of simultaneous auroral and geomagnetic events at Fort Rae, North West Canada, during the Second International Polar Year, a feature has emerged about which we consider it advisable to make a preliminary report. If the elevation above the horizon of an auroral arc be θ , and if θ be the elevation of a concentrated linear electric current to which the simultaneous vector components ΔH and ΔZ in the geomagnetic meridian field may be attributed, then in seventy cases selected solely on the basis of a substantial magnitude of each of ΔH and ΔZ , θ and ϕ are on the same side of the magnetic vertical plane five times as frequently as on opposite sides.

This result is significant only because Fort Rae is almost under the zone of maximum auroral frequency, where arcs are formed with equal frequency on either side of the zenith.

In 35 per cent of the selected cases, $\theta-\phi$ is less than 10° ; in 60 per cent within 20° . On occasion,

the movement of an arc across the zenith was accompanied by a simultaneous change in the direction of the vertical disturbance vector, indicating a movement of similar sense of the overhead current system responsible for the vector change.

We deduce that, at least in high magnetic latitudes, there is probably a closer spatial association than has hitherto been supposed between the current system which produces the major short-period perturbations in the earth's field and the currents which manifest themselves as auroral arcs at heights mainly between 100 km. and 115 km.

Sensitivity of the Geophone

IN experimenting with a magnetostriction seismometer originally designed for geophysical prospecting, some characteristics of the instrument were observed to be of interest. The geophone, when combined with a suitable amplifier, is capable of yielding a very high sensitivity, yet by itself it is so strong that it can be handled without a clamp just like a piece of metal, and it appears to be a most suitable instrument to study the effect of bomb explosions on buildings, steel structures and shelters. Actually it can be built into the steel structure and placed almost on the site of an explosion.

The geophone consists of a coil and a magnetized nickel rod carrying a weight. Working in combination with an amplifier, consisting of 4 D.C. valves coupled with resistances, and an improved Shire's oscillograph¹, the sensitivity of the instrument is of the same order as Jones's seismometer², one of the most sensitive portable instruments existing.

The accompanying plate is a record of these two types of seismometers placed side by side recording the same 'earthquake', which was produced by the dropping of a 20 gm. mass from a height of one metre on to a carpet-covered concrete floor about 20 ft. away from the instruments. Being an accelerometer, the new instrument shows a much sharper onset in its record. The natural frequency of the magnetostriction instrument is extremely high. Its oscillation is damped down by internal friction so rapidly that it is not detectable by the camera. In another model, a mechanical lever has been used which increases the sensitivity 30-50 times further.

Digestibility of Straw

STRAW contains large quantities of carbohydrates, which can only be partially digested by farm animals. Various attempts have been made in the past to increase the digestibility of straw by some pre-treatment.

In Great Britain, Godden¹ carried out some preliminary work with soda in 1920, and states that "There is obviously need for much further investigation of the possibilities of soda treatment before a final opinion can be expressed as to its merit for introduction into farm practice".

In the course of a wide investigation of the problem, we have treated oat- and wheat-straws with caustic soda solutions of varying strengths and for different lengths of time.

Our best results were obtained with a concentration of soda of the order of 1.25 per cent with an immersion period of 20-24 hours without any heating. With the volume of solution used, this represented 10 lb. of caustic soda per 100 lb. of straw. Weaker solutions were not so effective, even if the time of immersion were increased. Of the 10 lb. of caustic soda there is a recovery of 40-50 per cent, which can be made up to the correct level for subsequent batches.

The treated straw is easily washed with water, and is then readily eaten by ruminants.

The process seems to depend upon the breaking down of the lignin-cellulose complex to such an extent as to allow of more complete utilization of the material in the paunch than is possible with the untreated straw.

The effect of treatment is shown by the following preliminary figures for the starch equivalent values of treated and untreated straw, calculated from the digestibility data obtained in metabolism experiments with sheep.

	Lb. starch equivalent per 100 lb. straw	
	Treated	Untreated
Oat straw	42.1	21.7
Wheat straw	32.0	13.0

The process is simple in operation, and is now being used on our farm. Treated oat straw fed to fattening bullocks and supplying 7.4 lb. of starch equivalent out of a total of 11.8 lb. has resulted in a daily live-weight gain of just under 2 lb. over a period of 62 days. The animals are in prime condition and ready for the butcher.

Importance of Cytochrome B in Hydrogen Transport

It is quite definitely known¹ that dihydrooxymase can be oxidized by molecular oxygen in the presence of diaphorase I plus the 'cytochrome system', but the nature of the cytochrome reaction has not been clearly demonstrated. On the basis of the experiments reported here, we believe that both cytochrome B

and cytochrome C are required for the oxidation of both CoH₂I and succinate.

Using spectrophotometric technique, we have shown that the rate of oxidation of 60 γ of CoH by a preparation poor in cytochrome C was double when 4×10^{-6} mols of pure cytochrome C were added. By measuring the rate of cytochrome reduction in the presence of sufficient cyanide (10^{-6} mols per ml.) to block completely the action of cytochrome C oxidase, it was possible to show that CoH₂I would reduce cytochrome C rapidly in the case of a fresh enzyme preparation, and not at a or only slowly in the case of an acid-precipitated dried enzyme used in amounts which contained the same quantity of diaphorase I (as shown by the CoH₂I plus methylene blue reaction).

That the missing compound in the dried preparation might be cytochrome B was indicated, among other things, by the fact that the reduction of cytochrome C by CoH₂I in the presence of the free preparation is prevented by strong cyanide (10^{-6} mol per ml.). This is also the case when succinate is the hydrogen donor, and can be demonstrated spectroscopically or visually, using 10^{-7} mols of cytochrome C as the final reduced product. The degree of cyanide toxicity is undoubtedly affected by the enzyme concentration. The fresh enzyme mentioned above contained 3.5 mgm. per ml.

It seems possible that the missing component in the succinoxidase system described by Hopkins, Lutwak-Mann and Morgan² may include cytochrome B. Details and implications of our experiments will be reported later.

Temperature Activation of the Urease-Urea System

THE activity of several enzymes (for example yeast and malt invertase¹, and *E. coli* dehydrogenase²) has been shown to increase exponentially with temperature according to the Arrhenius equation,

$$K = Ze^{-\mu/RT},$$

where K is the rate, Z is a constant, e is 2.718, R is the gas constant, T the absolute temperature, and μ the energy of activation of the reaction in calories per gm. mol.

Hitherto, no comparison has been made of temperature activation of an impure and a highly purified enzyme. A study was made of the hydrolysis of 1.5 per cent urea in phosphate buffer at pH 7.0 using both crude and crystalline Jack bean urease³. The reaction was followed by measuring ammonia formation colorimetrically after Nesslerization, or carbon dioxide evolution volumetrically using the Barcroft differential manometer. For either crude or crystalline urease the rate of urea hydrolysis increases with temperature in accordance with the Arrhenius equation, where $\mu = 8,700$ or 11,700 cal. over the whole temperature range up to the inactivation temperature, or $\mu = 11,700$ below and 8,700 above a critical temperature of about 22° C. When urease is dissolved in water or in reducing or indifferent solutions, $\mu = 8,700$, but when dissolved in oxidizing solutions, $\mu = 11,700$. The activation energy seems

depend upon the oxidation-reduction potential of the digest. When the potential was adjusted with varying proportions of ferri- and ferrocyanide it was apparent that with an E_h above +0.46 v., $\mu = 11,700$, below +0.42 v., $\mu = 8,700$, and between +0.42 and +0.46 v., $\mu = 11,700$ below and 8,700 above the critical temperature.

It is suggested that the energy of activation of the urease-urea system is determined in part by the configuration of certain essential radicals such as the ulphydryl groups in the enzyme molecule. When such structures are in the reduced condition, $\mu = 8,700$, but when oxidized, $\mu = 11,700$. The change from the reduced to the oxidized form is reversible and is accompanied by this shift in temperature characteristic.

The temperature characteristic of 20,800 for soy bean urease is listed in most text-books. This value was calculated by Euler³ from the data of Van Slyke and Cullen⁴ and is incorrect. Recalculations indicate a value for μ of 11,700; this is identical with one of those obtained with Jack bean urease. It is apparent that the activation energy is independent of the source and purity of the urease, but does shift in a predictable manner with the oxidation-reduction potential of the digest.

Vitamin C Sources in Eskimo Food

It is the general experience among arctic explorers that when they 'live of the land', scurvy never occurs. Stefansson¹, who directed attention to this fact, cured three cases of scurvy with reindeer meat.

A Norwegian scientific expedition to Angmagssalik was made during 1936-37 for the purpose of examining nutrition, metabolism, physique and health of Eskimos. The accompanying table shows the vitamin C content of the available food. The numbers are means of at least two observations. We used the method of Emmerie and van Eekelen².

It must also be mentioned that 'mattaq' (epidermis of whale) which Bertelsen³ especially has pointed out as a good antiscorbutic remedy, contained 20 mgm. ascorbic acid per 100 gm. (from narwhal). In skin of young seals from the coast of Norway we found such enormous amounts as 180 mgm. per 100 gm.

It is well known that marine algae are used as food in Japan, China, Hawaii, and some algae are eaten on Iceland and on the coast of certain parts of Great Britain. The Eskimos eat them raw or dipped in boiling water (or broth) or with blubber oil. From this source, the Angmagssalik Eskimo get 50 per cent of their vitamin C.

The other 50 per cent is mainly obtained from organs of mammals and birds and also from fish. On an exclusive lean meat diet one gets about 25 mgm. vitamin C a day, even when the meat is boiled. By boiling, 50 per cent is extracted or

oxidized. If the broth also is used, one gets nearly 40 mgm. a day. This agrees with the experiences of Stefansson¹.

VITAMIN C (L-ASCORBIC ACID) IN COMMON ESKIMO FOODS

(Mgm. per 100 gm.)

FJORD SEAL (<i>PA. fastus</i>)		GUILLERMOT (<i>Ursus gryllus</i>)	
Adrenals	127	Liver	22
Thymus	20	Brain	16
Liver	18	Eye	9
Central nervous system	18	Intestine	5
Epithelium	17	KIDNEYDUCK (<i>Sonastoria melano-</i>	
Kidney	13	riae)	
Eye	10	Liver	17
Lymph gland	7	Eye	14
Pancreas	7	Brain	9
Ovary	7	Intestine	4
Skin	3	INVERTEBRATES	
Small intestine	3	Sea mussel (<i>Mytilus edulis</i>)	0
Blood	2	Crayfish sp.	3
Meat	2	COD (<i>Gadus callarias</i>)	
Heart	0	Liver	8
Blubber	0	Meat	2
Other organs (average)	1	Roce	44
PLANTS		Cod liver oil	0
Rosewort (<i>Sedum roseum</i>)	27	MARINE PLANTS	
Mountain willow (<i>Salix</i> sp.)	18	<i>Alaria</i> sp.	45
Dandelion leaves (<i>Taraxacum officinale</i>)	15	<i>Rhodomyrtus palm</i>	17
Angelica (<i>Archangelica officinalis</i>)	14	<i>Fucus</i> sp.	13
Craikberries (<i>Empetrum hermaphroditum</i>)	9	<i>Ascoplyllum nod.</i>	11

In the opinion of one of the authors (A. H.), who has been on sledging journeys of long duration in the Arctic, less than 15 mgm. ascorbic acid a day effectively prevents scurvy.

The Angmagssalik Eskimo get a daily average dose of about 40 mgm. per adult. In agreement with this finding, scurvy is unknown among Angmagssalik Eskimos.

A detailed report on the results of the work of the expedition will appear in a book this autumn.

Hormone from the Human Corpus Luteum of Early Pregnancy

THE human corpus luteum of pregnancy is cystic up to the fourth month of pregnancy. The fluid content of the luteal follicle may be as much as 1.5 c.c.

The action of single doses of the luteal fluid (0.5-1.0 c.c.) is different from progesterone ('Proluton', Schering).

The luteal fluid causes deturgescence to supervene in three stages whereas progesterone produces a sudden type of deturgescence; perineal rest is attained twelve days after the injection of luteal fluid whereas with progesterone the perineum returns to rest in five and not later than seven days; the perineal rest induced by luteal fluid lasts 10-11 days, but in the case of progesterone perineal rest is transitory and is over in twelve hours; the effects of luteal fluid are maintained for 20-21 days whereas progesterone does not act longer than seven days.

Progesterone in doses greater than 3 mgm. and less than 20 mgm. prolongs the cycle by 3-9 days whereas the luteal fluid shortens the cycle by 6-8 days.

In virgin rabbits, 0.1 c.c. of the luteal fluid administered intravenously leads within 48 hours to gross enlargement of the uterus (five times the normal), great enlargement of the follicles on the ovary some of which may contain blood, and a great increase in the interstitial cells.

An ether extract of the luteal fluid equivalent to 0.05 c.c. of luteal fluid injected intravenously into a virgin rabbit causes a great increase in the interstitial tissue of the ovary without any effect on the follicles, and the uterus is enlarged to three times its normal size. The fluid not soluble in ether leads to cystic change in the follicles of the rabbit's ovaries, scarcely any action on the interstitial cells, and the uterus is only slightly increased in size.

Progesterone represents probably only a part of the luteal hormonal complex, its chief action in the baboon being that of causing vascular alterations in

the uterine stroma and the perineum after these organs have been sensitized by oestrone. In the rabbit, progesterone causes progestational changes in the previously oestrone-sensitized uterus. The luteal fluid not only affects the uterus and perineum in the baboon but also the ovaries and perhaps even the pituitary. In rabbits both the ovaries and uterus are profoundly affected.

For these several reasons, we are of the opinion that the luteal fluid of the corpus luteum of early pregnancy contains one or more hormones which have not been identified hitherto, and which we suspect to be the true hormone or hormones of the human corpus luteum of early pregnancy.

Points from Foregoing Letters

A MECHANICAL device for eliminating the computations involved in obtaining a smooth curve, from a set of data such as the annual distribution of rainfall, is described by T. Sohumann. The device consists essentially of a vertical wooden board to which are attached movable glass cylinders filled with mercury in which iron rods are floating. The author gives the theory underlying the mechanical process involved and suggests that the device may be useful in dealing with economic and industrial data.

The Svedberg and Sven Brohult state that irradiation of haemocyanin, haemoglobin and serum albumin with ultra-violet light and α -rays, both at room temperature and at the temperature of liquid air, has shown that in the case of haemocyanin the effect (splitting into half-molecules) is a primary reaction while in the case of the two latter proteins the (rather irregular) breakdown is mainly caused by secondary reactions. The amount of haemocyanin dissociated by a certain number of α -particles can be accounted for upon the assumption that each molecule struck by an α -ray is split into halves.

H. von Halban, jun., F. Joliot and L. Kowarski show that secondary neutrons liberated in uranium irradiated with thermal neutrons can communicate to oxygen nuclei, in an oxygen-filled ionization chamber, a recoil energy of about 2.5 Mev.; the secondary radiation must, therefore, contain neutrons possessing an energy of at least 11 Mev.

In connexion with 'homometric' structures (which give the same X-ray diffraction pattern), A. L. Patterson discusses two point positions each of which leads to two non-identical homometric structures for positive and negative values of a single parameter. He inquires into the genesis of the homometric property, which appears to be associated in these cases with the trigonal and the cubic symmetry of the groups.

In the vacuum spark spectra of light elements certain groups of lines have been observed by B. Edlén and F. Tyrén which do not fit in the ordinary series spectra, but indicate atomic energy states of an unusual type very high above the ionization limit of the corresponding ion, approaching in their character X-ray levels.

J. M. Stagg and J. Paton consider that near the zone of maximum auroral frequency the electric current systems responsible for surface geomagnetic disturbance and those manifested as auroral arcs may be more closely associated spatially than hitherto supposed.

That the effect of bombs and explosions upon buildings and shelters can be suitably studied by means of the 'geophone' (a seismometer consisting of a coil and a magnetized nickel rod carrying a weight) is suggested by Weng Wen-Po.

R. E. Slade, S. J. Watson and W. S. Ferguson find that by treatment with cold dilute caustic soda solution the feeding value of oat straw can be increased by 100 per cent and that of wheat straw by 150 per cent. The digestibility of the product has been determined by experiments on sheep, and bullocks have been fattened for the market with the treated straw.

V. R. Potter and E. E. Lockhart suggest that both cytochrome *B* and cytochrome *C* are required as intermediate carriers for the oxidation of dihydro-coxymase and succinate by molecular oxygen and the appropriate enzymes.

I. W. Sizer states that the activation energy of the urease-urea system is independent of the enzyme purity when crude Jack bean meal was compared with the crystalline enzyme prepared from this source. The activation energy is determined by the oxidation-reduction potential of the digest.

It is pointed out by A. Heygaard and H. W. Rasmussen that arctic primitive foods are good sources for vitamin C and a table is given showing the vitamin C content of the most common Eskimo foods. On average diet the Angmagssalik Eskimo daily gets 40 mgm. ascorbic acid per adult. 20 mgm. is obtained from eating marine algae. Scurvy is unknown among Angmagssalik Eskimos.

The presence in the human corpus luteum of early pregnancy of one or more hormones distinct from progesterone is indicated, according to J. Gillman and G. Spence Smyth, by the distinctive action of the luteal fluid upon the uterus and the perineum.

Research Items

Prehistoric Pottery in Southern Africa

THE material from the excavation of the Mumbwa Cave, Northern Rhodesia, considered essential for the elucidation of the prehistory of South Africa, with the exception of part of the collection associated with the deeper burials, and the human skeletal remains, was destroyed by fire in the Ethnological Museum of the University of Witwatersrand. The excavators, Prof. Raymond Dart and N. del Grande, recorded in 1931 that pottery occurred in all the levels, though only sparingly in the deeper, down to the very base of the Late Stone Age deposits at a depth of two metres. It is the fragments from these deeper levels which survive, and have now been described and discussed further by L. W. Wells (*Man* of May, 1939). Not only do these fragments show that the pottery of the deeper levels was homogeneous, but also comparison with photographs of the pottery of the higher levels indicates an identity of characteristics and strong evidence for community of types between all levels. This agrees with the homogeneity of the lithic culture, and the continuity of the associated skeletal remains. The Mumbwa pottery holds an isolated position among African ceramics. It is of a type which, if found unassociated, would have been classified as Bantu; but as it is associated with a well-characterized lithic and human skeletal remains of predominantly Bush-Boekopoid character, devoid of recognizable Negro feature, it must be regarded as an integral part of a stone age culture, and the work of a non-Negro, pre-Bantu people—a conclusion of the highest importance, as hitherto it has been presumed that all unglazed pottery was of Bantu origin.

Desensitization through Histamine

L. FARMER (*J. Immunol.*, 36, 37; 1939) finds that the uterine strips of serum-sensitized guinea pigs which had been given injections of histamine at the height of sensitization were less sensitive to the specific antigen than were the sensitized uterine strips of control animals, while the uterine strips of normal guinea pigs which had received injections of histamine were less sensitive to histamine than were the uterine strips of the untreated controls. These experiments suggest (1) that histamine was the substance responsible for the anaphylactic contraction of plain muscle; (2) that it was possible to desensitize sensitized guinea pigs non-specifically by injection of histamine. In conclusion, Farmer points out that the phenomena observed were a further indirect proof of the correctness of Dale's theory of the anaphylactic mechanism, and that they also furnish a basis for understanding the mechanism of the non-specific desensitization by histamine.

Adrenals and Salt Intake

C. P. RICHTEB (*Endocrinology*, 24, 367; 1939) has found that the salt taste threshold of twenty normal rats averaged 0.055 per cent, that is, the animals detected salt in solutions of approximately 1 part of salt to 2,000 parts of water. Removal of the adrenals in eight rats greatly reduced the salt taste threshold.

It averaged 0.003 per cent; in other words, the animals distinguished between water and salt solution in a concentration of 1:33,000. The adrenalectomized rats showed a craving for salt offered in amounts which could not possibly have had a beneficial effect. The results show that adrenalectomized rats ingest more salt, not because they learn that salt relieves their deficiency discomforts, but because of chemical changes in the taste mechanisms in the oral cavity, giving rise to an enhanced salt discrimination.

Reproduction of 'Immature' Salmon

RECENT researches have directed attention to the occurrence of occasional examples of salmon parr which develop ripe gonads in fresh water without having made that descent to the sea which has generally been considered a prerequisite to reproduction. The observation is no new one; Rondelet, and after him Gosner, discussed it in the sixteenth century, and in 1886 the British naturalist Willughby came very near the mark in stating that while the male parr could fertilize the eggs of adult salmon, the female parr never had ripe eggs. Dr. V. Tchernavin has brought together references to papers dealing with the subject (61 in all) and very briefly summarizes the main results (*Proc. Roy. Physical Soc. Edinb.*, 23, 73; 1939). Both male and female parrs before descending to the sea may produce ripe germ cells, but the occurrence is much rarer in the female and at a more advanced age. Such male parrs take part in spawning with females which have already returned from the sea journey, and they have been known to spawn twice before leaving fresh water. Moreover, males and females of migratory salmon retained in fresh water develop functional gonads and produce progeny which in their turn are fertile.

Distinguishing Races of *Drosophila pseudo-obscura*

RACE A and Race B of *Drosophila pseudo-obscura* produce sterile male hybrids when crossed. They react differently to different ecological habitats and are differentiated by many of the criteria used for species differentiation. Nevertheless they are remarkably similar in morphological appearance and can only be separated easily by examination of their salivary gland chromosomes. K. Mather and T. Dobzhansky (*Amer. Nat.*, 73, 5; 1939) have shown by statistical analysis that the two races may be distinguished by the number of teeth on the sex combs of the males. Race A males have a mean number of teeth of 6.46 and 5.32 teeth on the proximal and distal sex combs respectively, whereas race B have 5.55 and 4.72 respectively. These are shown to be significantly different and the difference is shown to persist under different environments. The authors show that mathematical treatment is necessary to distinguish race A from race B by external characters.

Wood Wasps and their Parasites

H. S. HANSON has recently published an interesting article on this subject (*Bull. Entomol. Res.*, April, 1939). As a member of the staff of the Imperial

Institute of Entomology, he has been engaged on a study of these insects in connexion with a request for parasites of the wood wasp, *Sirex noctilis*, which was rapidly increasing in the coniferous forests of New Zealand. The accidental entry of the *Sirex* into the last-named country has led to a major problem in forestry, and the most feasible method of control seems to be by means of the introduction of certain parasites. Of the latter the most important is the large ichneumon *Rhyssa porusator*, while second in value is the cynipid *Ibalia leucopoides*. Under normal forest conditions, *Sirex* has never been known to become a pest in Britain owing to the control exercised by parasites. While *Rhyssa* is the superior insect as a parasite, *Ibalia* has also received much attention. The combined attacks by both species of parasite result in a higher percentage of host mortality than when either species is acting alone. *Rhyssa* is now established in New Zealand, but no attempt has so far been made to establish the *Ibalia*, which presents certain features making it more difficult to achieve. The method of biological control may be reasonably expected eventually to prove effective and give the desired results. It needs, however, to be carried out on an adequate scale over a period of years. As compared with sylvicultural methods of control it is vastly cheaper, and probably, in the long run, of greater value.

Blister Rust of White Pine in America

MANY years ago the European black currant (*Ribes nigrum*, L.) was introduced into the United States; but now it has been declared a public nuisance, and its cultivation prohibited by statute over a wide area. The reason for this (described in Leaflet 175 U.S. Dept. Agric.) is that the currant and gooseberry, especially the cultivated forms, serve as the alternate host for *Cronartium ribicola* Fischer, which causes blister rust disease of white pine. The fungus is perennial on the pine, living in the bark and wood of infected trees. In the spring spores are produced, which can be carried long distances by the wind, and after a period of growth on the currant or gooseberry, the life-cycle is completed and another type of spore capable of infecting the pine is produced. The disease is a serious menace in white pine plantations, and it attacks trees of all sizes, though resistance seems to increase with age. The pine is of great economic importance, being valued for scenic, recreational, soil retention and watershed purposes. Fortunately there is little demand for black currants on the fruit market, and the excellent progress made in the control of blister rust in those areas where these shrubs have been removed, bears out the wisdom of the new legislation.

Sterility in the Gage and Desert Plums

It is generally considered that the gages and several varieties of desert plums are inherently poor croppers and commercially unprofitable. Consequently little attempt has been made to grow them on a large scale. The recent work of M. B. Crane and A. G. Brown, however (*J. Pom. and Hort. Sci.*, 17, 51; 1939), has shown that the greengages and the majority of desert plums have the capacity to crop heavily if they are effectively pollinated. Complete self-incompatibility is common among these varieties, whilst many are only partially self-compatible. Bryanston Gage, Coe's Golden Drop and Transparent Gage are among those which fail completely to set fruit with their own pollen. Some kinds, however,

such as Laxton's Gage and Early Transparent Gage are self-compatible and also act as effective pollinator for other varieties. Among the wholly and partially self-incompatible varieties, cross incompatibility occurs; both complete and in degree. Sometimes it is reciprocal, but it may occur in one direction of crossing only, the reciprocal pollination yielding a full crop of fruit. For successful cropping, suitable varieties should be planted together to ensure effective pollination. Varieties in the same incompatible group and varieties whose flowering times do not coincide or overlap appreciably should not be planted together. The authors have provided data in this respect for an exhaustive list of gages and desert plums.

Geological Terminology

THE attention of geologists is directed to a most valuable "Lexicon of Geologic Names of the United States" compiled by M. Grace Wilmarth, which has just been published by the United States Geological Survey as *Bulletin* 896 (Part 1, A-L, pp. 1-1244; Part 2, M-Z, pp. 1245-2396). The definitions state briefly the lithology, thickness, age, underlying and overlying formations, and type locality, together with references. Most names have only one entry, which is essentially a digest of the original definition, as in most cases the original definitions are those still in current use. Some names have several entries, corresponding to redefinitions that have been suggested from time to time, while a few have had a long and interesting history, necessitating brief mention of the views of the geologists who have contributed towards present usage. Where there is disagreement as to definition or age the divergent views are fairly summarized. The time terms have also been listed, but the full definitions of the era, system and series terms having been already given in *Bulletin* 789 (1925), only brief definitions of these are given in the "Lexicon", with references to the earlier publication. The stratigraphical papers on which the "Lexicon" is based are those up to the end of 1935, together with some published in 1936. The compiler's hope that these volumes will "prove a time saver for the busy geologist" is certain to be realized—and not only in the United States.

Low Gas Pressure Measurement

MANY of the devices for measuring low gas pressures depend for their calibration on comparison with a McLeod gauge, and any improvement in the accuracy of this gauge is a distinct gain. Dr. Paul Rozenberg, of Columbia University, New York, has with assistance from the Adams Fund for Physical Research, succeeded in increasing the accuracy of the gauge considerably (*Rev. Sci. Instruments*, April 1939). The principal improvements he introduces are: the roughening of the bore of the capillary tubes, the sealing of the closed capillary in such a way that the outside of it remains cylindrical above where the bore terminates, the more accurate estimation of the change of volume of the bore due to sealing, bringing the mercury in the open capillary up to the level of the end of the closed one for reading, and the support of the mercury bulbs by plaster casts to avoid stresses in the glass. At pressures of 10^{-2} , 10^{-3} , 10^{-4} and 10^{-5} mm. of mercury he claims accuracies of 0.2, 0.6, 2 and 6 per cent respectively, and points out that these are higher than those of the absolute micro-manometer at pressures below 5×10^{-3} mm. and of the Knudsen absolute manometer above 10^{-4} mm.

Science and Social Problems

THE first meeting in London of the British Association's new Division for the Social and International Relations of Science was held in the Royal Institution on May 25. Sir Richard Gregory presided and in his introductory remarks sketched the genesis and adumbrated the programme of the new movement. Co-operative work in the special sciences was carried out for sixteen years by the International Association of Academies, and then by the International Council of Scientific Unions, which was formed during the Great War and is still active. Two years ago, on the initiative of the Royal Academy of Amsterdam, an entirely new outlook was adopted by including within the scope of the Council the social significance of the applications of science, thus endorsing the conviction of many that scientific workers can no longer remain indifferent to the social consequences of their discoveries. No definite programme of work has yet been formulated, but the essential idea is to apply the scientific method of inquiry to problems arising from the interactions of natural science and society. The British Association, acting in co-operation with its sister association in America, and through its new Division, is well adapted to promote such inquiries, and with this object in view it is arranging to hold meetings not only at the time of the annual meeting of the Association but also at other times and places as occasion may arise.

Dr. Ernest Barker, professor of political science in the University of Cambridge, then gave an address on "The Impacts of Science on Society". Natural science acts on society in two main ways: first, by developing a special science, or a body of social sciences, explaining society as a natural phenomenon, and thereby helping it to control itself consciously; and secondly, by producing discoveries and inventions which indirectly affect social behaviour and the general structure and functioning of society. The first way is mainly that of the biological sciences. To-day we do not see society as an engineering contrivance based solely upon matter and motion, but as something organic and vital, which evolves, and whose parts are permeated with interflowing dependence. This view has not only profoundly influenced the study of history, the study of law, and the criticism and understanding of art, but also it has altered our outlook on society itself. A society that interprets itself in biological terms behaves differently in virtue of that new interpretation; the difference may work for evil as well as for good—for example, in the direction of a perverted nationalism,—but the application of general biology to human society is not condemned by the possibility, or the fact, of misapplications.

The second way of action is one both of physical and chemical science and of biology. Physics and chemistry have revolutionized the methods and pace of communication, both material and mental; they have revolutionized industrial production and the art of war. The changes thus brought about are greater than the changes due to political causes. Should science attempt to control the changes which it causes? In Prof. Barker's view, science must proceed with the single regard of discovering truth;

if progress were stopped, an evil might be averted but a greater good might be missed; the utmost concession is a slowing down of the impact. It is the business of society, through its leaders, to control the effects, and the one duty of the man of science is to contribute the resources of his own training and technique to the making of a proper and exact estimate of the nature of the changes and of the nature of the relevant remedies.

Biology differs from physics and chemistry in its influence on society, in that its discoveries can be applied most directly, most intentionally and most fruitfully, through the soil and through plants and animals, to the relief of man's estate. The discoveries of genetics and eugenics can improve the strains of plants and animals and the human breed itself. But the improvements arrive very slowly owing to the impediments offered by human nature: "sentiments that team with embarrassing anachronisms, of which we are usually unconscious", embedded habits, traditions, instincts and emotions. Therefore the conscious application of science to the improvement of life will always be a slow-motion picture; the delay, however, may enable science to become sure of its discoveries before they are applied, and thus produce a greater security both of scientific and of human progress.

Sir Daniel Hall, unlike the previous speaker, discussed a concrete theme: "How the application of science to agriculture is impeded". It is necessary, he said, to distinguish between peasant farming, which is virtually self-contained and independent of world markets, and agriculture regarded as an industry, which can look to science for increasing, improving and cheapening its production. There is much peasant farming still in England, where 61 per cent of holdings belong to the 1-50 acre class, and upon which there is relatively little scope for scientific improvements. On farms of all types and sizes there is an average of one master to four or five workers, so that even the larger units of production are very small compared with the units of great urban industries. This fact, together with its consequences, lack of prospects for educated youths without capital, discontinuity of effort, and lack of capital, restricts the application of scientific developments. The importance of time-lag between preparation and production is sometimes exaggerated, but the handicap may be very serious when falling prices intervene. A greater handicap is that of variable weather, which may necessitate waiting for five years or more before the costs of production of a crop can be determined.

The adoption of inventions in machinery is limited by the small size of the farming units; the use of combine harvesters and crop driers is out of the question on most English farms. Equally impracticable are many large works of land improvement and organisation, which affect areas beyond the ownership of a single proprietor, but which science indicates would be practicable on a large scale and a long view. The retail structure of agriculture also precludes the exploration of scientific discoveries and inventions, because there are no great agricultural producers to act as intermediaries in translating a laboratory into a large-scale process.

Basic research is outside the farmer's scope, but he can put into practice some of the findings of research organizations; for example, those relating to the effects of fertilizers, improved yields of new varieties or stock, and disease treatment. State intervention is needed in many fields to secure the prosecution of research for the benefit of agriculture, and to make known its results. If increased and cheapened production is regarded as a necessity in the modern State, intervention of another kind is needed to free agriculture from some of the limitations imposed by its present structure; failing that, there is danger that the factory will replace the farm in the production of essential commodities.

The meeting was very well attended, and at the close Prof. A. Ferguson referred to possible research work that might be undertaken by the Division, such as a study of the development of nationalistic feeling, and the history of Western thought. Such interesting and important studies would be welcomed by many,

but it may be suggested that they should not take precedence over the essential task of attacking concrete problems in a scientific way. Sir Daniel Hall's remarks on the necessity for State intervention in agriculture suggest that a suitable study would be the very old, but still very important, question of land tenure, of public control of the land and its utilisation. Such a study, it might be objected, would inevitably lead to 'impact', that is, collision, with politics, but it need not be treated in a politico-controversial way. What is needed are the reasoned judgments of trained scientific workers, who have no economic, political, social or other axes to grind, who are capable of submerging the embedded sentiments, of which Prof. Barker spoke (except that of justice), and above all, who will take the vow of placing the common good above all the lesser loyalties, like political party, social class, and the 'old school tie'.

Hydrogenation

DURING May 24-26, a conference was held in Paris under the auspices of the five chemical societies which share the amenities of the *Maison de la Chimie* there. The selected subject was the various aspects of hydrogenation. This is the second occasion on which the same five societies have co-operated. An average attendance of more than three hundred was attracted. The meetings commenced at 4.30 in the afternoon, so enabling the participants to go about their ordinary affairs during the working day. The chief figure at the meeting was Prof. Sabatier of Toulouse, still hale and hearty at eighty-four years of age: his original researches are recognized as having given the first impetus to the study of all subsequent hydrogenation reactions, some of which are technically in the forefront of world interest to-day. The presidents of four of the societies presided in turn over the sittings.

The conference appropriately began with a paper from Sabatier, largely of an historical nature, relating to the addition of hydrogen to unsaturated compounds in presence of nickel. Prof. Paul followed with an account of the Raney nickel catalyst. The evening discourse delivered by Prof. Aubel, of Paris, dealt with the general phenomenon of hydrogenation in biology. On the next afternoon, Prof. N. V. Ipatieff, who now holds a chair at the Northwestern University of Chicago, spoke on the use and advantages of copper and copper chromium catalysts for the hydrogenation of benzene and its derivatives, describing work which

is being followed with considerable interest. The following paper was delivered by Dr. E. F. Armstrong, who dealt fully with the technical and industrial development of hydrogenation, first in regard to fat hardening, which has now largely become standard practice; afterwards he indicated the methods of manufacture of hydrogen and the approximate cost of this gas, describing also the line of attack which is being followed in the conversion of water gas into petroleum hydrocarbons, and of coal, under pressure, into methane.

At the conclusion of the meeting, Messrs. Ipatieff and Armstrong were each presented with a Chevreul Medal in recognition of their labours in their respective fields of inquiry. The meeting ended with a banquet held in one of the large lecture rooms of the *Maison de la Chimie*, which readily lent itself to this conversion and was provided with the necessary auxiliary accommodation behind the scenes. The excellent facilities provided here for our French colleagues are the cause of renewed admiration and envy on every occasion we avail ourselves of them. They enabled a first-class banquet with wines to be staged for the modest charge of 60 francs.

The third day was primarily concerned with the official celebration of the twenty-fifth birthday of the *Société de Chimie Biologique*, but even here the role of active hydrogen was not overlooked, being made the subject of a paper by Prof. Thunberg of Lund.

Work of the Cornish Engineers

IN the form of a reprint from the *Journal of the Royal Institution of Cornwall*, there has been published at the Royal Printeries, Truro, a paper by W. Tregoning Hooper entitled "The World's Debt to Cornish Engineers", one of the aims of which is to commemorate the historic experimental trials of the Austen's 80 in. Cornish pumping engine. At these trials, this engine established a record of accomplish-

ment which demonstrated to men of science, engineers and economists the great potentialities of the power of steam, and the occasion is, therefore, a fitting one to be recalled and celebrated.

In the year 1835, in collaboration with his chief engineer, West, Joseph Thomas Treffry erected a new 80 in. engine and it was stated to have done a duty of nearly 98 million foot-pounds of work per

bushel of coal (94 pounds). This claim was disbelieved and a special trial was arranged to take place before a number of competent and impartial engineers and pitmen. When it was held on October 22 and 23, 1835, the results showed the actual duty performed by the engine to be 125,095,713 ft. lb. This is the highest performance of any Cornish pumping engine, and the most remarkable fact about it is that it was rather more than six times as great as the work done by the best of Watt's engines.

The author of the paper explains the developments which led to this striking result. Newcomen of Dartmouth, working on the ideas originated by Papin, produced his atmospheric engine—the first practicable and effective steam engine to be brought into use. In 1720 he erected at Wheal Fortune, Ludgvan, the first engine in the county of Cornwall of which there is authentic record, and its marked success proved it to be suitable for the drainage of Cornish mines. Newcomen was followed by several members of the Hornblower family, to one of whom the invention of the compound engine is due, the first engine of this type being made in 1776 at Penryn. From this time until the expiry of Watt's patent or monopoly in 1800 there was a pause, and then began a new era of progress, one of the early results being the invention by Trevithick of the Cornish boiler, the construction of which has remained unaltered to this day. Its introduction must have contributed greatly to the success of the Cornish

engines which were being installed in the mines in replacement of the much less economical Watt engines.

Doubts continued to be expressed as to the performance of the Cornish engines and one engineer "proved by theoretical principles that the highest possible duty that such engines could do was only 44,000,000". Wicksteed, principal engineer of the London Waterworks, carried out further trials and it was found that, in practice, the Cornish engines and engines were exceeding this figure by more than one hundred per cent. In addition to many other interesting details regarding these engines, the paper gives accounts of their adoption in many parts of the country and abroad, notably for the drainage of the Haarlemmer Meer in Holland. One of these engines has recently been placed in a state of preservation by the orders of the Dutch Government. Many items of special interest to engineers are touched upon, such as Trevithick's intuitive perception of the principles of thermodynamics—a subject on which in his time nothing was experimentally known. In his correspondence with Gilbert, his remarks show how far he had anticipated the principles which were definitely established by Carnot many years later. The author concludes with a plea for the support of the Committee for the Preservation of Cornish Engines so that it will be enabled to preserve for all time some of those splendid engines which still remain as monuments to the Cornish engineers.

Psychological Treatment of Crime

THE report to the Home Office on "The Psychological Treatment of Crime", by Dr. Norwood East and W. H. de B. Hubert deals with an investigation carried out over a period of four years by a retired prison medical officer and prison commissioner, and an assistant physician in the department of Psychological Medicine at St. Thomas's Hospital and psychotherapist at Wormwood Scrubs Prison*.

The selection of cases for treatment depended, in the first place, on prison medical officers, who were invited to send in reports about prisoners whom they considered suitable for psychological treatment. Such reports, together with any relevant information available, were first examined by the senior investigator, and prisoners selected by him were transferred to Wormwood Scrubs. Here each case was first studied by the senior medical officer of the prison, and then by him in consultation with the senior investigator before determining the treatment. This procedure, it is stated, was found effective and satisfactory. Nevertheless, it is possible that the inquiry might have taken a different course had a psychologist been consulted earlier. The individuals chosen were mostly those who had failed, or seemed likely to fail, to respond to ordinary discipline and training, but who yet showed willingness to co-operate with the psychotherapist; no general classification, however, determined the selection of any case, since personal factors were always given careful consideration.

* Home Office. Report on the Psychological Treatment of Crime. By Dr. W. Norwood East and W. H. de B. Hubert. Pp. III+166. (London: H.M. Stationery Office, 1939.) 2s. 6d. net.

No reason is given for the fact that the experiment was restricted to youths and men, though one of the investigators at least found it necessary to extend his research in one instance to a control group of women prisoners. Among their recommendations, the investigators include the appointment of a woman psychotherapist at a prison for women. Of the interesting facts that emerge in the course of the report are several that point to the need for early diagnosis and guidance; among boys sentenced to detention at a Borstal institution but deemed unlikely to benefit from their experience without previous treatment, there were a surprising number who had been sent to an institutional school on account of misbehaviour in early life. Another group of ex-Borstal boys afterwards committed to prison and recommended for treatment included a number suffering from some psychotic disorder. Prisoners subject to more or less severe symptoms of cyclothymia were often found to have committed their crimes at the time of the mood-swing. Hysteria seems to be the commonest, and obsessional behaviour the rarest, affective disorder among the prisoners.

The report as a whole emphasizes that while such treatment is not suitable for all, yet much might be done for a considerable number by psychiatric treatment and control. The most novel change recommended is the establishment of a special penal institution serving four functions: (1) a clinic and hospital for psychotherapeutic treatment, (2) a psychiatric institution for selected cases, (3) a prisoners' colony, and (4) an observation and treatment centre for difficult adolescents.

Science News a Century Ago

Mode of Operation of Poisons

In a paper entitled "Experimental Researches on the mode of operation of Poisons" read to the Royal Society on June 6, 1839, J. Blake gave an account of experiments undertaken to show with what rapidity the blood is circulated through the body. He summarized his conclusions as follows:

"(1) The time required for a substance to penetrate to capillary vessels may be considered as unappreciable. (2) The interval elapsing between the absorption of a substance by the capillaries, and general diffusion through the body, may not exceed nine seconds. (3) An interval of more than nine seconds always elapses between the introduction of a poison into the capillaries, in veins, and the appearance of its first effects. (4) If a poison be introduced into a part of the vascular system nearer the nervous centres, its effects are produced more rapidly".

The Great Lakes of North America

AN American correspondent of the *Athenaeum*, writing from New York on June 7, 1839, referred at some length to the theories of rain put forward by the meteorologist J. P. Espy (1786-1860). He then went on to remark: "The water subject reminds me of an interesting statement respecting our great north-western lakes, which appears in the last Report of the *Michigan State Geologist*—a region, by the way, which has been but two or three years a *State*. Such facts show that practical science, as I have hinted before, like practical literature, is really exciting some attention amongst us. The following is the only authentic tabular view of these waters I have seen; it may be of novelty to some of your readers.

	Mean Length	Mean Breadth	Area Sq. Miles
Superior ..	400	80	32,000
Michigan ..	220	70	22,000
Huron ..	240	80	20,000
Green Bay ..	100	20	2,000
Erie ..	240	40	9,600
Ontario ..	180	25	4,500
St. Clair ..	20	14	280

"The same tabular statement exhibited also the depth and the elevation of each above tide water.

	Mean Depth Ft.	Elevation Ft.
Superior ..	900	506
Michigan ..	1,000	578
Huron ..	1,000	578
St. Clair ..	20	570
Erie ..	84	563
Ontario ..	500	232

"It is computed that the lakes contain about 14,000 cubic miles of water, a quantity more than half of all the fresh water on the earth."

American Convention of Civil Engineers

THE *Mechanics' Magazine* of June 8, 1839, had a note to the effect that the American civil engineers, after various preliminary meetings, resolved to form a society similar in its aims to the Institution of Civil Engineers, in London. The Franklin Institute, Philadelphia, offered its co-operation, the headquarters of the convention were to be at the Franklin Institute and the *Franklin Journal* was to be the recognized organ of the new body. Mr. Benjamin H. Latrobe, of Maryland, was elected president.

W. H. MCCREA: Matrices of quaternions and the representation of Eddington's *H*-number. An 'algebra' consists of the body of theorems which can be proved true of a set of 'elements' or 'quantities' obeying stated rules of addition and multiplication. For example, we have the well-known algebras of real numbers, of complex numbers, and of Hamilton's quaternions. It is known that under certain conditions the quantities of one algebra may be represented by 'matrices' composed of the quantities of another algebra. In recent years Sir Arthur Eddington has given a formulation of quantum theory and relativity theory based upon the algebra of what he calls '*H*-numbers'. The main object of the present paper is to show how Eddington's algebra may be represented by matrices of quaternions.

ENID CHARLES: Differential fertility in Scotland. (2). The mining and metal industries were associated with either average or very high gross reproduction rates. Low fertility was associated with (a) textile industries, (b) commerce and finance, (c) personal service. In the predominantly agricultural counties, high rates were found in the north-eastern district and Wigtown, low rates in the typically crofting counties and those with large sheep farms. Some correspondence was found between high fertility and intensity of cultivation. All regions with a high proportion of women gainfully employed exhibited low fertility. In general, high fertility of married women was associated with a high nuptiality rate.

R. S. BARCLAY and W. O. KERRMACK: The fertility of Scottish married women, with special reference to the period 1926-1935. An investigation has been made of the applicability to Norway and Scotland of the 'Diagonal law', previously found to hold in respect of the specific legitimate fertility rates of certain European countries. The specific legitimate fertility rates for Scotland, 1931, have been employed to calculate standardized general legitimate fertility rates for various regions of Scotland for the period 1926-1935. The results are summarized in various tables and maps.

H. P. DONALD: Sources of variation in human birth weights. On the basis of birth weights of 3,000 full-term infants, it is concluded that those born in summer are slightly heavier than those born in winter. The effect of sex is greater than that of month of birth, is about the same as that of birth order but accounts for comparatively little of the total variation. Age of mother and time between births had no demonstrable effect. By far the greatest source of variation arose from differences in the family averages, an intra-familial correlation of 0.5 being found. This is of significance in connexion with infant mortality, and mental and physical development.

E. L. INCE: Relations between the elliptic cylinder functions. As the elliptic cylinder functions may be regarded as generalizations of the circular functions, the question arises as to whether there corresponds to the addition theorems for the circular functions

relations between elliptic cylinder functions of various types. By manipulating the nuclei of the integral equations relative to each of the four types of elliptic cylinder function, relations, though of infinite form, between the functions of any one type and those of each of the others, and likewise expressions for the derivatives have been obtained.

ALAN MCKELLY: The freshwater Mollusca of the Tanganyika Territory and Zanzibar Protectorate. A study of the systematics and local and geographical distribution of East African molluscs carried out under the auspices of the London School of Hygiene and Tropical Medicine. Two species, *Physopsis lobosa* and *Biomphalaria pfeifferi*, are of considerable importance there as intermediate hosts of schistosomes parasitic in man. Their local distribution and diverse means of destroying these undesirable snails are described, and suggestions are made regarding the application of these data to specific infested localities.

HUGO MEHTON: Studies on reproduction in the albino mouse. (2). Maturation of spermatozoa. Active spermatozoa from the vas deferens and cauda epididymis possess a protoplasmic droplet at the posterior end of their middle piece. This is not a remnant of the expelled cellular protoplasm, but is a special substance required for the completion of their maturation process.

F. A. E. CREW and P. C. KOLLER: Cytogenetical analysis of the chromosomes in the pig. The diploid chromosome number in the spermatogonial cells is 48. The largest chromosome is 7.5μ long, the smallest is $1.5-2 \mu$. The rest form a graded series between these extremes. The two sex chromosomes are unequal in size; the Y being $1/3$ of the total length of the X chromosome. The position of the centromere in the X is subterminal; in the Y it is terminal or nearly so. The type and the structure of the sex bivalent suggests that the centromere separates the pairing and differential segments. Chiasma formation is localized in the five larger bivalents, and consequently gene recombination in these bivalents is limited. In one individual a chromosome pair was heterozygous for a small and distal inversion.

Paris

Academy of Sciences (C.R., 208, 1177-1256, April 17, 1939).

E. BORREL: Certain problems of distribution and the virtual probabilities.

J. DRACH: Application of Darboux's method to equations with explicit characteristics, x, y .

L. LECORNU: Propagation of spherical waves.

J. HAAG: Cauchy's formula and the problem of Dirichlet.

A. MAIGE: Cellular autotrophy and heterotrophy and evolution of the plastid.

L. DANIEL: Graft of a hybrid cineraria on *Senecio scandens*.

C. CHABAUTY: Demonstration of a theorem of Thue, independent of the theory of diophantine approximations.

J. LE ROUX: Free mobility in geometry.

A.-Y. AMIN: The F -points of the surface of Del Pezzo in space of five dimensions.

S. MANDLBERGT: Some new considerations on classes of functions of which the derivatives are bounded.

J. DUFAY and D. SMOUKOVICH: Optical density of the Milky Way in a direction perpendicular to the galactic plane, deduced from star counts.

J. LAGRULA: Measurements of the intensity of gravity in Tunisia.

F. CARBENAY: Weakening of high-frequency transmissions on power transport lines.

A. LALLEMAND: Experimental results obtained by photo-electronic photography.

S. PROCOPTU: Determination of the thickness of the thinnest layer of electrolytic iron at which magnetization discontinuities disappear. Magnetic induction and thickness give a straight line relation, magnetic induction being zero at a thickness of 1.75μ .

L. BLOCH, E. BLOCH and L. KOUANG-TAO: Vacuum spark spectrum of silver. A great number of new radiations, often very intense, have been observed.

MME. T. GRIVET-MEYER: Secondary effects of cosmic rays in lead.

C. MAGNAN: Concerning the neutrons emitted during the splitting of uranium under the action of neutrons.

L. GIRAULT-ERLIER: Theory of differential potentiometric titration.

MME. N. DEMASSINUX and B. FEDOROFF: Dehydration of potassium cobalt sulphate and of cobalt sulphate. The changes have been followed by Debye and Scherrer diagrams.

G. LIEBOWITZ: Solubility of ether oxides in solutions of strong acids.

P. CHOVIN: Researches on the Pechmann colouring matters. Mechanism of formation of the mono-acid by hydrolytic scission.

C. COUETOT and J. KROUSTIN: New syntheses in the dibiphenylene-ethane series.

Z.-C. GLACOT and J. WIEMANN: Condensing reductions.

S. GOLDSCHTAUB: Arrangement of the atoms in laurionite, $PbOHCl$.

J. BRICARD: Study of the formation of rime at the summit of the Puy de Dôme.

D. BARBIER and D. CHALONGE: Night temperature of the upper layers of the atmosphere. Comparison of the ozone bands of stellar spectra indicates a very low temperature in the upper atmosphere.

M. and MME. J. FELDMAN: Development of carpospores and the alternation of generations in *Asparagopsis armata* Harvey.

S. SABETAY and L. TRABAUD: Presence of eugenol in the essential oil of jasmine.

G. TRÉGOUBOFF: Plankton larvae of sponges.

G. JORET and H. MALTERRE: Mechanical constitution of soils and the solubility of phosphoric acid.

P. DE BERRIDO-CARNEIRO: Strychnolethaline, curare and curarization.

MME. M. PHISALIX: The white venom of vipers of the Département du Gers has no vaccinating power.

M. PIÉRY, J. ENSELME, MME. J. ENSELME and C. PESCHERA: Experimental study of the biological influence of a prolonged stay at a height. Blood modifications. Geese and rabbit were sent to the scientific station at the Jungfraujoch (3,457 m.) for six months. A lowering of blood carbon dioxide and of the oxygen saturation of the arterial blood, already known, due to decreased partial pressures of these gases, and also an increase in the number of red corpuscles and in the oxygen capacity of the blood, were observed.

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

ASSISTANT LECTURER IN ECONOMICS in the University of Manchester—The Registrar (June 10).

Academic Appointment in the DEPARTMENT OF PHYSICS in University College, Hull—The Registrar (June 10).

ASSISTANT III for the EXTERNAL BALLISTICS DEPARTMENT of the Ordnance Board, Woolwich, S.E.18—The Secretary (June 10).

ASSISTANT COUNTY EDUCATION OFFICER under the Southampton Education Committee—County Education Officer, The Castle, Winchester (June 12).

FELLOW AND TUTOR IN CHEMISTRY in Jesus College, Oxford—The Principal (June 13).

DEMONSTRATOR IN THE DEPARTMENT OF ZOOLOGY in Bedford College for Women, Regent's Park, N.W.1—The Secretary (June 15).

UNIVERSITY CHAIR OF PATHOLOGY at St. Thomas's Hospital Medical School—The Academic Registrar, University of London, Senate House, W.C.1 (June 15).

ASSISTANT at the London Museum, St. James's, S.W.1—The Keeper (June 15).

JUNIOR ASSISTANT PHYSICIST at the Radium Beam Therapy Research, 1 Biding House Street, W.1—The Honorary Secretary (June 24).

ASSISTANT PHYSICIST at the Radium Beam Therapy Research, 1 Biding House Street, W.1—The Honorary Secretary (June 24).

RESEARCH OFFICERS (2), Grade III, in the AGRICULTURAL ECONOMICS RESEARCH INSTITUTE, University, Oxford—Secretary of the Committee for Rural Economy, School of Rural Economy, Parks Road, Oxford (July 1).

LECTURER IN PATHOLOGY AND DIRECTOR OF THE PATHOLOGICAL UNIT at Prince Henry Hospital, Sydney—The Secretary, Universities Bureau of the British Empire, Gower Street, W.C.1 (August 31).

TECHNICAL OFFICERS at the Air Ministry Headquarters—The Under-Secretary of State, Air Ministry, Berkeley Square House, W.1 (quoting B.197).

A PATHOLOGIST in King Edward VII Hospital, Windsor—The Secretary.

Planning in House and City

WHILE we may acquiesce in the necessity at the present time of concentrating effort on the gigantic task of national defence, we are nevertheless acutely aware that much is seriously amiss with a civilization in which such use of scientific effort should be necessary. On the credit side, however, it will be granted that the importance of social factors in industrial and national problems is widely recognized both within and without the ranks of scientific workers themselves, and the necessity for reorientation of research effort between the biological and social sciences and the physical sciences now appears to command general assent. There are, moreover, indications that at last some of the new powers that science has put at our disposal are beginning to find expression in ways appropriate to their purpose and less dominated by traditions or ideas of the past. True it is that the development of aviation remains warped by military ideas and demands, but the development of the motor-car, for example, is at last finding expression in its own appropriate forms rather than those dictated by the functions or purpose of the horse-drawn vehicle. Similarly in architecture, there have been some striking examples of the use of the newer materials, free from limitations imposed by traditional ideas or practice.

None the less, it has to be admitted that progress on the whole has been comparatively slight, and it is in the changed attitude to new ideas rather than in actual achievement that the strongest reasons for hope are to be found. When, for example, such a radical proposal as the removal of population from a derelict area like that of Merthyr Tydfil to an entirely new but more suitable site, which offers the community a prospect

of economic development, can be seriously considered instead of being derided or rejected out of hand, progress is being made. The keen interest which is being taken in the location of industry has, of course, been stimulated by the PEP report and by the evidence given before the Royal Commission on the Geographical Distribution of the Industrial Population, but these two inquiries are really the outcome of public consciousness of the importance of this problem.

There are, however, few, if any, problems arising out of the transformation of industry and society under the influence of mechanical science, in which there is greater need for bold and radical action and for the discovery of more appropriate forms of expression for the new forces at our disposal, than in those arising out of the housing of the community, whether in the aspect of building, town planning, the location of industry or provision of services and amenities.

An imaginative contribution to fundamental thinking about the whole problem of the modern city, whether from the point of view of amenities, industry, defence or housing, has been provided by Mr. Lewis Mumford in "The Culture of Cities"*. He makes a strong plea for casting aside all preconceived ideas and for a determined attempt to think out the real purposes which a city, whether as a whole or in the individual units of houses, is intended to serve in the conditions of to-day and with the resources which are at our disposal.

Even those who do not instinctively recognize that, in this way alone is possible a scientific approach to the problem of really effective planning, cannot but be impressed by the picture

* The Culture of Cities. By Lewis Mumford. Pp. xii+586+52 plates. (London: Martin Secker and Warburg, Ltd., 1938.) 21s. net.

which Mr. Mumford gives of the evils which have in the past resulted from unco-ordinated development, the clinging to obsolete methods of construction or attempting to force new materials into the forms used for earlier products and other purposes. Again and again, advances of earlier generations have crystallized in hard forms which prove intractable obstacles to the progress of later generations, and rob them of many of the advantages placed within their reach by progressive knowledge.

The appeal which Mr. Mumford makes in his latest book is for vision and a sense of values. He would have us examine the institutions which make up city life, from the individual household to the school, the scientific society, the church, and determine the exact functions which they are required to fill in the light of medical knowledge to-day, the advances in means of communication, whether of transport or in such fields as the telephone or broadcasting. Too often we maintain forms or institutions long after the needs for which they were originally created have disappeared or are met more effectively in some other way.

It is easy to overlook the exact social significance of some of these changes. Until, however, we realize that the new means of transport and power production, with the telegraph, the telephone, the radio, the teleprinter and television, have enlarged the sphere of activity and at the same time diminished the need for physical movement and close settlement, we cannot begin to determine accurately the functions and needs of city life; and time, energy, money, and human vitality will continue to be expended in activities of no intrinsic value, as in the crowded transport systems of every metropolis and even in other public services such as water and sewage disposal.

Clear-cut conceptions of the purposes our institutions are to serve in this age, not merely in the age in which they were originally designed, form the basis of adequate planning. Of the dwelling-house we must recognize, as Mr. Mumford points out, that certain of its functions, though domestic in origin, may be better served by communal institutions; for example, child-birth and the care of infective illnesses, weddings and funerals. Other functions, notably on the recreational side, have gained in importance, through the advent of radio, television and the telephone, and will continue to do so as leisure develops. When we have agreed on the exact functions which the modern dwelling-house is intended to serve,

we can begin its rational design and eliminate many of the conventional requirements which no longer serve these functions. Moreover, we shall then be free to form an unbiased judgment as to the use which can be made of the new material at our disposal, the possibilities in the way of fabrication of floors, roof and the walls, and the proportioning of mechanical services or utilities and space or storage.

Treatment of the housing problem along such lines as these demands creative as well as scientific thought. Vision and some ordered conception of family and civic life are also demanded, and this is no less true of other civic institutions such as the school, the church, the public assembly hall, the library, and the scientific or literary society. Definite objectives must be visualized in the provision of the best possible environment for human nature and culture, the priority of consuming and creative activities over mechanical processes and the expression of vital standards in terms of leisure, health, biological activity, aesthetic pleasure and social opportunity. One of the great dangers of the present moment is that the opportunities which the necessities of defence impose upon us of altering both the design and construction of towns and cities should be missed or stereotyped for lack of imagination.

Mr. Mumford, discussing the new functions of the city, suggests that under the new conditions it should become, as it has often been in the past, the chief instrument of education, and that what should distinguish the new community is not so much the introduction of any essentially new institution as their adequate organization and incorporation as an essential part of the whole. He urges accordingly that cities should be deliberately designed to serve those purposes, and that their size should be a function of the social relationship to be served.

Essentially we have here a positive conception in place of the merely negative one, which has already led to the recognition that definite steps must be taken to prevent the continued industrial expansion warping or enfeebling the life of the rest of the country. Moreover, it is a conception which guides the planning of the whole of society. Economy must be a regulating principle in all design, for it is only by saving on the means and instruments of life that a community can command the necessary abundance at the higher levels of art, science and education. A modern plan must embrace every human need appropriate to the

structure without waste of space, duplication, or clumsy and indifferent means of circulation.

It follows from this that a first task in the planning and survey required is to educate citizens, to give them the tools of action and to prepare the stage as well as to suggest the socially significant objectives. Ultimately, this is an essential duty of every school and especially every university. With it there must go the further utilization of science through the regional survey, regional exploration and regional construction, if we are to increase the area of rational human control. Nor should our inability to devise at once the appropriate structure for our civilization, as Mr. Mumford further reminds us, be a cause for permanent discouragement. Most of the forces working towards international co-operation are young, while the opposing forces are old and deeply ingrained in institutions and organizations. A generation is too short a space of time for the reorganization of modern society, whether within or across national frontiers.

If therefore we should not be too readily discouraged at the rate of progress, the problem is

too urgent for any opportunity to be neglected. Even while citizens are being educated to appreciate the need for imaginative reconstruction, further obstacles to progress are continually crystallizing out, amenities are disappearing and the problem threatens to become more formidable and intractable. The Brassey report on Highway Development Survey (Greater London) provides already a classic example of the consequences of procrastination or neglect in such matters. Scientific workers undoubtedly have a great part to play in the development of the new and appropriate forms in which the forces they have placed at man's disposal can be utilized for the most effective service of the needs of the community. The achievement of that ideal of fitness for the purpose demands equally, however, the co-operation of art and the humanities, and we may well hope that the very urgency of the present threats to all the richest treasures of our heritage may yet stimulate that co-operation, and issue in the creative expression of a new culture worthy to be compared with any recorded in the long history of mankind.

History and Scientific Endeavour

The Cambridge Ancient History

Vol. 12: The Imperial Crisis and Recovery, A.D. 193-324. Edited by Dr. S. A. Cook, F. E. Adcock, M. P. Charlesworth, N. H. Baynes. Pp. xxvii+849. 35s. net. Volume of Plates 5. Prepared by C. T. Saltman. Pp. xv+243. 15s. net. (Cambridge: At the University Press, 1939.)

THE issue of the twelfth and last volume of the Cambridge Ancient History is so notable an event that a word must be said about the whole enterprise and the way in which the two ancient universities of Great Britain have divided the work of learning between them. Something must also be added, more especially appropriate to this review, about the point of view from which the man of science is inevitably driven to regard the study of history as a whole.

First as to Oxford and Cambridge. While Cambridge has been elaborating this series of forty volumes on ancient, medieval and modern history, Oxford has given us the standard dictionary of the English language and has just completed a revised and enlarged Greek dictionary based on and improving the traditional "Liddell and Scott".

Of these works we have nothing to say at the moment, except that the division of labour speaks well for the co-operation of the two learned bodies concerned and throws a cheering light on the industry and power of organization of both.

The histories which Cambridge has just completed have also a memorable connexion with one of the most learned men whom Great Britain has ever produced. Lord Acton, in 1896, the year after his appointment as regius professor of modern history at Cambridge, was approached by the syndics of the University Press with a suggestion that he should undertake the direction of a history of the world. They can proudly claim that the idea first came from them. Acton replied modestly that such a work was beyond the capacity of any one man. A syndicate of learning was the only conceivable method; but before the end of that year he had himself accepted the editorship of the modern section and had drawn up a plan which the Press approved. He got together a team of assistant editors and contributors and impressed them with his ideals. He died in 1902, the year of the appearance of the first volume. The last of the twelve appeared in 1910, and became at

once the standard book of reference which it has ever since remained. But the wider idea had already taken root and Prof. Bury undertook the planning of a Cambridge Medieval History, of which the first volume appeared in 1911, the year after the completion of the 'Modern' work. 'Modern', it should be understood, begins with the Renaissance and 'Medieval' with the death of Constantine. Owing to the Great War and the death of several of its editors, the Medieval History was not completed until 1936. During its publication, Prof. Bury, with the help of Profs. S. A. Cook and F. E. Adcock, had begun on the third section—the 'Ancient'—which though the earliest in the date of its contents, thus turned out, rather by accident, to be the latest in publication. Its first volume, however, appeared in 1923, thirteen years before the 'Medieval' was finished. It has taken altogether sixteen years to bring the work to a conclusion in the volume which has just been issued. Again, as in the case of Acton, the editor-in-chief of the Ancient and Medieval sections did not live to see his work completed. Dr. Cook's name stands first among the four who have brought the great undertaking into port.

Clearly it is impossible to review in a short space even the fortieth part of this colossal work. One can only mention that this twelfth volume of the ancient history deals with the last hundred and thirty years of the history of imperial Rome before the triumph of Constantine which ushered in the triumph of the Christian Church, marked by Lord Acton as the beginning of the medieval age.

It should not be overlooked that the success of the work and the termination of its scope at 1910 have prompted a continuance. Prof. Harold Temperley has for this purpose stepped into the shoes of Acton and Bury. To many of our younger contemporaries all the history which they wish to learn is post-War or even post-Hitler. To this doctrine Prof. Temperley seems to give his adhesion when he says (in his foreword to the first volume of this new series) "that a survey of the origins of the War exceeds all others in importance, for this period weighs upon us with insistence and has become part of the air we breathe. . . . Upon a right appreciation of the nature and objects of the War depends the future of history in this generation".

No doubt it is important; no doubt, also, it will in the competent and impartial hands of Prof. Temperley and his co-adjutors be a popular and useful corrective to the wild and conflicting theories which fill the Press and din our ears from the radio. Yet one cannot help thinking that there is a profound and rather dangerous fallacy concealed in the seductive words of the editor of the next great historical compilation which is to issue from the

Cambridge University Press. Is it really true that a knowledge—if we could obtain it—of the origin and issue of the last Great War exceeds in importance all else that history has to tell us? No doubt it now seems so to many people who are trembling at the result of the present international bifurcation and strife of nations. But might it not have seemed equally dangerous and important at many earlier crises in human history had we been there to feel the shock? We know in fact that it did so appear to thoughtful men at the time when the Roman Empire was giving way to the barbarians.

We need some other yardstick to measure the gravity of events; above all, we need a knowledge of and a faith in the permanence and force of other elements in the human and historic story than those which fill by far the larger part of these forty volumes and will apparently be the main if not the only, topic in the new series which Prof. Temperley is devising. The things he is to tell us are of great moment and should undoubtedly be spread abroad by all responsible and impartial agencies like the Cambridge University Press and every institution where the truths of history are handed on to future generations. But let us think for a few moments of the other side of human activity; that, for example, which is represented by the persistent and almost equally colossal work of George Sarton in *Isis* and many other publications. Here we have the growth of thought and the discovery of the universe which is going on even now at an accelerating pace though some countries may be able to expel every impartial man who is struggling to add his mite to the treasure. It may be said, "But if the dogs of war are let loose, all this may be devoured and the human race if it survives will have to emerge again from its cave-shelters in a world of desolation". This is a supposition somewhat on a par with the chance of our planet's extinction by collision with another wandering heavenly body.

We can indeed imagine both these catastrophes, but we do not seriously believe in the measurable probability of either. It would probably be admitted that the recent international discord and warlike preparations have not at all diminished the progress of science. In fact, in many ways they have accelerated it; and it is a tenable proposition that the expulsion of so many Jewish and other men of science from their homes in Central Europe will actually give fresh stimulus to their work and the works of others in the countries of their adoption. The totalitarian States, we must hope, will gradually throw off the incubus of the anti-scientific bias which at the moment is hindering research, diminishing the number of disinterested students, besides inflicting incalculable loss and suffering to those who fall under the ban.

The human spirit has, however, in the past always displayed an unconquerable power for re-establishing itself and making fresh advances. This is the lesson which should be aimed at in all great historical compilations such as that which Cambridge has just completed. In this and many other works the reader is overwhelmed by the mass of learning set out before him. The Cambridge forty volumes make a mighty historical encyclopedia which no one would think of tackling from beginning to end, but in which he would find ample and trustworthy information about any particular subject or person in which his interest was already aroused.

Such preliminary interest and a sketch of the whole in the spirit which we have just indicated, are the things most needed, and in supplying them we would put in an earnest plea for pre-eminence in the treatment of the growth of science or, if you will in a more general sense, the continued growth and enrichment of the human spirit. The notorious political events and figures would still be there, but in a much humbler attitude. We need them as landmarks just as it is useful to remember that Newton's greatest discoveries and the completion of "Paradise Lost" took place almost simultaneously in the year of

the Great Plague of London. So many of these popular and traditionally remembered events were actually plagues in the body politic. Who would not have avoided the Great War had he the power and foresight in 1914, just as now we are all absorbed in an attempt to avert another war, still more terrible if it occurred? But those things which we would not avert, but welcome and prize for ever as constructive achievements of humanity, should stand in the forefront of the picture. The foundation of mathematics and astronomy by the Greeks, their work in sculpture and architecture, the law-making genius of the Romans, the Madonna of the Middle Ages, the scientific synthesis of the seventeenth century, the mind of Goethe and the poems of Wordsworth, the ameliorative medicine and the widening of the universe in our own days—these are the things on which history should work most zealously, and make them stand out as the landmarks of the history to be taught in the generations to come.

The whole of the matter is too vast for us to comprehend; it is indeed infinite. Some selection and therefore emphasis are imperative. A higher degree of truth, and stronger hope for the future, would be the aim and the natural result of such an effort.

F. S. MARVIN.

Ancient Egypt and Its History

The Making of Egypt

By Sir Flinders Petrie. Pp. xv+188+85 plates. (London: The Sheldon Press; New York: The Macmillan Company, 1939.) 12s. 6d. net.

SIR FLINDERS PETRIE is the creator of Egyptian archaeology and is still at work. The advances made have been so gigantic in the period of a single lifetime that the world is liable to forget how very new the study is. In the book before us the author sums up his views of the various influences, immigrations and infiltrations into Egypt—and they were many. He gives us more than eighty plates, showing hundreds of objects of all sorts. These he considers qualified to support his theses, which are based on his unrivalled knowledge of the archaeology. The line drawings especially are of the beauty we have long grown accustomed to associate with his publications.

The various objects are grouped according to the periods of history, so that in looking through them the reader gets an idea of the characteristic products of each age. The scheme of work is ambitious, envisaging, as it does, the whole range

of man and his activities from the time the Nile Valley became habitable down to the Ptolemaic period. A bold attempt has been made to compress all this into the aforesaid 82 plates and 161 pages of text. To these are added three appendixes. They are: an arrangement of the Hyksos kings by a classification of their scarabs; a table of Egyptian skull measurements; a table of periods of history. There is also a complete table of references to the original publication of each of the illustrations.

The author directs attention once more to the existence since Early Predynastic days of a signary in the Mediterranean area, and to the fact that about half of these signs have survived as letters in various alphabets; a curious fact which has never been given the consideration due to it. The conclusion concerning Egypt's share in the world's progress is "that Egypt never originated any new civilization, but was a fertile ground for implanting the products of other lands". The reviewer would add, however, that there has been an artistic sense in Egypt, which lies dormant until brought to life by some movement from outside.

This is more than can be said for some neighbouring countries.

The layman will find much profit and pleasure in studying the plates, but to read the text requires more detailed knowledge than he could possess. The attempt to squeeze so much into so small a space entails a style which at times becomes almost telegraphic in its compression. It also necessitates allusions which are sufficient for the Egyptologist, but must be meaningless to the

public. Again, it induces a statement as of fact of much that really needs a discussion which would result in a probability, or perhaps only in a possibility. The system of dates used is the author's own, which is much longer than anything accepted by others. In putting Menes to 4326 B.C., S. Flinders Petrie puts him a thousand years or more earlier than would anyone else, though even this is a thousand years later than he used to date him.

G. A. WAINWRIGHT.

Universities of the British Empire

The Yearbook of the Universities of the Empire, 1939 (Published for the Universities Bureau of the British Empire.) Pp. xlv+1197. (London: G. Bell and Sons, Ltd., 1939.) 15s. net.

IN its main outlines the *Universities Yearbook* retains the shape given to it twenty-five years ago by its original designers. Its principal features are still: a directory of the officers and members of the staff of each university, general information as to origin, organization, equipment, courses of study, etc., and reports of events of outstanding interest which occurred during the past academic year. The reports, by the way, are in some cases excessively meagre, even such an important university as Bombay, for example, reporting nothing more than the total number of full-time students and the number of degrees conferred.

Preceding the sections dealing with the universities of Great Britain and Ireland, of Canada, of Australia, of South Africa and of India, respectively, are introductory chapters treating briefly of their history, regulations and practice. The first of these, which has a rather jejune appearance, concludes with an interesting account of the genesis of a Consultative Committee of Vice-Chancellors and Principals. That some such body should exist to co-ordinate policy in matters of common concern and stimulate adjustments to the changing social environment and national needs is sufficiently obvious. What surprises one is that it did not exist before 1918. The chapter about the universities of Australia has been extensively revised for the present issue of the *Yearbook* by the Australian Vice-Chancellors' Committee.

In eleven appendixes, covering some two hundred and fifty pages, are assembled an assortment of notes on admission to universities, professional bodies, student organizations and other matters, contributing to make the *Yearbook* a sort

of 'inquire within upon everything' connected with universities. Among them are useful particulars of post-graduate scholarships and grants for advanced study and research and centres of scientific research and information. These reflect the conspicuous defects in the organization of the finance, distribution, direction and co-ordination of scientific research in Great Britain to which Prof. J. D. Bernal has directed attention so forcibly in 'The Social Function of Science'. Another appendix epitomizes returns (not published elsewhere) from universities and university colleges in Great Britain and Ireland of their students from abroad. The total number, 6,214 includes 1,614 from other countries in Europe, 2,180 from Asia, 1,061 from Africa, 1,034 from America and 325 from Australasia. Of European countries the largest contributors were: Germany (532), Poland (195), Holland (77), Hungary (71), France (65) and Norway (64). Students from India numbered 1,350, from China 233, from Egypt 383, from Palestine 146, from South Africa 532 from the U.S.A. 517, from Canada 271.

The body responsible for the production of the *Yearbook* is the Universities Bureau of the British Empire. Full particulars of its constitution appear together with its last annual report, on pages xi-xlv. An important event in the Bureau's history was the secretary's tour of the Canadian universities, which took place in the spring of last year. He visited all of them and discussed with members of their staffs ways and means whereby the Bureau could be of service to them. He returned via the United States, and while there discussed with the presidents of Harvard and Yale, the president of the Carnegie Corporation of New York and the director of the Institute of International Education, the possibility of the visit to England in 1941 of some of the heads of universities in the United States, with a view to their meeting the heads of universities in the British Empire at the congress to be held in Manchester.

Communication :

a Philosophical Study of Language. By Karl Britton. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvi+290. (London: Kegan Paul and Co., Ltd., 1939.) 12s. 6d. net.

LANGUAGE has become again a central point of interest for philosophers, logicians and psychologists. Historically this has always been the case when thinkers begin to question the reality of values and the import of the ultimate principles of explanation of the world. The Greek sophists, the medieval nominalists, Hobbes, the eighteenth century sensualists, and the modern positivists are in the direct lineage of the contemporary analytical philosophers who make of language the leading real problem of knowledge. From this angle, Mr. Britton's book is of particular importance, in so far as it retraces in an orderly fashion the manifold cross-currents which enrich the field of logical controversy.

It begins with a discussion of four principal kinds of language: the language of empirical propositions, necessary principles, moral judgments, and poetry; and it endeavours to show that all these can be explained in terms of the informative and of the emotive function of language. When a language refers to what we may experience, it is informative; otherwise it is emotional. It is easy to confuse informative and emotive uses of words; and the chief object of analysis would be to distinguish these clearly. One of the results of the analysis is to show the place of necessary rules in linguistic behaviour, never to indicate the mutual relevance of psychology and logic. Mr. Britton discusses these problems with competence and skill. He also discusses the views of many recent writers, including Russell, Moore, Wisdom, Empeon, Sheffer, Lewis, Wittgenstein and Carnap. Hence the interest of this volume, which may be read as an excellent introduction to the theory and practice of modern logical analysis.

T. G.

The 1938 Mental Measurements Year-book of the School of Education, Rutgers University
Oscar Krisen Buros, Editor. Pp. xv+415. (New Brunswick, N. J.: Rutgers University Press, 1938.) 3 dollars.

THE output of mental tests is now so great that no worker in educational psychology can hope to know more than a small fraction of them. The seriousness of the problem for the conscientious teacher of educational psychology or director of research in that subject is not lightened by the consideration that most of the tests produced are of little or no value, for it has become almost impossibly difficult for him to discover what are the useful new tests and which are worthless.

The fact that this Year-book lists 312 new tests makes it useful to every worker in educational psychology. If it merely did that, it would only be one more of the too numerous psychological publications which preserve equally the valuable and the worthless in psychological production. In fact, it does much more since it contains a critical evaluation

of all the tests and the publications on educational psychology which are described. This feature makes it invaluable. It is excellent to see at the end of the description of a test: "these tests serve to increase the number of mediocre tests that are now on the market, without making any scientific contribution to the development of group testing of intelligence". Whether or not this criticism is just in the particular case to which it is applied, it shows the right spirit. Let us hope that this Year-book marks the end of the period of merely listing psychological work without attempting to distinguish the bad from the good.

R. H. T.

The Wild Asses :

a Journey through Persia. By W. V. Emanuel. Pp. 352+12 plates. (London: Jonathan Cape, Ltd., 1939.) 12s. 6d. net.

HERE Mr. Emanuel records a journey through Persia of a mixed party, described on one occasion by Reuter as of "undergraduates". Though the author repudiates this designation, it does in some degree characterize them and their spirit of adventure. They belonged to the National Union of Students. Their route lay across Europe to Russia, and through the Caucasus into Persia, which they traversed to Meshed; and there they crossed the Afghan frontier for a brief stay at Herat. On their return they crossed the great Salt Desert of Persia, to their edification, if discomfort. Although this record is not intended to be in any sense a scientific study—anything in that nature is precluded by the rapidity with which the party travelled—the author has a keen eye for the distinctive characters of both peoples and places; and the freshness of his point of view and the acuteness of his observation give his book something more than a passing interest. It may be noted that the points which impressed him most in Persia were the sophistication of Persian people and society and the penetration of the Germans everywhere, especially in business, education and military matters.

Quelques Techniques actuelles en physique nucléaire
Méthode de la Trochoïde; Électrons positifs; Spectrographie de Masse; Isotopes; Compteurs de Particules à Amplification linéaire; Compteurs de Geiger et Müller. Par Prof. Jean Thibaud, Louis Carta et Paul Comparat. Pp. vi+276+12 plates. (Paris: Gauthier-Villars, 1938.) 100 francs.

THE greater part of this volume is devoted to a critical study of methods in mass-spectrography, and more particularly of the methods and results of the work of the last four or five years. This section, therefore, forms a valuable and needed supplement to the standard treatise of Aston. The remaining sections deal in considerable detail with the construction and uses of counters and counting circuits. Within these somewhat severely prescribed limits the treatment is remarkably complete, and it is typically French in its lucidity. The book, which is lavishly illustrated, is a notable addition to the literature of the experimental part of nuclear physics.

Elementary Mathematical Statistics

By Prof. William Dowell Baten. Pp. x+338. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 15s. net.

BOOKS concerned with statistics fall roughly into two classes, those which aim at providing a variety of methods for the analysis of data without making any serious attempt to prove the formulæ given, and those which concentrate on the proofs of the propositions under discussion.

Dr. Baten's work falls into the latter class. It will undoubtedly be criticized as too narrow by those who desire a compilation of methods, and such criticism would not be entirely unjust, as exact tests of significance, experimental design and analysis, orthogonality and degrees of freedom are either mentioned very briefly or entirely omitted. The discussion of correlation is very full, but leaves one wondering whether a discussion of regressions would not have been of more value. To the research worker and the student, therefore, the book is not to be recommended for uncritical use. To the teacher, however, it should prove of value, as the approach to many of the questions raised is of attractive simplicity. Where it is necessary to provide algebraic demonstrations to students with limited mathematical knowledge this book should be a useful guide.

K. M.

A Guide to Chemical Laboratory Practice:

for Beginners. By Prof. H. Bassett. Pp. viii+94. (London: Macmillan and Co., Ltd., 1938.) 2s. 6d.

IN this book an attempt is made to supply the information which is usually provided by the demonstrators in the elementary laboratory. In this way time and trouble may be saved. Some of the information may seem rather trivial, as when the student is warned not to stumble and fall when carrying a desiccator; but most of the hints given are useful. Every teacher knows that it is of the utmost importance to instil into beginners those habits of neatness and orderly work without which no real progress can be made in practical chemistry, and this modest volume will certainly assist in this way if students can be persuaded to read it and carry out the good advice which will be found in abundance on its pages.

Principles of Electricity and Electromagnetism

By Prof. Gaylord P. Harnwell. (International Series in Physics.) Pp. xiii+610. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 30s.

PROF. HARNWELL'S book is an interesting, and on the whole successful, combination of the classical-theoretical and modern-practical treatments of electromagnetism. We have, for example, in Chapter I the conventional elementary treatment of electrical images, while Chapter V treats at some length of current-voltage relations in non-ohmic circuit elements, including the interesting ceramic material, thyratron. A good deal of space is given to conduction in gases and to thermionic vacuum tubes, and in

general any topic taken up is given a space very nicely proportioned to its present-day importance rather than to its historical interest. British students will find the book more suitable for reference than as a regular companion in a degree course—and its strongest appeal will be to the physicist with marked bias towards the practical side of his subject or even towards the more academic side of electronic techniques.

Logical Aspects of Educational Measurement

By B. Othanel Smith. Pp. x+182. (New York: Columbia University Press; London: Oxford University Press, 1938.) 12s. 6d. net.

THE author of this book has attempted to clarify his ideas about the meaning of measurement in education, in which he has found most help from the well-known writings of Dr. Norman Campbell. Approximately the first five chapters are devoted to the logical foundations of measurement, the last four to questions more particularly concerned with educational measurement.

The logical treatment is nothing like so rigorous as that found, for example, in the paper by Mr. J. Guild on "Are sensation intensities measurable?", in the current Report of the British Association for the Advancement of Science, but it follows somewhat similar lines. Mr. Othanel Smith concludes that quantitative units have not been established in educational measurement. The requirement of *order* has often been fulfilled, but not that of *addition*. Just now in educational measurement, he thinks, it is more important to concentrate on the operational interpretation of *order* and *equality* than to seek for an additive structure.

Nauka Polska:

jej Potrzeby, Organizacja i Rozwój (Science and Letters in Poland: their Needs, Organization and Progress). Tom 24. Pp. x+587. (Warsaw: Kasy imienia Mianowskiego, 1939).

UNDER the able editorship of Prof. S. Michałski *Nauka Polska* each year acquaints Polish men of science with the tendencies and general advances over a wide field. In the latest volume there are four articles (three short and one fairly long) entitled respectively, "Science and the Irrational Element", "Humanities and the Vital Needs of the Nation", "Visual Thinking" and "Scientific Life in Modern Cracow". In the second of these, the author, Prof. K. Dobrowolski, discusses the part that each branch of the natural sciences can have in enhancing national and cultural life.

Most of the volume is taken up with numerous shorter items, reviews and a bibliography of the "Science of Science". Some of these shorter notes, such as that describing the foreign literature available for students in Polish libraries, are of direct interest to British readers, and it is perhaps significant that some thirteen English books are among the thirty reviewed in this issue of what may be regarded as a most influential scientific publication in Poland.

Use of Oxygen on the Mount Everest Expedition, 1938

By Peter Lloyd

THERE were two types of oxygen apparatus available to the Mount Everest Expedition of 1938. One was the open type, used by the 1922 and 1924 expeditions, in which the climber breathes a mixture of oxygen and air. The other was a closed circuit apparatus in which pure oxygen is breathed. Now the essence of the oxygen problem is the fact that the apparatus cannot be effectively tested except at very high altitudes. Serious oxygen lack does not make itself felt below about 23,000 ft., so that a test in the Alps is not conclusive even with the closed apparatus, and with the open apparatus it would be useless. Similarly, a test in a pressure chamber is of little value since it cannot include the vitally important acclimatization factor. There was therefore no possibility of making a comparison of the two units in Europe, and it was decided by the leader of the Expedition that both must be taken.

The open apparatus was similar in principle to that devised for the 1922 expedition¹. The oxygen was contained in two Vibrax steel cylinders of 500 litres capacity at 120 atmospheres pressure, and was fed through an adjustable spring-loaded governing valve to a small canvas bag acting as a reservoir, and thence to the mouthpiece. A pressure gauge was fitted, but no flowmeter, and the governing valve was intended to be set and looked at the required delivery rate. If the lung ventilation of a man doing hard work at 29,000 ft. above sea-level (245 mm. mercury) is taken as 60 litres a minute, then an apparatus of this type delivering oxygen at the rate of 2 litres a minute (as measured at 760 mm. mercury) will raise the partial pressure of oxygen in the inspired air from the original 51 mm. to 71 mm., corresponding to an atmospheric pressure of 341 mm., or an altitude of 20,800 ft. Similarly, a climber at 25,000 ft. (285 mm. mercury) with the same oxygen delivery and lung ventilation will have an oxygen pressure in his inspired air corresponding to that obtained at 17,500 ft. Since at 20,000 ft. an acclimatized man can still move almost as fast as at Alpine altitudes, it is generally assumed that a delivery rate of 2 litres per minute is about right, and at this rating the apparatus with its charge of 1,000 litres would last a little more than eight hours. The total weight was 25 lb., the charged oxygen cylinders accounting for 19 lb.

The closed unit was similar to that taken by the 1936 expedition² and was of the type which

is used for rescue work in mines. It had been improved as a result of tests carried out by Dr. Warren in 1937, in the course of which he used the apparatus on the Matterhorn and the Wellenkuppe. The oxygen was contained in a single cylinder of 750 litres capacity, and from the cylinder the gas passed through the reducing valves into a low-pressure reservoir. The user drew oxygen from this reservoir through his face mask, covering nose and mouth, and the expired gases passed back into the reservoir through a canister packed with soda lime in which the carbon dioxide was absorbed. There were, in effect, three separate automatic valve systems; the pressure-reducing valve which lowers the pressure to about 2 atmospheres and from which a weep of $\frac{1}{4}$ a litre a minute is fed into the reservoir, the breathing valve which opens when the flexible reservoir begins to collapse under external atmospheric pressure, and the lightly spring-loaded mica valves on the flexible connexions to the face piece, which control the direction of flow through the circuit. All these had to work correctly if the apparatus was to succeed. In addition, there were two hand-operated valves, one the screw-down valve on the main supply and the other a by-pass by means of which the supply of fresh oxygen to the reservoir could be supplemented. As on the open apparatus, a pressure gauge was fitted to indicate the residual pressure in the cylinder.

Every effort was made to lighten the construction, even at some sacrifice of rigidity, but the apparatus weighed 35 lb. for a supply which was calculated to last 5 $\frac{1}{2}$ hours. This was a weight which a fit man could easily carry over moderately difficult ground, but it might become an impossible burden on steep rocks or if the climber were weakened by lack of food or any other cause. Of the 35 lb. weight, only 14 $\frac{1}{2}$ lb. was in the charged oxygen cylinder, 10 lb. was in soda lime and the remaining 10 $\frac{1}{2}$ lb. was in the frame, the canister and the valve gear. But although the quantity of oxygen was small, virtually all of it could be effectively used, while with the open apparatus most of the oxygen would go to waste in the expired air. It was thought that the high oxygen pressure obtained and the greater efficiency of utilization would outweigh the obvious disadvantages.

A preliminary test on the closed apparatus was done on the journey out to Tibet, at Thapgu, in Sikkim (12,800 ft.). In the main, the results were

satisfactory, but it was found that in still air the oxygen may get so overheated by the reactions in the soda-lime that conditions become thoroughly unpleasant for the wearer of the apparatus.

The first high-altitude test in the closed apparatus was done by Dr. C. B. Warren on the snow slopes above the North Col (23,000 ft.). He found that, although the unit seemed to be in perfect mechanical order, it tended not to stimulate but rather to suffocate him. He was actually moving more slowly than the other climbers, and was forced to stop after every dozen steps to recover his breath.

When the camp on the North Col was re-occupied about ten days later, this gave me a chance for a comparative trial of the two forms of apparatus between Camps iv and v (23,000–25,700 ft.). The open unit was tried first, and it was found that within half an hour the breathing technique had been mastered and the tricks of the apparatus had been learnt. The oxygen was drawn into the lungs through a rubber mouthpiece which was held between the teeth. The technique consisted in biting the rubber to prevent an outflow of gas when breathing out and releasing it when breathing in. When the flow of oxygen was stopped by biting the mouthpiece, the oxygen accumulated in the small canvas bag mounted above the cylinders.

The apparatus was perfectly comfortable. As to speed, I found that I was moving as fast as the fastest member of the party and therefore much better than without the help of the oxygen. But the main difference was the absence of strain or fatigue. The day before, climbing from about 21,000 ft. to 23,000 ft., I had felt really tired, whereas on this day climbing from 23,000 ft. to 25,700 ft. and down again left me comparatively fresh.

Partly to economize oxygen, and partly to test the effect of suddenly removing its stimulus, I turned off the supply at every halt, but this did not seem to produce any reaction whatever. On the other hand, when the first cylinder was running out and I was climbing with a rapidly decreasing supply, the effect was immediately noticeable. The oxygen flow had been set the previous night to a rate corresponding to 2.2 litres a minute at one atmosphere, and at this setting the first cylinder lasted until ten minutes below Camp v. The oxygen supply was turned off six hundred feet above Camp iv and the descent completed without it.

On the following day I took the better of the two closed units and started off with a Sherpa, intending to climb about 1,500 ft., and to compare my times and sensations with those of the previous day. But it soon became evident that there was

something very wrong. Mechanically everything was perfect, and the valves were opening and closing like clockwork, but inside the mask was nearly suffocating, and I had to stop frequent to take a dose of fresh air. If the whole of the system was filled with fresh oxygen, then for time conditions were pleasant enough, but very quick deterioration followed. The absorptive seemed to be satisfactory, for the soda lime canister was warm—uncomfortably warm in fact—but the effects of the overheating were much more serious this time than they had been under similar conditions at Thangu. The mica valves on the mask were tested and found to be functioning, as the breathing valve controlling the supply to the reservoir was short circuited by opening the by-pass valve, but nothing that I could do improved the results in any way.

The open apparatus was used again on an attempt on the summit involving three days' climbing, the first day up to Camp v, the second up to Camp vi, and the third for the attempt. It worked perfectly for the second ascent to Camp v, and just over one cylinder was used. On the following day we set off over heavily snow-covered rock for Camp vi, which had been pitched at 27,200 ft. Thanks to the oxygen apparatus, which was working perfectly, I was feeling very fit and reached Camp vi half an hour or an hour ahead of the others who were not using oxygen. The camp was magnificently situated on a gently inclined scree slope, and I was interested to find the scree in several places cemented together with ice, which is not known to have been found before at this height*. Even here I felt absolutely no ill-effect on turning off the oxygen supply when I stopped climbing.

The story of our attempt to reach the main ridge of the mountain on the following day has already been told. We were forced to retreat after advancing only a short distance above the camp. In spite of oxygen, I seemed to feel the early morning cold as much as my companion Tilman and I made no more impression than he did on the rocks we were trying to climb. On easy ground however, it increased climbing speed, as was immediately evident when we were roped together.

It is not an easy matter to do scientific work above 23,000 ft., for Everest has a way of sapping one's energy and leaving little inclination for detailed work. As a result, the tests which were done on the oxygen apparatus are neither so complete nor so precise as one would like them to have been, and our conclusions cannot have the force of proofs. The failure of the closed apparatus in two independent tests on the North Col has yet

* In "Everest 1933", p. 348, L. B. Wager reports the greatest height at which ice was found as 25,700 ft. Some névé was seen at about 28,000 ft.

to be satisfactorily explained, but the fact of its failure, coupled with the mechanical troubles which were experienced with it, give powerful backing to the arguments which have already been advanced against it. A closed apparatus was brought back from Everest, and was tested again under actual climbing conditions to ascertain whether there had been any mechanical fault which might have caused the failure. Some repairs were necessary, but the canister was not exchanged, and neither the breathing valve on the flexible reservoir nor the mica valves on the face-piece were touched. The test showed that at these low altitudes (up to 2,000 ft.) the apparatus worked perfectly well.

Perhaps the hardest thing of all is to estimate the advantage conferred by the use of oxygen. Comparison of climbing speeds is difficult and dangerous, but from the trials of 1938, it would seem that from 23,000 ft. to 28,000 ft., the use of oxygen in the open apparatus at 2 litres a minute

has only a slight effect on natural climbing speed. The reduction of strain and fatigue, however, provides ample justification for its use at this height. Above 28,000 ft., the increase in climbing speed becomes more and more apparent. The maximum advantage is obtained, as one might expect, on easy ground where the climber moves with steady rhythm. More difficult climbing requiring greater exertion results in an increase in the rate of breathing, and with the open apparatus this implies a fall in the partial pressure of oxygen entering the lungs.

We suffered in 1938 from the necessity of taking two different forms of apparatus each with different sized cylinders, but it is hoped that the results we obtained will enable a future expedition to make a definite choice.

A Hundred Years of Photography

THE satisfactory recording of a scene by photographic means first became possible in 1839, when Daguerre published details of the process which bears his name. The 'base' consisted of a silver or silvered metal plate iodized on the surface, and the exposure amounted to about ten minutes in bright sunlight. 'Development' took place in mercury vapour, which acted preferentially upon the exposed portions, yielding a direct positive. A serious disadvantage of the process was the fact that only one picture was obtained, and there was no known process of copying originals. Fox-Talbot in 1840 carried the art a stage further by obtaining negatives on paper, using silver iodide as sensitive material, developing in gallic acid, waxing the paper to make it transparent and making prints by exposing in front of a piece of paper sensitized with silver chloride.

The chief drawback at this time was the length of exposure necessary. Scott-Archer in 1851 considerably increased the speed with his wet collodion process. This latter process was the first successful attempt to use a protective colloid for suspending the light-sensitive substance. The wet collodion process was very successful and its chief drawback was the fact that the plate had to be exposed while still wet, thus necessitating the preparation of the plate 'in the field' immediately before exposure.

The next important step was taken in 1871, when Maddox used gelatine instead of collodion as

protective colloid and produced the first dry plate. The dry plate was not successful until later, when it was found essential to remove the salts formed by the reaction between silver nitrate and soluble halide. In addition to a gain in speed, the dry plate had an enormous advantage over the wet plate for field work, but the wet plate is still extensively used to-day in the photo-engraving industry.

The spectral sensitivity of the silver halides is confined to the blue and violet end of the visible spectrum, but it was discovered in 1873 that the addition of certain dyes conferred added sensitivity in the direction of increasing wave-length. Since then a systematic search has been made, and is still going on, for other sensitizing dyes giving greater sensitivity and extending the spectral range of the added sensitivity. It is possible to-day to sensitize to all wave-lengths up to about 11,000 Å.

Since the discovery of the dry plate, no fundamental changes have taken place in photography. All the advance has been towards improved photographic quality (for example, latitude and gradation, speed, graininess and spectral sensitivity). The inherent sensitivity of the silver halides to ultra-violet, X-rays and γ-rays has found its application in scientific work. Indeed, during the last fifty years, photography has been an invaluable tool in scientific research. One has only to recall the part played by photography in

astronomy and spectroscopy to realize how difficult, and in some cases almost impossible, much of the work would have been without it. On the other hand, the manufacture of photographic emulsions is still largely governed by trial and error, though of course a great deal of knowledge has been gained empirically. The gelatine used is a natural product which contains compounds essential to the production of a satisfactory emulsion, and although something is known of the nature of these compounds their significance is not yet fully understood. Photography has gained much from the advance in organic chemistry, which has paved the way towards the synthesis of sensitizing dyes. Enormous numbers of dyes have been prepared and tested for the sake of a small percentage which have proved useful. The mechanism of dye sensitization is not yet understood, but by a systematic study of the behaviour of dyes sufficient empirical knowledge has been obtained at least to guide the search for new dyes into more fruitful channels.

It is a far cry from the *thé* Daguerreotype plate of 1839 requiring 10 minutes' exposure in sunlight to the plate or film of 1939 requiring 0.01 second under similar conditions of lighting and lens aperture, and it appears to-day that the speed cannot be greatly increased while retaining other factors such as grain within reasonable limits. The same could, however, have been said five years ago, yet the speed of the fastest available material has been increased several times since then.

Even a brief review such as this would be incomplete without a word on colour photography. A practical method of additive colour reproduction was conceived so early as 1868, but could not be developed into a practical process until satisfactory panchromatization was achieved. The mosaic screen processes of to-day are the outcome of these early theories and have reached their present stage of perfection largely by the increase in speed and colour-sensitivity of photographic materials in general. Subtractive colour processes have within the last few years received added impetus by the development of colour former and developer coupling methods, as well as improvements in emulsion-making technique. Most of the practical advance in colour photography has taken place during the last thirty years, mainly because improvement was not possible in any colour process until efficient sensitization in the red region of the spectrum had been achieved.

The pioneers of photography were concerned with discovering a process by which the beautiful little pictures shown on the screen of the camera obscura could be permanently recorded, but the art has proved of such important application in the field of scientific research that we may well

pause to commemorate the centenary of photography.

The Royal Photographic Society held a series of special centenary lectures during last winter session; celebrations were held in Paris earlier this year, and on May 17 a joint meeting of the Royal Society of Arts and the Royal Photographic Society was held in the lecture hall of the Royal Society of Arts, London. This joint meeting was particularly appropriate, because it was out of the Royal Society of Arts that the Royal Photographic Society, the first photographic society in the world was formed in 1853. Dr. Olaf Bloch opened the proceedings from the chair and the first speaker was Mr. Peter le Neve Foster, the great-grandson of Peter le Neve Foster who, as a member of the Royal Society of Arts, was partly instrumental in the formation of the Royal Photographic Society. The speaker referred to papers on photographic subjects read before the Society between 1840 and the formation of the Royal Photographic Society.

The next speaker, Miss M. T. Talbot, gave a very interesting sidelight on the character and family life of her grandfather William Henry Fox Talbot, who may be called the pioneer of photography in Great Britain. He was the originator of the negative-positive process, whereby any number of copies could be obtained from one original.

Mr. Dudley Johnston then spoke on behalf of the Royal Photographic Society and stressed the cordial relations that had always existed between that body and the Royal Society of Arts. He gave an outline of the history of the formation of the Royal Photographic Society, which arose out of the exhibition of photographs held in 1852 under the auspices of the Royal Society of Arts. He read extracts from correspondence between the early organizers who were responsible for the formation of the Royal Photographic Society, from which it appeared that Fox-Talbot generously relinquished his patent rights on the calotype process in favour of the amateur photographer in order to make the formation of a photographic society possible.

Mr. A. J. Bull then gave a demonstration of Fox Talbot's photogenic paper, and the wet-collodion process originated by Scott-Archard in 1851 and still extensively used in the photo-engraving industry.

A number of exhibits of historic interest were on view. Some early cameras of Fox-Talbot were supplied with a hole and cork in the front, so that the operator could remove the cork and apply his eye to see how the exposure was getting on. Of scientific interest was the result of an attempt by Sir William Crookes to photograph the moon in 1855. In addition, photographs made by the early processes, fine as some of them were, showed the enormous progress that has been made in the last hundred years.

Submicroscopic Morphology of Protoplasm and its Derivatives*

CYTOPLASM

CYTOPLASM is neither a true liquid nor a true solid, but has an interesting combination of characters which place it between the two states. It may contain as much as 97 per cent water, and in some circumstances exhibits streaming, or flow; in contrast, it has some measure of rigidity, tensile strength, and elasticity. It is not perfectly elastic, however, but undergoes plastic deformation; the surface is sticky, and the material may be drawn into fine threads. To these properties must be added thixotropy (a change from the semi-solid to the semi-liquid state caused by stirring), imbibition, semipermeability, and optical anisotropy. Earlier attempts to explain the properties of cytoplasm, for example, the 'alveolar', 'granular', and 'fibrillar' hypotheses, have proved inadequate, and have been discarded in favour of a gel structure: whereas the former postulated structural units of microscopic dimensions, the latter involves a structure beyond microscopic resolution. A colloid is described as having a dispersed phase in a continuous dispersion medium. Ostwald describes nine possible combinations, since either of the two phases may be liquid, solid, or gaseous, and eight of these are recognized in Nature (that is, all except the gas-gas combination). A consideration of the properties of each fails to explain all the properties of cytoplasm, and it would appear that the substance cannot be an ordinary colloid with dispersed particles.

Within limits, the shape of the particles does not affect the properties of a dispersoid, but if they are filamentous, as indeed is known to be the case in cellulose and proteins, they will be in frequent contact with one another, and form a continuous framework, that is, a reticular system instead of a corpuscular one, so that both phases are continuous and mutually interpenetrating. It is essential that the 'framework phase' be solid, though the second phase may be either solid, liquid, or gaseous. In order to follow so far as possible the terminology of Nägeli, who laid the foundations on which the

present conceptions have been built, the framework phase is called the 'micellar framework', and the meshes of the network the 'intermicellar spaces'. The material occupying these spaces is called the 'imbibition medium', as distinct from the dispersion medium of ordinary colloids. Whereas reduction in size of the particles of a corpuscular dispersoid would, when molecular dimensions were reached, result in a true solution which would not have colloidal properties, a similar reduction in the dimensions of a micellar framework would simply mean a decrease in thickness of the micellar threads, leading ultimately to a molecular reticulum which would retain many of the properties of a colloid, and if the points of attachment were sufficiently numerous would still be a gel. It may now be considered how the known constituents of cytoplasm can be fitted into such a plan.

In addition to water and inorganic constituents, the cytoplasm consists of proteins, phosphatides, and lipoids. The fats, which may be taken as representative of the last group, are formed from fatty acids esterified with glycerol. The molecule may be pictured as a three-pronged fork (Fig. 1a), the prongs representing lipophilic, fatty acid chains. They have neither hydroxyl nor carboxyl groups, and, in consequence, are immiscible with water. The phosphatides, by way of contrast, are of a polar character. For example, lecithin is a glycerol ester with two fatty acid chains and one hydrophilic choline phosphate group. As the hydrophilic and lipophilic groups are mutually repellent, the molecule may be compared with a tuning fork having two lipophilic prongs and a hydrophilic handle (Fig. 1b). The proteins are polypeptide chains of indeterminate length with various side chains, which may be hydrophilic, lipophilic, acidic, or basic, according to the protein. These chains have three important characteristics:

(a) A repetition of similar links, comparable with the metameric segmentation in zoology; (b) a great variety of composition due to differences in possible arrangement of the side chains; and (c) a reversible contractibility which is probably important in vital processes.

Of the three constituents mentioned, the protein chains alone have a structure capable of forming a molecular reticulum. Moreover, this framework is capable of carrying the other constituents of the cytoplasm in association with suitable side chains. Indications of 'possible

* Prof. A. Frey-Wyssling, professor of botany in the Swiss Federal Institute of Technology, Zurich, delivered a series of three lectures at University College, London, on March 6, 7 and 9. The contents of the first two, dealing respectively with the submicroscopic structure of cytoplasm and chloroplasts, are summarised in this article; the principal contents of the third lecture, which treated the submicroscopic structure of cell walls, are covered by the article which appeared in *NATURE*, 148, 899-904 (1938); the lecture is to be published by Prof. Frey-Wyssling in the October (1939) number of *Science Progress*. Details of the subject, with an extensive bibliography, are given in Prof. Frey-Wyssling's book, "Submikroskopische Morphologie des Protoplasmas und seiner Derivate" (Berlin: Gebrüder Borntraeger, 1938).

Fig. 1.

Fig. 2.

combinations of this type are suggested in Fig. 2. Fig. 3 indicates types of union such as might occur at points of attachment of the chains themselves. Type I, between two lipophilic groups ($|\text{—CH}_2\text{—H}_2\text{C—}|$) is a homopolar cohesion bond of the kind found in paraffin wax; it would be affected by changes in temperature. Type II, between hydrophilic side chains ($|\text{—OH} \dots \text{HO—}|$) represents a heteropolar cohesion bond, or secondary valency bond; it may be loosened by heteropolar agents, and is capable of swelling. Type III, between acidic and basic side chains ($|\text{—COO}^- \dots \text{NH}_3^+ \text{—}|$) forming a salt by ionic valency bonds, is affected by changes in hydrogen ion concentration. Type IV is a primary valency bond, and this particular type is dependent on redox reactions. A loose reticulum of the kind illustrated in Fig. 4, held by such bonds, would be sensitive to many kinds of change in environmental conditions.

The property of semipermeability may be controlled by lipoids incorporated in the protein network. These must be accumulated in the peripheral zone, because dyes which cannot penetrate the plasmatic surface spread freely in the cytoplasm when introduced by micro-injection. The high water content of cytoplasm together with mechanical rigidity, elasticity, and tendency to retain shape, are readily explained on the basis of a reticular framework, but would be difficult to account for on other systems. The properties of plasticity, viscosity, and protoplasmic streaming are less easily explained. It may be assumed

that under certain conditions some of the bonds are loosened for a short time so that the micelle threads may slide over one another, and find new points of attachment. Not all the bonds would be loosened at the same time, for the polypeptid chains move in parallel groups as shown by the optical anisotropy, and this arrangement is responsible for the stickiness, tensile strength, and the possibility of being drawn into threads. Finally Seifriz has shown that protoplasmic movement has a pulsating rhythm, and it is suggested that this is associated with the periodic contractions of the polypeptide chains.

CHLOROPLASTS

Following the lines which appear to have been so successful in the investigation of cytoplasm, the molecular constitution of the main constituents of the chloroplasts was studied. Approximately half the chloroplast consists of protein, rather more than one third of lipoids, and about eight per cent of inorganic substances. The pigments (chlorophyll *a* and *b*, xanthophyll and carotin) constitute only a very small proportion (for example, 1.5 per cent in tobacco leaves). It would appear probable that the proteins form a micellar reticulum as in the cytoplasm, and that the smaller molecules of the lipoids are lodged within the reticulum. The pigments are probably associated with the lipoids. The chlorophyll molecule may be likened to a signet, or rubber stamp, the disk representing

Fig. 3.

Fig. 4.

so-called porphine ring, which is hydrophilic, and contains the nitrogen and magnesium of the chlorophyll, and the handle representing a lipophilic chain (Fig. 5a). The carotinoids are hydrocarbons ($C_{40}H_{56}$), and are completely lipophilic. The xanthophylls are alcohols with one or more OH groups, and their affinity for water varies accordingly. Fig. 5b is a diagrammatic representation of the molecule.

Some indications of the probable arrangement of these units within the chloroplast are afforded by the optical properties. From observation of double refraction, and of the changes of this property with change in the imbibition medium, it is inferred that the chloroplast is composed of submicroscopic layers, and that

able arrangement of these units within the chloroplast are afforded by the optical properties. From observation of double refraction, and of the changes of this property with change in the imbibition medium, it is inferred that the chloroplast is composed of submicroscopic layers, and that

Fig. 6.

one type of layer consists of regularly orientated lipid molecules. Since about half the chloroplast is protein, perhaps this alternates with the lipid layers. Menke has actually observed a microscopic layering in some instances, and it would therefore appear likely that this suggestion is correct. Chlorophyll exhibits fluorescence when dissolved in alcohol or acetone, but the property is lost when water is added, because the molecules tend to form aggregates in which the lipophilic portions are directed towards one another and away from the water. Chlorophyll also exhibits fluorescence in the living chloroplast, and when in the form of mono-molecular layers on aluminium hydroxide, or with layers of lecithin. It is concluded that in the chloroplast chlorophyll occurs in layers, and, as already mentioned, in association with the lipoids.

Studies of the absorption of light by chlorophyll in the living chloroplast and various solvents,

however, indicate that in the chloroplast it must occur in contact with an aqueous phase. Fig. 6 shows a possible arrangement of the units involved which satisfies all the requirements mentioned, including the association of the chlorophyll with the lipoids as required for fluorescence, and with an aqueous phase as required for light absorption. Moreover, the scheme is quite compatible with the findings of plant physiologists. Although some assert that the chlorophyll is concerned in the reduction of the carbon dioxide molecule, there is much evidence that its function is the capturing of energy from light. There is no stoichiometric relation between the carbon dioxide assimilated and the chlorophyll present, but for the assimilation of one molecule of carbon dioxide some 2,000 molecules of chlorophyll are involved. This number is called the assimilation unit, and it is estimated that even if the suggested layered system is complete within grana of about 0.5μ diameter, every chlorophyll layer might well contain about a hundred assimilation units.

Prof. Baur, of Zurich, has obtained traces of formaldehyde photolytically from carbon dioxide esterified with higher alcohols when brought together with a fluorescent pigment and a redox system. The method has striking parallels with the scheme outlined in Fig. 6. Molecular layers of chlorophyll mixed with cetyl alcohol in molecular proportions of about 1 : 30 were fixed by adsorption on threads of cellulose acetate. This system was dipped in a solution of methylene blue buffered with calcium carbonate, which acted as a redox medium (similar to the small amounts of ascorbic acid or iron compounds in the living chloroplast) in an atmosphere of carbon dioxide. In this system the chlorophyll appears simply to capture light, and may be replaced by other fluorescent dyes. It is important to notice also that the chemical reactions occur in a lipid medium, as, for example, cetyl alcohol. Although Baur's system has an efficiency greatly removed from that of the chloroplast, it offers valuable contributions to fundamental knowledge.

GENERAL CONCLUSIONS

Evidence from chemistry, physics, and botany, indicates that many important constituents of plants are built of 'mixed systems'. The loose reticulum of the cytoplasm is as yet not well understood, but more is known of the cell wall with its 'rodlet mixed system', and the chloroplast with its layered, or 'platelet mixed system'. Such systems are not uncommon in other biological fields. Rodlet structure is found in the framework of chitin, silk fibroin, keratin, collagen tendons,

muscle myosin, etc., and a stratified structure with alternating lipid and protein layers in the sheaths of myelinated nerves, the rod-shaped cells of the retina, and the red blood corpuscles. It is interesting, moreover, to trace a 'linear principle' through chain-molecules, micelles, and fibrils, to fibres in the mechanical tissues, and a 'foliar principle' through molecular layers of pigments associated

with layers of lipoids and proteins, in discoid grana in disk-shaped plastids which are exposed to light in a flattened leaf. The study of morphology must be pursued not simply to the somewhat arbitrary limit of microscopic resolution, but to the molecule, in which any change results in a change in the nature of the material itself.

S. H. CLARKE.

Obituary Notices

Mr. E. H. Richards

IT is with deep regret that we record the death of Eric Hannaford Richards, of the Rothamsted Experimental Station, Herts, which occurred at Bovey Tracey on May 16.

Richards was born on June 28, 1878, at Hanwell, Middlesex, only son of Joseph Peek Richards, medical superintendent of the Middlesex County Asylum in 1867-92, and educated privately. In 1902 he joined the staff of the Royal Commission on Sewage Disposal, working under Dr. George McGowan, and was put in charge of the Commission's large-scale experiments at Dorking on different methods of sewage purification. These were brought to a successful conclusion. In 1909 he was transferred to Belfast to study methods of dealing with the excessive growth of seaweed in Belfast Lough: this was done in association with Prof. Letts of Queen's University. He then returned to Dr. McGowan's laboratory at Ealing, where he remained until 1913.

In that year, the Hon. Rupert Guinness (now Lord Iveagh) decided to arrange for investigations into the possibility of utilising organic waste materials as fertilizers. His experience of the Bagshot sands at Woking had impressed upon him the need for making greater use of organic manure, while the growing tendency to substitute motors for horses was decreasing the supply of the stable manure which had hitherto been the mainstay of market gardeners, potato growers and dairy farmers around London. He saw, therefore, the need for opening up new supplies, and he provided the funds for the Rothamsted Experimental Station to carry out a full investigation. E. H. Richards was chosen for this work, and he fully justified the selection.

For the first few years, in collaboration with me, Richards studied the changes taking place in the making and storing of farmyard manure and showed how the losses occurred, and how also they might be reduced. Information was also obtained about the decomposition processes that occurred during the making and storing of the manure. This side of the work was greatly developed by an investigation made in association with H. B. Hutchinson on the factors determining the rate and extent of the microbiological decomposition of straw. The essential conditions were an adequate supply of nutrients, particularly of nitrogen, which was generally deficient in the straw

itself; not too acid a reaction; and proper supplies of moisture and of air. The important practical result emerged that straw and other vegetable matter could be fairly rapidly decomposed with production of a humus manure by the simple expedient of adding a source of nitrogenous food for the micro-organisms bringing about the decomposition, and ensuring that the heap did not become too acid. The principles of compost-making were thus for the first time set out, and, although others have applied them in various ways, no new fundamental principles have been found.

One method of using the new principles, and the simplest that has yet been devised for use under British of similar conditions, was developed by Adeco, an organization set up for this purpose by Lord Iveagh; it has been so successful that some 100,000 tons of manure are said to be made annually in this way, chiefly by private gardeners and market gardeners in Great Britain and by planters overseas. The method is also used in France for the making of mushroom beds. It is, however, less suitable for farmers, though modifications are from time to time devised which cheapen it.

In recent years Richards was also engaged on an investigation into the purification of effluents from sugar beet factories and milk factories. This was carried out for the Department of Scientific and Industrial Research in association with D. Ward Outler and his colleagues in the Microbiological Department at Rothamsted, and with S. H. Jenkins, who supervised the large-scale experiments, while Richards himself had as collaborator N. W. Barritt. This work led to the discovery of the conditions necessary for decomposition and purification of the effluents, and methods were then devised whereby these conditions could be secured in factory practice. The whole investigation affords an excellent example of successful collaboration of three groups of workers for the solution of a difficult technical problem.

All his life Richards had suffered from a deformity which might have crushed the spirit of a less courageous man. But his spirit was indomitable, and he let nothing stand in the way of the work he had set himself to do. He had perforce to renounce some of the pleasures of life, but he had the satisfaction of gaining in the highest degree the respect and affection of all who were associated with him. He was a loyal

colleague and a considerate supervisor, but as he was insparing of himself so he expected and obtained the best that his associates could contribute to the work they had in hand.

E. J. RUSSELL.

Rev. W. J. O'Leary, S.J.

FATHER W. O'LEARY, S.J., whose death occurred recently, was born in Dublin in 1869, son of Dr. W. O'Leary, M.P., a well-known Home Ruler. After the usual course of study—in Louvain and Dublin—he was occupied chiefly in teaching physics and astronomy in one or other of the Jesuit colleges in Ireland.

Father O'Leary's work on pendulums aroused his interest in seismology, as the result of a visit to Prof. F. Milne's observatory at Shide, I.O.W. He designed a form of inverted pendulum seismometer in which he replaced the suspension suggested by Tchebicheff by one designed by himself. The shaft of the pendulum was supported on a steel plate which was suspended in a concrete pit by three steel wires. The pendulum thus suspended was extremely sensitive and almost unstable. A suitable arrangement of levers and pens traced a record on smooth paper moving on a rotating cylinder. The weight of the 'bob' was one and a half tons. This instrument gives a very wide and clear record. In connexion with this he designed a recording clock on the free pendulum principle. It is of interest that Father O'Leary made and mounted every part of both seismograph and clock himself—with the exception of the castings for the bob. The instrument constructed by him in 1916 is still functioning in the Rathfarnham Castle observatory, and the steel wires have not been replaced. It is the only one of its kind in existence.

On the death of Father Pigot, director of the Riverview College Observatory at Sydney, Father O'Leary was appointed to succeed him in 1929. Until last year he held this post, when he retired, but still continued his work. In addition to his seismological activities, he did valuable work on the observation of variable stars, and designed a special form of blink comparator for this purpose. His work also included observations on solar radiation.

With the exception of a text-book on mechanics and the results of his observations, Father O'Leary published very little. The detailed description of his free pendulum clock, a piece of original and first-class work, awaits publication. It has only been described in the patent specification.

Father O'Leary was a past president of the New South Wales branch of the British Astronomical Association. He was well known to members of the British Association, before whom he preached on more than one occasion. The end came with great suddenness. For some time his heart had been giving him trouble, but this did not interfere with his work, and only the night before he had been working as usual in the observatory. A most kindly and popular man, he will be missed not only as a scientific worker, but still more as a friend.

H. V. GILL.

Sir George Kenrick

BY the death on May 28 of Sir George Kenrick, the educational world has lost a man whose record for public service is remarkable even in a city, Birmingham, which is outstanding in its reputation for the production of leaders in civic work.

Sir George was born in 1850, and after a training as an engineer in the Nettlefold works, he entered the well-known firm of hollow-ware manufacturers founded by his grandfather. At thirty years of age he was elected a member of the Birmingham School Board. He was elected to the City Council in 1903 and was made chairman of the Education Committee, a post which he held for eighteen years. Together with George Dixon, he founded the Birmingham Day Training College for Teachers, giving £5,000 for its endowment. In 1886, as a member of the Council of the Birmingham and Midland Institute, he gave £1,000 towards the equipment of its metallurgical department. When Mr. Joseph Chamberlain announced his scheme for the creation of a University of Birmingham Kenrick subscribed £10,000. He went, with the late Profs. Poynting and Burstell, on a tour of inspection of American universities to acquire first-hand knowledge of the development of engineering departments in the United States with a view to the creation of such a department in the new university. He became chairman of the Building Committee which was responsible for the buildings on the new site at Edgbaston. When the formal opening of the new buildings by King Edward VII was arranged for 1909, it was fitting that George Kenrick should be Lord Mayor, and his services to education were recognized by the King in the conferment of a knighthood. When Mr. Joseph Chamberlain made a second appeal for funds for the University, Sir George again made a donation of £10,000, and in 1914 on the death of Prof. J. H. Poynting he gave £18,000 to endow the Poynting chair of physics.

So far back as 1881, George Kenrick introduced compulsory physical training into the elementary schools of Birmingham—the first attempt made by any school board to introduce physical training as part of the curriculum. Nor did his interest end with the training of the children, for he founded and endowed the Birmingham Athletic Institute for young men and women. He himself was a devotee of outdoor sport—fishing and shooting, cricket, lawn tennis, cycling and walking (even in old age he scorned an overcoat). He was an enthusiastic gardener; and, as a keen entomologist, he had made a fine collection of Lepidoptera in his extensive travels in India and the Americas. He had literary leanings, was specially interested in Shakespeare, and had a fine library.

In disposition, though modest and retiring, Sir George was characterized by quickness of judgment, untiring energy and tenacity of purpose. The city of Birmingham recognized its indebtedness and admiration for his services by conferring on him the highest honour at its disposal, that of an honorary freeman, in 1923. He was unmarried.

News and Views

Sir Thomas Holland, K.C.S.I., F.R.S.

THE Albert Medal of the Royal Society of Arts for 1939 has been awarded to Sir Thomas H. Holland, "for his services to the mineral industries". Sir Thomas Holland is principal and vice-chancellor of the University of Edinburgh, and in the course of a long and distinguished career has rendered eminent services to industry and industrial research, both at home and in the Empire. Outstanding among the results of his overseas activities is his close connexion with the development of Indian industry, which to-day is based upon the recommendations of the Indian Industrial Commission over which he presided in 1918. He has held many high appointments in institutions connected with science, geology, mining, metallurgy and petroleum, and was chairman of the Council of the Royal Society of Arts during 1925-27. The Albert Medal was instituted in 1862 as a memorial of H.R.H. the Prince Consort, for eighteen years president of the Society, and is awarded annually for "distinguished merit in promoting Arts, Manufactures or Commerce".

Use of Oxygen in Climbing

PROF. YANDRELL HENDERSON's article on "The Last 1,000 ft. on Everest", published in *NATURE* of June 3, p. 921, gives expression to the physiologist's doubts about the possibility of climbing to 29,000 ft. without the use of oxygen. Prof. Henderson attempts the difficult task of analysing the fall in climbing speed with increase in altitude and suggests that it reaches zero at 29,000 ft. If this conclusion is correct, it is folly to attempt the ascent of Mount Everest without oxygen, but mountaineers may answer that information about climbing speeds at great altitudes is too scanty to justify any precise estimate of limiting altitudes and may point out that, so far, climbers have done as well without oxygen as with it. The most compelling argument in favour of the use of oxygen would be the production of a really effective apparatus. On this point Prof. Henderson is emphatic that the so-called open apparatus is valueless and that a closed unit, involving absorption of carbon dioxide, is essential. But in spite of the possible theoretical advantage of the latter type, it has never been successfully used for climbing at high altitudes. The open apparatus, however, as is pointed out in an article on p. 961 of this issue, by a member of last year's Everest expedition, has twice been used with some success. For the future, it is clear that there is ample room for improvement in methods of oxygen administration in climbing. Increase in efficiency of utilization is desirable provided that it does not sacrifice other essential qualities, but another and perhaps easier line of attack is the reduction of weight, by mechanical improvement of valves and cylinders.

Scientific Psychology in France

THE centenary of the birth of Théodule Ribot, and the jubilee of the foundation of the chair of experimental psychology in the Collège de France, of the Laboratory of physiological psychology at the Sorbonne, and of the famous thesis, "*L'Automatisme psychologique*", submitted by Pierre Janet, will be celebrated by a gathering at the Sorbonne on June 22, under the presidency of the Minister of National Education. Among those who will take part will be E. Faval, head of the Collège de France Prof. P. Janet, and Prof. H. Piéron, who succeeded Binet as director of the laboratory at the Sorbonne. A jubilee volume, in which many psychologists are collaborating, is to be published in honour of Ribot, Binet and Janet, who were the pioneers of scientific psychology in France in its chief lines of advance, namely, physiological psychology and laboratory investigations, the study of the child, pathological psychology and the study of mental anomalies. The general principle of the comparative method affirmed by Ribot has dominated the development of scientific psychology in France, and has contributed notably to the application to teaching and to industry of the science of the mind. The secretary of the committee responsible for the commemoration is Prof. H. Piéron, Collège de France, Paris.

Philosophical Approach to Religion

THE sixteenth Unity School was held at Jordans Hostel in Bucks on May 12-15. The general subject was "The Philosophical Approach to Religion", and an address introducing the subject was given by Mr. F. S. Marvin on the evening of May 12, when he reaffirmed his belief in positivism, possibly modified in certain aspects to relate it to certain more recent ideas. In the discussion, Lord Samuel put forward a view involving in one aspect the idea of causality leading to a creator God. On May 13, Dr. Helen Wodehouse, Mistress of Gorton, in an address characterized by beauty of expression, introduced the question of what is the philosophical approach to religion. The discussion was opened by Prof. J. H. Muirhead, and the Rev. J. H. Brittain contributed some remarks on the historical element in current religion. Prof. John MacMurray gave a stimulating discourse in opening a session on "Religion as the Basis of Reality" and sought to find the essence of religion in personal relationship. He also made some comments on the differences between the scientific and the religious attitudes; discussion of this subject was continued on May 14, when Dr. C. H. Deech spoke on the effect of the development of science on religion. In a concluding address on the future prospects of religion, Prof. Harvey considered a number of factors that have to be taken into account, and put forward some tentative conclusions. Though

the discussions sometimes seemed to show difference rather than unity of opinion, at the last meeting it was felt that there was common agreement in rejecting the objects of devotion put forward by the military States and in seeking to unite men to serve some worthier purpose, which has been known by various names. Valuable interludes were provided by Dr. R. N. Salaman, who spoke on the Society for the Protection of Science and Learning, and by Mrs. Beer, who described a recent visit to Germany and Austria. Further information on the Unity Schools can be obtained from Mr. F. S. Marvin, Pantiles, Coneydale, Welwyn Garden City, Herts.

Experimental Work on A.R.P.

DR. R. E. STRADLING, chief adviser for research and experiment, A.R.P. Department, Home Office, delivered the first of three lectures arranged by the Institution of Civil Engineers on air raid precautions. After referring to the creation some months ago of the special Research Branch of the A.R.P. Department of the Home Office, and to the recent appointment of a Civil Defence Research Committee under the chairmanship of Dr. E. V. Appleton, which would ensure that the full resources of the scientific world would be enlisted in the services of that section of Government activity, Dr. Stradling dealt with the question of protection from the effects of the high-explosive bomb. On detonation, a very high pressure is produced which causes the metal case to expand to possibly one and a half times its original size and then burst into fragments. In addition to the formation of splinters, the expanding gases have two effects: actual movement of gas giving the effect of a very 'high wind', and a wave sent out through the air which is similar to a sound wave. The first effect causes major destruction on a surprisingly local scale; about 30 feet from a large bomb, the effect has practically disappeared. Outside that zone the acoustic type of wave can spread a very long distance. Its effects on a structure can be disastrous, but more especially on those portions which have a high natural frequency, such as windows and the like. Experiments show that the effect is dependent upon the structure itself, as well as upon the form of the wave. Due to the adoption of basements as shelters, the question of earth movements around an exploding bomb is also of importance. There is a zone around the bomb in which few normal structures can be expected to stand, but it is very limited in extent. The wave which is effective at longer distances is somewhat similar to a very slight earthquake and has little effect upon a normal building. Further lectures in the series will be given by Colonel F. J. Wyatt, on camouflage, on June 12; by D. Anderson, on the design of bomb-proof shelters, on June 20; and by Brigadier C. A. Bird, on the work of the military engineer in war, on June 27.

Roman Frontiers in the East

SIR AUREL STEIN has recently completed a survey of the boundary line of the ancient frontier of the Roman Empire in Iraq and Transjordan. This is

a part of a projected survey of the eastern frontier of the Empire, of which the Syrian section, with which Sir Aurel Stein's work connects, has been surveyed by Father Poidebard. Sir Aurel Stein's expedition was supported by the British Academy and the Society of Antiquaries of London and carried out with the co-operation of the Royal Air Force and the Iraq Petroleum Company. In a summary account of the survey (*The Times*, June 1) Sir Aurel states that he traced the line of forts along the south and north sides of the Jebel Sinjar. Between Nisibin and Mosul he found the old defences, which had commanded the road of invasion between Mesopotamia and northern Syria. Turning thence to Kirkuk, he visited and determined to his satisfaction the exact site of the battle of Arbela in Alexander's campaign, and along the middle Euphrates had made the remarkable discovery of a comparatively well-preserved castle, which was clearly Roman, and had at its side a barrage, which bore the stamp of Roman work. This affords evidence of the protection given to the trade route so far down as central Mesopotamia, possibly in the reign of Septimius Severus. The Roman track was traceable from the air and in places even on the ground. The last month of survey work covered the Via Nova, constructed in the reign of Trajan from the port of Aqaba on the Red Sea to Petra and the great centres of Syria. This route has now been determined and mapped for a distance of about 120 miles. Several old Roman milestones, from which the inscriptions had almost disappeared, were found in the Wadi Yitm. The distances between the milestones is remarkably accurate. Thence the road climbs to the top of the chain of mountains above the rift valley of the Wadi-el-Arabah, south of the Dead Sea, and follows the line of cleavage to Petra.

Finds from British Bronze Age Barrows

FINDS from the recent excavation of two bronze age round barrows, one at Stockbridge Down, Hampshire, and one at Reffley Wood, King's Lynn, Norfolk, are now on exhibition in the Prehistoric Saloon of the British Museum (Bloomsbury). Both barrows belong to the Early Bronze Age and date from about 1700 B.C. The Hampshire barrow was excavated by Dr. N. Gray Hill, and that at Reffley Wood by Mr. P. L. K. Schwabe and Mr. I. J. Thatcher. While the sites exemplify the two types of ground on which such barrows are found, namely, chalk down and sandy heath, in their characteristics they exhibit a striking similarity. In each the body had been laid approximately in the centre in the contracted position and accompanied by earthenware beakers. At Stockbridge the skeleton was in a remarkably good state of preservation and was accompanied by an almost intact beaker, but at Reffley Wood the skeleton had disappeared and no complete beaker was found, although the whole area under the mound was strewn with fragments. At both sites there were secondary interments in the mound, belonging to the later period of the Middle Bronze Age about 1400 B.C., when cremation was

practised. In both barrows examples of the small segmented Egyptian faience beads were associated with the secondary burials. About eighty finds of Egyptian beads have now been made in Britain. The segmented type occurs in Egypt in the Eighteenth Dynasty from about 1800 B.C. onward, and is especially abundant at Tell el-Amarna (1380-50 B.C.). These beads have also been found in Hungary, Moravia, and Holland, and are thought to have reached Britain through Greece, travelling across Europe along the amber trade-route.

Journal of Endocrinology

A new journal, to be devoted to endocrinological subjects, under the title *Journal of Endocrinology*, has recently been founded. Its scope will be the publication of communications which advance knowledge concerning the internally secreting glands, the mode of their actions, the nature of their secretions, and the disorders of their functions. It is hoped that strong support will be given by contributors from abroad. There may be some who question the desirability of any step which might seem to accentuate the division of the field of medical and biological sciences into specialised departments and groups, but there can be little doubt as to the necessity for this new journal. The large and rapidly increasing amount of work on endocrinology published by British investigators, and the lack, hitherto, of a British journal specifically devoted to this subject, has led to the overcrowding of journals having other and more general interests. As a result, there has been increasing difficulty for endocrinologists who have work to publish, as well as for those who need ready access to the published work in this field. The foundation of this new journal was preceded by consultation with the editorial boards of a large number of journals, and it is significant that, without exception, these boards were in favour of the project. The control of the journal is vested in a Council of Management, and it will be edited by Prof. E. C. Dodds, who will be assisted by an editorial board consisting of Dr. P. M. F. Bishop, Prof. C. R. Harington, Prof. G. F. Marrian, Dr. A. S. Parkes, Dr. F. G. Young, and Dr. S. Zuckerman. Dr. R. L. Noble has been appointed as assistant editor. The journal will be published, in the first place, four times a year, and the subscription is 30s. or six dollars. The first number is due to appear during this month.

Society of Rheology

THE Society of Rheology was founded in 1929 to further the study of the deformation and flow of matter in the broadest sense. The tenth annual meeting was held at the end of last year. At the banquet it was pointed out that expenses were not being met, and a discussion took place on the status of the Society and its publications programme. The policy favoured, almost unanimously, was to continue publication of the *Rheology Leaflet* and to enlarge it to include invitation review papers, while ordinary research papers would be published, as at present, in the *Journal of Applied Physics*. It was agreed that abstracts and bibliographies should be limited to

those covering specific topics (not specified in the report) and that no attempt should be made at any complete covering of rheological literature. The co-operation of members was sought for increasing membership, but it was not mentioned how far this drive was to be international. The obvious method of circularising authors of papers on rheological subjects, which does not seem to have been carried out in the past, was not mentioned. Rheology is one of those fields which include several sciences—physics, chemistry and physical chemistry and, of late years, biology. Its importance and scope are only now beginning to be generally recognised. Given the necessary increase of support, the Society should then fulfil a very useful function. It would be especially valuable if its finances reached the point where it became possible to list (without full abstracting) all papers bearing on the subject. Now the Society is staking its reserves on the drive for increased membership in such manner that they will be exhausted in two years if the drive fails. It is to be hoped that the Society will receive the required support. Those interested should apply to the American Institute of Physics, 175 Fifth Avenue, New York. The subscription for associate members, who will receive the *Rheology Leaflet*, is 2.50 dollars.

University of Minnesota Hydraulic Laboratory

IN *Engineering* of May 26 is an illustrated article on the large hydraulic laboratory recently completed on the Mississippi River at St. Anthony Falls, Minneapolis, for the University of Minnesota. The laboratory is on Hennepin Island, which is joined to the banks of the river by a dam constructed for the purpose of power development at the falls, and it is designed to operate practically entirely by water diverted above the falls. There is a natural drop of fifty feet and the laboratory can handle for experimental purposes rates of flow in excess of 300 cusecs. Flows up to this amount can be accurately measured by volumetric basins. The laboratory consists of five units, namely, the main experimental laboratory, the hydraulic machinery and pump laboratory, the turbine testing laboratory, the large-scale volumetric tanks, and the lecture room and administration rooms. In the first of these units is a river model section where at present there is under construction a working model, 160 ft. long and 36 ft. wide, of the Mississippi in the vicinity of St. Anthony Falls. The lecture room has been arranged so that large quantities of water can be handled readily at the platform. Below the platform runs the main overhead supply flume of the laboratory, while above it is a head control room containing a constant-level reservoir situated in the tower above the auditorium. The experimental flume which runs through the main laboratory can be used for experiments with ship models.

Improvements in Submarine Telephony in 1938

IN the *Engineering Supplement* to the *Siemens Magazine* of May, an account is given of three submarine cables laid last year to the order of the

British Post Office and manufactured by Submarine Cables, Ltd. The first is an additional cable between Nevin (North Wales) and Howth (Eire). The second connects Dartmouth (Devonshire) and Guernsey and the third is laid between Guernsey and Jersey. The cables are of the concentric type insulated by paraffin and, with the exception of the sheathing, which is made suitable to the conditions prevailing round the British Isles, are similar to the cable laid three years ago from Australia across the Bass Strait. The *C.S. Foraday* left Greenwich in July 1938 carrying the Anglo-Eire and the two Channel Islands cables, weighing in all 1,440 tons. When the cable had been laid for ten miles from Nevin, a dense fog came on which completely obscured the buoys marking the course, but nevertheless the ship proceeded on its course and luckily sighted a marked buoy when the fog cleared. The submarine cables are operated by two carrier frequency systems the terminals of which are at Dublin and Nevin, with intermediate repeaters at Howth. The two concentric cables carry eighteen telegraph and fifteen telephone circuits. The laying of the Channel Islands cables presented little difficulty. A single core cable, which had formerly been part of an Atlantic telegraph cable, was relaid in 1914 between Compass Cove, near Dartmouth and Plemont, Jersey. In 1931 this was diverted into Saints Bay, Guernsey, to provide a telephone channel between England and Guernsey. The new cables provide two telephone circuits between England and Guernsey, and six telephone circuits between England and Jersey.

Progress of the Grid

THE report of the Central Electricity Board for the year 1938 is very satisfactory, although there was a slight reduction in the rate of increase at which electric power is being generated. For the first time since 1932, this rate of increase fell below 10 per cent per annum. The aggregate production is still substantially in excess of the estimates adopted by the Board and those made by the commissioners when planning the various grid schemes. The total output of electricity from public supply stations was 24,400 million units, an increase of nearly 1,500 million units over the previous year. Apparently the stimulus provided by the re-armament programme made up for the loss in demand of the shipbuilding, textile and other industries. At the end of 1938, the grid comprised 4,378 miles of transmission lines, nearly 3,000 miles of which operated at 132 kilovolts, the remainder operating at 66 kilovolts or less. The number of selected stations remained constant at 137 and their total installed capacity was more than 8½ million kilowatts. During the year, the Board investigated special air raid precautions. It was decided to provide a pool of switchgear, transformers and other equipment, which could readily be made available to replace, temporarily, apparatus that might be damaged. The research work into surges, defective lightning arresters and other troubles arising from atmospheric effects was continued throughout the year. Alterations were also made on switchgear

so as to increase their rupturing capacity. The average cost of fuel per ton was 14s. 9d. in 1937 and 20s. 3d. in 1938. This increased cost of fuel more than counterbalanced the benefits which would otherwise have accrued to electricity consumers from the improved efficiency of generation.

Electric Development in South Africa

THE rapid economic development of South Africa during the last twenty years is illustrated by the remarkable growth that has taken place in the development of electricity both for industrial and domestic purposes. The extent to which the Union of South Africa is electrified is shown by the sales of electrical energy being 1,670 units per head of population per annum (excluding natives). This figure is twice that for the United States of America and nearly four times the corresponding figure for Great Britain. In a paper on "South African Activity" by H. A. Eastman, published in the *Electrical Review* for June 2, some of the reasons for this rapid and continuing growth are given. Three fifths of the total demand for electricity is due to the requirements for gold mining purposes. When the numerous mines in process of development are brought to the production stage, this will be greatly increased. The use of electricity for other industries and for domestic purposes is also increasing. The average price received by the generating stations is 0.6d. per unit. The Electricity Act which came into force in 1922 provided for the establishment of an Electricity Control Board, which is the licensing and controlling authority for all private electricity undertakings. It also controls the Electricity Supply Commission, the members of which are appointed by the Government, but which, nevertheless, is free from parliamentary control. The Electricity Supply Commission operates its undertakings at neither a profit nor a loss and adjusts its charges accordingly. Other licensees are required to refund each year to their consumers, *pro rata* to their payments, 25 per cent of the surplus profits of the undertaking for that year.

Baking Quality Tests for Flour

IN 1934 the Imperial Bureau of Plant Breeding and Genetics published its first bibliography of papers on baking quality tests, which was an immediate success, and in a new supplement recently issued (Imperial Bureau of Plant Breeding and Genetics. Bibliography of Baking Quality Tests, Supplement. Pp. 32. Cambridge: School of Agriculture, 1939. 1s. 6d.) the Bureau has fully maintained the high standard it set itself in the earlier publication. A list of more than three hundred and thirty titles to original papers is given here, set out in alphabetical order. The list is remarkably complete and no really important communication appears to have been overlooked. One excellent feature of this bibliography which greatly commends it is the translation of the titles of the foreign publications into English. At the present time, extensive investigations are being made in Great Britain and abroad on the physical

properties of dough and its connexion with the baking quality of flour. The baking test, as such, has admittedly many disadvantages, and it is the ultimate aim of workers in this field to supplement the baking test by some other and better standard, and the Imperial Bureau of Plant Breeding and Genetics has rendered a most useful service to those engaged in this particular line of investigation by the publication of this supplement. The bibliography shows almost at a glance where further information may be obtained of what is being done in this highly important and interesting field.

Predatory Birds and their Economic Status

THE British Field Sports Society is pursuing an enlightened policy in endeavouring to educate gamekeepers and others in the identification of predatory birds and in recognising the economic standing of each species, so that only those seriously harmful to game and other wild birds should be destroyed. In a foreword to a pamphlet of 83 pages, just published by the Society and entitled "Predatory Birds of Great Britain" (price 2s. post free), an appeal is made to gamekeepers and their employers to see that the law regarding the protection of such birds is known and enforced, and the knowledge is made easy by lists embodied in the pamphlet showing the amount of protection given in each British country to each predatory bird. The main part of the pamphlet, by Eric Parker, consists of short descriptions of the birds themselves, with illustrations by G. E. Lodge, and brief notes upon range and feeding habits. The last set out very fairly the main character of the birds' food, though we note that the little owl is condemned, contrary to the findings of the Report of the British Trust for Ornithology, that the author does not realize that the damage done by rooks depends not so much upon their numbers as upon the kind of farming where they occur, and that the black-headed gull in Scotland is condemned on the strength of one opinion for its destruction of eggs and young birds. That is an opinion not shared on balance by Scottish county councils, which, by the way, obtain county orders from the Secretary of State for Scotland and not from the Home Secretary.

Agricultural Progress

THE current issue of *Agricultural Progress* (16, Pt. 1, 2s. 6d.), the official organ of the Agricultural Education Association, which is the most influential body of agricultural teachers and research workers in Great Britain, contains much interesting and instructive matter. The early days and later growth of the South-Eastern Agricultural College at Wye are described in the series dealing with the development of agricultural educational and research institutions, whilst the articles on the teaching of agriculture in schools, county instruction in farm machinery, and the educational value of tours for agricultural students, afford evidence of the real advances that are taking place at the present day on the practical side. Two particularly important topics are very fully dealt with. Mastitis disease, which causes

serious losses to the milk industry, is discussed from the point of view of the veterinary surgeon, the cheesemaker and the bacteriologist. Methods of field laboratory diagnosis are explained. The other subject is afforestation, and while one author backs up his protest against the afforestation of farm-land with numerous examples of the way in which the Forestry Commission has operated in Suffolk, one of the Forestry Commissioners puts forward the other side of the case. Other articles deal with such matters as the foot-rot diseases in cereals, manganese deficiency in relation to soils and crops, and the separation and analysis of soil clay fractions. A considerable space is devoted to book reviews. *Agricultural Progress* will in future be published twice yearly, in February and September.

Higher Education in Belgium

THE "Fondation Universitaire" was created in 1919 with funds appropriated from the final closing balance of the Commission for Relief in Belgium, of which Mr. Herbert Hoover was president. Last year Mr. Hoover accepted a joint invitation from the Fondation and the universities of Belgium to visit that country, and the occasion was marked by eloquent expressions by representatives of Belgian higher education of their sense of its indebtedness to him and to the United States and the value of the consequent cultural relations between the two countries. One of the principal functions of the Fondation is to make higher education available to poor students by means of loans, generally of 1,500-4,000 francs a year. The Fondation relies for the recovery of the loans on the sense of honour of the recipients. That this confidence is not misplaced is strikingly shown in its recently published annual report by a chart exhibiting the amounts of loans granted and refunds received from 1919 until 1938. In recent years the receipts have equalled or exceeded the grants, the annual total being in the neighbourhood of 800,000 francs. The Fondation's resources are also used for encouraging Belgian students, by means of bursaries, to study abroad, for subsidizing publications and scientific societies, for promoting international exchanges between professors and, since 1936, for the maintenance of a Bureau of University Statistics in which has been merged a commission for the study of overcrowding of the universities and unemployment of 'intellectuals'. This body has formulated recommendations for reforming the content of primary and secondary education, making more stringent the tests for promotion from one class to another, for determining what a secondary school-leaving certificate should imply and for restricting to persons intellectually fit for them admission to institutions of university rank.

The Czechoslovak Research Council

THAT the leaders of science in Czechoslovakia have made every endeavour to continue scientific investigations during the past fateful year is indicated by the fifteenth annual report of their National Research Council. At the annual general meeting in March,

Prof. B. Némec referred to the interruption of scientific work occasioned by the country's loss of territory and institutions. Research activities were therefore upon a restricted basis though, he emphasized, it is necessary for a small nation to maintain its cultural activities at the highest possible level. He urged that renewed efforts be made to utilize all the country's remaining scientific institutions and resources for the continuance of all programmes of research. Dr. Ulrich, secretary of the Council, stated that donations were received from industries, corporations and private individuals so that as many students as funds permitted are being supported in the continuance of their work. Investigations in all branches of the natural sciences are still in progress at the universities and at approved institutes. This report also contains a brief account of work completed during the past year by research workers supported by the National Research Council, and the hope may be expressed that it will now continue uninterrupted by further disturbances.

Medical Research in India

SUMMARIES of some of the medical research work in progress in India are contained in the annual reports of the Indian Institute for Medical Research, Calcutta, and of the Haffkine Institute, Bombay, recently issued. In the former, studies on the cholera vibrio and production and therapeutic value of an anti-cholera serum, and on an anti-typhoid serum, have been pursued. Researches on malaria and kala-azar, and the problem of a nutritional survey of Indian food-stuffs and dietaries, have also been undertaken. The Haffkine Institute is the centre for the preparation of anti-plague vaccine, of which more than thirteen million doses were issued during 1937, and work is in progress to improve the efficiency of this vaccine. A survey of the rat population of Bombay in connexion with the epidemiology of plague brings out the interesting fact that the brown and black rats, forming 70 per cent of the rat population of the city, are now highly resistant to plague, though formerly highly susceptible. In the Anti-Rabic Department, more than three thousand cases were treated, with a mortality of 0.08 per cent.

Division of the Circle

In the *Askania Review*, the journal of the Askania-Werke A.G. of Berlin, the well-known makers of instruments, there is an interesting and instructive article on 'The Divisions of the Circle'. It is pointed out that all topographic services of the Reich are adopting the division of the circle into 400 grades instead of 360 degrees. A history of the adoption of these units is given. The Babylonians knew that the sun completes the zodiac once within 360 days approximately, so that 1° is approximately the sun's daily travel. The adoption of 360° is advantageous inasmuch as the figure is readily divisible by 2, 3, 4, 5, 6, 8, 10, 12, etc. The resulting arcs of the circle or the angles of 180° , 120° , 90° , 72° , 60° , 45° , 36° , 30° , etc., are of great importance in connexion with regular diagrams as well as in technique. Since the absolute angular unit defines the angle by the

ratio of the arc length to the radius, it has no 'physical' dimensions. In Germany, therefore, it is not given any special name. In other Anglo-Saxon countries it is usually called the 'radian'.

Medical Supervision of University Students

In his inaugural thesis (*Thèse de Paris*, No. 136; 1939), Dr. L. Katz maintains that there is an increasing tendency in modern universities not only to provide a professional centre for students but also to supervise their mode of life, work and health, so that they can pursue their studies under the best conditions. It is in the United States that the oldest and most important university health centres have been founded, the object of which is threefold, namely: (1) to provide the students with a personal medical service including medical examination on joining, medical supervision in the course of their studies and sometimes in the treatment of illness, and medical supervision of sport; (2) to supply all students with an elementary knowledge of hygiene; and (3) to insure a hygienic condition of the universities and the life and work of the students. In European countries a similar movement is on foot, though it has not reached the same development as in the United States. The medical centres in European universities, especially in France, confine their activities to prevention and education.

The Nations and Child Welfare

THE Child Welfare Information Centre of the League of Nations has issued a "Summary of the Legislative and Administrative Series of Documents" received and published in 1938 (League of Nations Pamphlet, 4, 1; 1939. London: Allen and Unwin, Ltd., 1s.). This summarizes the principal administrative measures taken or enacted by Governments all over the world, and the progress made in the different countries in the sphere of maternal and child welfare, and of the training and status of social workers specializing in that sphere.

Conference on Spectroscopy

THE seventh spectroscopy conference will be held at the George Eastman Research Laboratories of the Massachusetts Institute of Technology during July 17-19. Papers and discussions on analysis of material by the emission spectrum, absorption spectrophotometry, photographic photometry, biological and chemical effects of spectral radiation, and industrial applications of spectroscopy, are being prepared. Copies of the detailed programme of the conference will be sent on request to anyone interested, but as the attendance at the conference is limited to two hundred, those expecting to attend from a distance are urged to signify in advance their intention of being present. No fee is charged. The usual summer courses on practical and applied spectroscopy will be offered at the Institute during June 12-July 22. Further information can be obtained from Prof. George R. Harrison, Department of Physics, Massachusetts Institute of Technology, Cambridge, Mass.

Earthquake in Greece

ACCORDING to a *Times* message, a severe earthquake was felt on Wednesday, May 31, with most damage being done near Kalavryta, about midway between Patras and Corinth on the Island of Morea in the south of Greece. The epicentre appears to have been near lat. $38^{\circ} 1' N.$, long. $22^{\circ} 8' E.$ Earthquakes are not uncommon in Greece though some areas are more seismic than others. Recently earthquakes appear to have occurred mostly near Chalcis, north of Athens, but the present shock may indicate that seismicity has again moved south. There is apparently a seismic zone stretching in an east-west direction across Greece and passing through the present epicentre, for Davison noted 306 shocks during 1896 near the Island of Zante, and there was a very severe shock near Corinth on April 22, 1928. Miss Bellamy has also recorded 27 distinct shocks from epicentres between lat. $37.5^{\circ} N.$ and $38.5^{\circ} N.$, long. $21.5^{\circ} E.$ and $23.2^{\circ} E.$, during the years 1913-30. In the present instance, a considerable amount of damage was done to property at Kalavryta, but no casualties are reported.

Comets

COMET PONS-WINNECKE (1939 c) is rapidly approaching the earth and will soon be visible in a small telescope. An ephemeris is given below from which it will be seen that the nearest approach to the earth will be about July 3, when it will be a little more than 10 million miles away. Towards the end of June it will be close to the moon and will probably be difficult to see as the moon will then be near the full.

	α 1950-0	δ 1950-0	r	Δ
June 13	15h. 16.3m.	$34^{\circ} 33'$	1.112	0.201
20	31.7	21 24	1.103	0.154
30	06.6	11 06	1.105	0.117
July 2	16.6	19 26		
4	25.1	27 37		
6	40.6	35 18	1.114	0.119

Dr. M. Davidson and also Dr. E. Bucher have computed a general orbit for Comet Jurlof-Ashmarof-Hassel (1939 d). It is now established that it has a long period, probably several hundred years.

Announcements

A JOINT meeting of the Division for the Social and International Relations of Science of the British Association and the Manchester Literary and Philosophical Society will be held in the Physics Department of the University of Manchester on June 21, beginning at 11 a.m. Sir Richard Gregory will give an introductory address on "The Aims of the Division", and will be followed by Prof. H. Levy, who will deliver the Alexander Pedler Memorial Lecture on "Social Relations of Science: Principles and Methods of Analysis". In the afternoon, an old-established industry and a new industry which has arisen out of scientific research will be discussed. Dr. F. C. Toy will speak on "The Influence of Science on the Cotton Industry", and Dr. V. E. Yarsley and Mr. E. G. Couzens will speak on "The Plastics Industry". Admission to the meetings will be free without ticket.

THE new buildings of the Department of Glass Technology of the University of Sheffield will be opened by the Right Hon. Lord Riverdale, chairman of the Advisory Council for Scientific and Industrial Research, on June 12.

At a meeting of the General Council of the British Standards Institution held on May 9 Sir Percy Ashley, formerly secretary and now a member of the Import Duties Advisory Committee, was elected chairman of the Institution for the ensuing year. The annual general meeting will be held at the Dorchester Hotel, Park Lane, W.1, on June 15 at 11.15 a.m.

THE Imperial German Academy at Halle, has awarded the Cothenius Medal to Dr. Alfred Vogt, professor of ophthalmology at Zurich, for his pioneer work in certain branches of his speciality.

DR. RAJCHMAN, director of the Section of Hygiene of the League of Nations since 1921, has retired and has been succeeded by Dr. Gautier of Geneva.

THE DECHEMA, the German Chemical Engineering Society, has removed its offices (Dechema-, Achema- and Standard-office) from Berlin to Frankfurt a.M., Dechema-Haus, Bismarckallee 25. A branch office will remain in Berlin, Haus des Vereins Deutscher Chemiker, Potsdamer Str. 111, Berlin W 35.

THE Mullard Wireless Service Co., Ltd., of 221 Tottenham Court Road, W.1, has sent us a leaflet describing a new Mullard cathode ray tube unit. This unit employs a high-vacuum cathode ray tube with four deflection plates. Owing to the reduction of plate and stray wiring capacities to a minimum, it is suitable for use at all frequencies up to those corresponding to ultra-short radio waves.

AN arrangement has been concluded whereby Johnson, Matthey and Co., Ltd., have acquired a controlling interest in Mallory Metallurgical Products Ltd., and the offices of this company have been removed to those of Johnson, Matthey and Co., Ltd., 78, Hatton Garden, E.C.1. A new factory is being erected at Wembley for the production of the Mallory range of Elkonites and copper alloys for use as electrical contacts, switchgear components and resistance welding electrodes. Dr. L. B. Hunt continues to act as technical manager of the company.

THE Cambridge University Press is about to publish a book by Dr. Lewis F. Richardson entitled "Generalised Foreign Politics". This is a more complete version of Dr. Richardson's address to the British Association last year, in which he applied mathematical methods to problems of international relations.

ERRATUM. In NATURE of May 27, p. 885, col. 2, line 16, for "square centimetre" read "square metre".

The F_2 Region as an Indicating Mechanism for Solar Activity

THE fact that F_2 region critical frequencies and solar activity correlate in a general way is well known. Moreover, I have shown¹ that the effect of changes in ionization which occur throughout the year can be eliminated in such a way as to bring out a clear-cut correspondence between these critical frequencies and smoothed average sunspot numbers. In an effort to find a more sensitive index for correlation purposes, a study has been made using both whole disk and central zone character figures for calcium and hydrogen flocculi as well as relative sunspot numbers. It has been found that the central zone indexes are better than those for the whole disk. When the monthly averages of the character figures for calcium flocculi are used, it is found that no smoothing is necessary, provided the effect of changes that occur throughout the year is eliminated.

The data used in this study consisted of monthly average values of the central zone character figures for calcium flocculi, and the monthly average for undisturbed days of the critical frequency values, giving equal weight to all hours of the day. The calcium character figures were obtained from the bulletins of the International Astronomical Union, while the radio data for Washington, D.C., have been published by the National Bureau of Standards in

Fig. 2.

CENTRAL ZONE CHARACTER FIGURES BASED ON OBSERVATIONS OF CALCIUM FLOCCULI AND RADIO MEASUREMENTS.

various issues of the *Proceedings of the Institute of Radio Engineers*.

The radio data show a progressive variation from one month to the next during periods of constant solar activity. This variation may be separated from that due to solar activity by plotting the data for each of the twelve months separately. This is done in Fig. 1, where for each month the radio data are plotted against the character figure for that month.

Having obtained the straight lines of Fig. 1, we now use these curves and the radio data to obtain a radio character figure for solar activity. This character figure is plotted in Fig. 2 along with the calcium figures for: (1) the average of several observatories (international) and (2) the value obtained at Mt. Wilson. It is seen that the general trend of all three curves is substantially the same. The curves for the Mt. Wilson data and the radio data indicate a maximum in 1937, while the middle curve indicates a less pronounced maximum for 1938. In this respect the curves for Mt. Wilson data and the radio data are alike. In general, it may be concluded that the radio data give a reasonably good measure of solar activity.

Fig. 1.

MONTHLY CORRELATION CHARTS: AVERAGE CRITICAL FREQUENCIES AND CENTRAL ZONE CALCIUM CHARACTER FIGURES.

From one point of view we may regard the F_2 region of the ionosphere as an indicating mechanism for solar activity. In the case of the character figures, the calcium flocculi observations are made directly in the sunlight. In the case of the radio observations, the solar effect causes the ionization of the F_2 region and the measurements are

made by observing the critical frequencies of this region. Since the critical frequencies are a measure of the ionization, it is seen that this whole process is merely a different way of measuring solar activity. Of course we would not be justified in using this method if other factors entered in such a way as to confuse the result. It is believed that the correlation results shown in this note indicate that other factors, if present, can be ignored, at least to the first approximation.

From the point of view of the ionosphere, there are a number of interesting points which for completeness should be discussed. Limitation of space, however, requires that this phase of the subject be discussed elsewhere. It may be pointed out, however, that for constant solar activity at other times than at minimum activity, the monthly average critical frequencies have two maxima, one in February-March and one in October. This may be seen in Fig. 1. A similar effect is well known for magnetic activity:

Position occupied by the Activator in Impurity-activated Phosphors

ALTHOUGH it is often assumed that the activator in impurity-activated phosphors is in solid solution in the matrix of the material, direct evidence of this

X-RAY PATTERNS OF ZINC ORTHOSILICATE (A) PURE, AND (B) CONTAINING MANGANESE; CALCIUM TUNGSTATE (C) PURE, AND (D) CONTAINING LEAD.

has hitherto been lacking. Recently, G. R. Fonda¹, in a general paper on fluorescence, mentions briefly that he has found an expansion of the lattice due to manganese in the case of zinc orthosilicate, but gives no experimental details.

During the past twelve months, we have investigated an extensive range of impurity phosphors by the X-ray method and have been able to demonstrate in several cases a measurable change in the lattice dimensions of the matrix material due to the presence of the activator. Among the phosphors for which lattice changes have been detected may be mentioned zinc beryllium orthosilicate, calcium tungstate and zinc orthosilicate.

The X-ray patterns were taken in a 10 cm. diameter diffraction camera of the type described by Bradley

and Jay², with knife edges arranged to cast a shadow at an angle of 170° . A and B in the accompanying reproduction illustrate the difference between pure zinc orthosilicate and a zinc orthosilicate containing $2\frac{1}{2}$ per cent manganese by weight added as manganese nitrate. The displacement of the lines away from the knife edge shadow from the positions for the pure material, corresponding to a lattice expansion will be noted. The magnitude of the lattice expansion can be seen from the accompanying table, in which the interplanar spacings for two or three lines at the high diffraction angle end of the X-ray patterns for three different percentages of manganese are recorded. It is clear that this is the kind of lattice change that be expected from the replacement of zinc atoms by manganese atoms, and the activated phosphor can be regarded as a solid solution of manganese orthosilicate and zinc orthosilicate.

INTERPLANAR SPACINGS NEAR DIFFRACTION ANGLE 85° FOR ZINC ORTHOSILICATE ACTIVATED BY VARIOUS PERCENTAGES OF MANGANESE (COPPER $K\alpha$ RADIATION).

Copper $K\alpha$ radiation	0% manganese	1% manganese	$2\frac{1}{2}$ % manganese
a_1	0.7723 ₂	0.7738 ₂	0.7783 ₂
$a_1 a_2$	0.7739 ₂	0.7745 ₂	0.7753 ₂
$a_1 a_3$ (mean)	0.7867 ₂	0.7873 ₂	0.7878 ₂
$a_1 a_4$ (mean)	0.7911 ₂	0.7917 ₂	0.7923 ₂

Calcium tungstate is representative of a class of phosphor in which the deliberate introduction of an activator is not essential for the production of luminescence. Lead is, however, sometimes used as an activator in calcium tungstate, the effect being to shift the centre of gravity of the fluorescent bands towards longer wave-lengths. The X-ray pattern in C and D clearly show the solid solution effect in the case of calcium tungstate activated by approximately 3 per cent by weight of lead.

It is hoped to publish the results in more detail elsewhere.

Luminescence and Photoconductivity of Solids

WHEN ultra-violet radiation is absorbed by atoms in a solid, one of two things may happen. Electrons may be freed from the parent atoms or impurity centres, in which case these electrons are able to take part in conduction processes and are said to be in the conduction band. On the simplest view, it follows from this that photoconduction is to be associated with a hyperbolic decay law. On the other hand, electrons may be raised to states lying below the conduction band, in which case the electrons are still bound to the parent atoms and are unable to take part in conduction. Electrons in this condition are said to be in excitation states, and the phosphorescence decay law should then be exponential.

We have carried out measurements on the photoconductivity and phosphorescence decay curves of a large number of luminescent solids, and from the results have obtained direct evidence of excitation

states in uranyl salts and tungstates, and also in a number of impurity compounds activated by manganese and chromium.

Uranyl salts, as was to be expected, show no photoconductivity, and the exponential phosphorescence decay curves are in agreement with the idea¹ that the luminescence of these salts is a result of the absorption of energy within the co-ordination group of the uranyl ion.

The tungstates of calcium, magnesium and zinc do not show photoconduction under radiations giving rise to strong fluorescence. This new fact, together with the exponential decay², supports the suggestion that the luminescence of these compounds is similar in origin to that of the uranyl salts, and arises from transitions between the excitation states and the ground state of the WO_4 ion.

It has recently been shown by one of us³ that the fluorescence of pure manganous compounds, and of solids activated by manganese, is in many instances due to transitions within the Mn^{++} ion. Our measurements on photoconductivity and phosphorescence have now confirmed this view. Pure manganous chloride ($MnCl_2$) is not photoconducting, neither are the compounds cadmium chlorophosphate, cadmium borate, cadmium silicate, or zinc mesodisilicate when activated by manganese. We have also measured the phosphorescence decay curves for these compounds and find them to be exponential. Other examples of non-photoconducting solids we have found are alumina with chromium impurity (ruby), and pure calcium oxide.

As the fluorescence spectra of the uranyl salts, the ruby, and calcium oxide are of the well-resolved type, it would appear that this type of spectrum is in general to be associated with lack of photoconduction.

It is well known that luminescent energy can be stored in certain phosphors at low temperatures; this energy is released on warming the solid. We find that solids showing this effect of 'thermal glow' to any marked extent are photoconducting solids such as willemite and the zinc sulphides. Non-photoconducting solids show little or no thermal glow.

In zinc sulphide phosphors we find also that it is the long period phosphorescence that is enormously delayed by cooling. The medium period decay of the order of milliseconds takes place rather more rapidly when the solid is cooled to 90° K.

Spectrographic Analysis of Three Arthropods

Two species of insects and one species of chilopod have been analysed by the methods¹ developed in the spectroscopic laboratory of the Experiment Station of the Hawaiian Sugar Planters' Association. These methods give information only on the metallic and semi-metallic elements present in the sample. Although the analyses are essentially qualitative, clear distinctions between the major, minor and trace constituents can be made.

The specimens analysed were selected to cover a wide range of feeding habits. They included sugar cane beetle borers (*Rhabdoonemius obscura* (Boisd.), segregated according to sex); large common centipedes (*Scolopendra subspinipes* Leach); and cypress cockroaches (*Diploptera dytiscoides* Serville). The beetle borers are plant feeders, spending all their lives except the adult stage within sugar cane stalks. The centipedes are predators, feeding principally on small insects. The cockroaches are omnivorous scavengers; the particular ones analysed were found in dusty soil under stones and bits of refuse. None of these species is indigenous to Hawaii.

The specimens were washed in boiling distilled water and then ashed in platinum for six hours at 500° C. Two-milligram samples of the ash were used in analysis.

A similarity in metallic constitution was found for the three species, the general composition being:

Chief constituents: Phosphorus, silicon, potassium, calcium and magnesium (the chief mineral elements found in plant material).

Less plentiful constituents: Iron, manganese, copper and sodium.

Trace constituents: Zinc, aluminium, strontium, barium and titanium. (No titanium found in the centipede ash.)

Four additional trace elements were found in the cockroach ash, namely, lead, boron, chromium and nickel. In addition, this ash was strongest in iron, silicon, aluminium, and perhaps calcium and potassium. On the other hand, the centipede ash contained the *least* of the chief soil elements, iron, aluminium and titanium, and of the plant material elements silicon, potassium and perhaps manganese. The beetle borer ash was strongest in barium, and showed a trace of tin. No differences between the composition of male and female borers were noted.

The large number of mineral elements present in the cockroach ash, and the heavier concentration of metals in this sample, suggests a correlation between feeding habits and metallic composition.

Ash analysis results for several other species of insects have been compiled by Uvarov².

Thanks are due to Mr. R. H. Van Zwaluwenburg, associate entomologist at the Experiment Station, for suggesting these analyses and for furnishing the specimens.

Ionization in the Troposphere

W. KOLHÖRSTER¹ has recently expressed the opinion that G. A. Suckstorff's measurements² have proved the existence in the troposphere of additional ionization caused by radioactive substances to be found in the temperature inversion layers. Suckstorff found in the higher layers of the troposphere enormous oscillations of ionization, amounting sometimes to 50 per cent of the measured value. The amplitudes of these oscillations increased with height; thus, Suckstorff formed the opinion that the oscillations were due to radioactive substances of extra-terrestrial origin present in the upper troposphere.

In order to obtain more information concerning this question, analogous measurements have been carried out. During three balloon flights (March 26, 1936 and June 18, 1936, results still not published; May 14, 1938) the ionization was explored² between 6 km. and 10 km., within which range Suckstorff has detected the greatest oscillations.

Within the limits of observational errors (generally a few per cent) quite smooth curves have been obtained, displaying no irregularities. The most convincing results were obtained in the last flight, when two ionization pressure chambers were used, filled with krypton and nitrogen, respectively, the specific ionization in nitrogen and krypton being quite different for cosmic and radioactive gamma rays⁴. The velocity of the ascent of the balloons was of the same order of magnitude as in Suckstorff's flights (in the first flight it was even less). The apparatus used were at least twenty times more sensitive than that used by Suckstorff. We are compelled to assume that the oscillations observed by Suckstorff were due to some instrumental faults.

As regards the anomalies observed by J. Juilfs⁵ in his measurements carried out in the lower troposphere (up to the height of 5.7 km.), we agree that radioactive substances of terrestrial origin are not unlikely to cause deviations in the ionization curve from its normal shape. It would be highly desirable to have these interesting observations repeated with modern sensitive instruments.

Anomaly of the Specific Heat of Potassium Dihydrogen Phosphate at the Upper Curie Point

THE dielectric properties of Rochelle salt, potassium dihydrogen phosphate and potassium dihydrogen arsenate, depend on the electric field in the same way that the properties of ferromagnetic substances depend on the magnetic field. The spontaneous polarization is large between the two Curie points and depends on temperature. Approaching the higher (normal) Curie point from lower temperatures, the spontaneous polarization vanishes. As a consequence the specific heat shows an anomaly, corresponding to the magneto-caloric effect in ferromagnetics.

This anomaly was found by Kobeko and Nelidow¹ and Rusterholz² in Rochelle salt. Wilson³ and Hicks and Hooley⁴, however, could not detect it. The variation of the spontaneous polarization as a function of temperature is so slow, that the anomaly of specific heat is spread over a wide temperature range and therefore the deviations are small. Although the maximum of specific heat measured by Rusterholz was considerably higher than was expected from the theory, the total anomalous heat capacity $\int \Delta C dT$ agrees well with the values calculated from recent results of the spontaneous polarization (Hablitzel⁵).

As the change of spontaneous polarization of potassium dihydrogen phosphate is larger and more

rapid with temperature, it is probable that the electro-caloric effect will be more pronounced. The specific heat of this salt was therefore measured in a vacuum calorimeter. The salt was heated by a constant flow of radiation and the increase of temperature was measured as a function of time.

SPECIFIC HEAT OF POTASSIUM DIHYDROGEN PHOSPHATE

The results plotted in the accompanying graph show a strongly marked anomaly of specific heat of about 180 cal./mole/degree. The integral $\int \Delta C dT$ representing the energy necessary to destroy the internal field, was found by this method to be 60 cal./mole. With this value and a maximum polarization $P_{\max} = 4.8 \times 10^{-6}$ coulombs/cm.² measured by Busch⁶, the Lorentz value f is found to be 0.5, applying the Langevin-Weiss formula $\int \Delta C dT = \frac{1}{2} f P_{\max}^2$. This is in fair agreement with the value $f = 0.4$ calculated by Busch from dielectric investigations.

The variation of the specific heat as a function of temperature can be calculated from the differential Langevin-Weiss formula. Owing to the rapid increase of P_{spont} as a function of temperature, it is therefore not possible to give an exact maximum value of ΔC , but the agreement between observed and calculated values is fairly satisfactory. It is intended to investigate potassium dihydrogen arsenate and also the effects at the lower Curie point.

Crystal Structure of Diphenyldiacetylene

DIPHENYLDIACETYLENE¹ ($C_6H_5-C \equiv C-C \equiv C-C_6H_5$) crystallizes from acetic acid in monoclinic prisms. From rotation-, Weissenberg- and Laue-diagrams the symmetry and dimensions of the unit cell have been determined.

$a = 6.61 \text{ \AA}$; $b = 6.04 \text{ \AA}$; $c = 14.92 \text{ \AA}$; $\beta = 105^\circ$.

With two molecules per unit cell the density should be 1.163, observed density 1.16. The most probable space group is C_{2h}^2 ($P_{21/c}$).

As C_{2h}^2 has four equivalent sets of two-fold positions, the centres of symmetry of the two molecules may be put at 000 and 011. By the method of trial and error the following details were found. The long axes of the molecules form angles of 42° , 38° and 78° with the a , b and c axes respectively. Within the limits of error the molecules are flat with straight carbon chains; the planes of the phenyl rings of the two sets of molecules are not parallel with each other or with one of the basal planes. The lengths of the primary bonds are in accordance with experience. The smallest distance between carbon atoms of two different molecules is 3.45 – 3.65 Å.; it occurs between carbon atoms of the phenyl groups. It thus seems that the forces of cohesion are acting mainly between these.

A Fourier synthesis is in progress with the aim of specifying the shape of the carbon chain, especially the length of the 'single' bond in the middle of the molecule. It will be interesting to compare the complete structure with the results of Robertson and Woodward's investigation¹ of the structure of tolane ($C_6H_5-C\equiv C-C_6H_5$).

Centrifugal Stresses in Rotating Disks

In recent experiments at this laboratory, the photo-elastic method has been successfully applied to the determination of centrifugal stresses in rotating disks. The new technique depends upon the double structure of Bakelite BT-61-893¹. Bakelite consists of two phases, one of which (the A phase) fuses at relatively low temperatures. If a sample is heated, the viscosity of the A phase is rapidly lowered until it becomes virtually negligible at about 115° C., whereas the C phase is little affected. At this temperature the modulus of elasticity is reduced to 1/640 of its value at room temperature and the stress-optical coefficient is increased twenty-five times. If the specimen is subjected to external load at this temperature, and allowed to cool slowly to room temperature while still under load, the deformation and photo-elastic optical effect are 'frozen in'. This is brought about by the solidification of the liquid A phase within the space lattice formed by the C phase. Subsequent removal of load leaves the deformation and optical pattern virtually unaltered.

Use is made of these properties by spinning (at constant speed) a Bakelite model of the rotor to be studied, raising its temperature to about 110 – 115° C., and slowly cooling to room temperature. The specimen may then be removed from its mounting and studied while at rest. This technique eliminates the tremendous handicaps of the stroboscopic method, which has the disadvantage of requiring high speeds, high intensity of illumination, and extremely accurate synchronization. A stroboscopic study also requires the construction of a mounting which permits the viewing of the central portion of the

disk during rotation—a great hindrance because the axis of rotation and the axis of the polariscope must be practically coincident. The increased optical sensitivity at an elevated temperature makes possible the use of relatively low speeds and small models (the accompanying photograph was made of a model $5\frac{1}{4}$ in. in diameter and 1 in. thick; speed, 1,800 r.p.m.). The technique is applicable to all problems of centrifugally induced stress distributions where the speed of the rotor is constant.

A more detailed account of these investigations will be published upon completion of the current experiments.

Does the Rabbit Chew the Cud?

SOME years ago my attention was directed to a paper by Morot (1882)¹ (carefully abstracted by A. V. Wills²). It seems to have been overlooked in physiological literature. Since his results seemed strange, I carried out some experiments to test them.

Morot stated that rabbits produce two sorts of faeces, the first during the night—soft, mucous; the second during the day—of the familiar appearance. The night faeces are taken directly from the anus, and without being chewed, swallowed like pills. These pills, which are regularly met with in the stomach (a well-known fact), are only seen free when the animals are prevented from getting at their anus.

That Morot's claims were correct was shown in two ways. I provided a rabbit with a wooden collar, which allowed it to jump around a little. In a cage with wire mesh floor two sorts of faeces immediately appeared in a day-night rhythm. Nine rabbits were fed simultaneously with fig seeds and killed intermittently. It appeared that the food in about twenty-four hours had passed through the intestines twice. An especially convincing case was presented by a rabbit, which was killed at 3 o'clock in the morning.

It had 'stomach buns' both in the rectum and in the stomach, and in both was found a nematode, *Passalurus ambiguus*, being a common caecum and colon parasite. Morot was of opinion that the difference in consistency of the two sorts of faeces is due to the food having passed once or twice. But since the two sorts were still produced by a collared rabbit even after a month, the difference in consistency must be due to an intestinal rhythm in the rabbit itself.

In the physiological literature it is commonly known that rabbits are coprofagous¹; but it has not been commonly acknowledged that this is really a fully normal and regular physiological process. Some points in literature seem to show that similar processes are found in guinea pigs and other herbivorous rodents². Further investigations are to be directed towards the meaning of this peculiar process in the form of analyses of the contents of digestible matter, salts and vitamins in the two sorts of faeces. An analysis of the intestinal rhythm would seem to be of great interest³.

THE curious food pellets described by Morot and mentioned in Dr. Madsen's letter must be familiar to all laboratory workers who have occasion to open the rabbit's stomach. They have frequently been seen in the parasitological department of this Laboratory during the course of work carried out on the stomach worm *Gnathidium strigosum*, and we have wondered how it could be possible for the mucous membrane of a large hollow organ to form such perfectly rounded pellets.

The explanation given by Morot and confirmed by Dr. Madsen was new to us and at first we were inclined to regard it as too fantastic for serious consideration; the pellets frequently constitute more than one third of the stomach contents and refection to such a degree seemed too improbable for us to believe it without further proof. In view of the importance of the rabbit as an experimental animal and the significance of information on such a point to workers in nutrition or in parasitology, one or two observations were made at this laboratory to ascertain whether there was a sound foundation for Morot's theory.

Although in arranging these experiments we did not expect to be able to confirm Morot and Madsen's observations, we acknowledged in the end that in all probability their conclusions are correct, and that, presumably, for reasons of the digestion of cellulose, the rabbit is in the habit of swallowing large amounts of its own faeces in bolus form directly from the anus, so providing an example of physiological refection to a more marked degree than had previously been thought to exist.

This point in the special physiology of the rabbit is of considerable significance for the correct interpretation of metabolism experiments in which the animal has been used, and there can be little doubt that the observation brought forward by Morot and Madsen will invalidate some and perhaps many of the conclusions that have been arrived at in past metabolism experiments on this animal.

A series of observations on the fate of ingested copper recently carried out on the rabbit at this laboratory might be cited as a case in point. It was found that the excretion of copper in the faeces following an experimental feed, was spread over a period of between four and five weeks, and it has been tentatively concluded that in all probability the copper is temporarily stored in the intestinal mucous membrane and gradually passed into the intestine by a process of exfoliation of the cells. I now appear that a more rational explanation would be the repeated refection of the copper-containing faeces.

The few observations made at this laboratory may be briefly stated as follows:

Examination of the stomach pellets in a few rabbits showed them to be of varying sizes ranging from 0.2 to 1.0 cm. in diameter, more or less spherical soft in consistency, coated with a thin layer of mucus and so well separated from one another that they fall apart when shaken out of the opened stomach. They occur almost invariably at the cardiac end composing up to one half of the stomach contents but a few pellets may sometimes be found mixed with the general mass.

An observation made on three muzzled and three control rabbits kept in individual cages overnight showed that two kinds of faeces had been passed in both experimental and control groups, which was contrary to the refection theory.

Rabbits are almost invariably infected with coccidia in the mucous membrane of the intestine and frequently in the liver, but not in the mucous membrane of the stomach. Examination of the stomach pellets, however, showed them to contain large numbers of coccidial oocysts, not quite so many as were found in the faeces of the same rabbit, but eight or ten times as many as could be found in the general mass of the stomach contents. This was greatly in favour of the refection theory.

Examination of the stomach contents forty-eight hours after an experimental feed containing *Lycopodium* spores¹ showed many spores still to be present. As the stomach of a control rabbit fasted overnight contained very little food indeed, this observation is also suggestive of refection.

None of the observations, however, quite ruled out the possible explanation of the presence of oocysts or spores in the stomach as the result of the casual refection that might occur in an animal confined to a small cage. Another observation was therefore made on a series of six rabbits that were first fasted for 48 hours; three of these were then fastened into rubber bags leaving only their heads uncovered and all were given food *ad lib.* Post-mortem examination on the following morning revealed the presence of numerous stomach pellets in all three of the control rabbits, and the complete absence of stomach pellets from the stomachs of the rabbits that had been tied into bags. Numerous coccidial oocysts were also found in the stomach pellets of the control rabbits but oocysts were absent from the stomach contents of the other three, which appeared to prove the faecal origin of the pellets.

We were therefore led to conclude that the rabbit practises physiological refection to a very marked degree, between one third and one half of the stomach contents normally being of faecal origin. This observation has an important bearing on the interpretation of results of metabolism experiments in the rabbit.

I look forward with much interest to the publication of Dr. Madsen's further observations.

Owls and Infra-Red Radiation

In a paper published in 1934, F. L. Vanderplank¹ records certain observations which are interpreted as showing that the tawny owl, *Strix aluco* L., is able to perceive infra-red rays visually, and thus to see in total darkness the small animals on which it preys.

To test this possibility we have carried out the following experiments on the eye of a tawny owl.

(1) In the intact animal (under urethane anaesthetic) we recorded, with an oscillograph and suitable amplifying system, the retinal potential produced in response to stimulation by white light, using an electric bulb as source. There is a large and clearly marked response, as in other animals.

RETINAL RESPONSE OF THE DARK-ADAPTED EYE OF THE TAWNY OWL TO SUDDEN ILLUMINATION OF APPROXIMATELY SIX FOOT-CANDLES.

Electrodes on the cornea and in the mouth.
1 cm. = 150 microvolts. Time, 0.02 sec. intervals.

No potential could be detected, even with the highest possible amplification, in response to stimulation by infra-red radiation from a large black body at 40°–400° C. close to the eye.

(2) We placed the eye of a tawny owl, immediately after removal from the animal, between a source of infra-red rays and a sensitive Moll thermopile. The sclerotic and retina were removed, so that the cornea, lens and humours were in the path of the rays. When the eye was interposed, we could detect no response from the thermopile, and if any transmission occurred it was less than 0.5 per cent.

We obtained consistently negative results in both experiments, using a black radiating body as source at temperatures from 40° C to about 400° C. Transmission through the mammalian eye² practically ceases for wave-lengths longer than 15,000 Å., and we conclude that the eye of the tawny owl, like that of other animals that have been examined, is opaque to long infra-red rays. Even if the retina should be sensitive to long infra-red rays, none can reach it in the undamaged eye.

Our experiments lend no support to the view that the owl can see a small animal in darkness by its own infra-red radiation.

Specificity of the Evocator in *Hydra*

Tissue from *Hydra viridis* boiled in water for ½–1 minute and implanted into the blastocoel of *Triton* gastrulae evokes the formation of neural tissue and in some cases neural tubes¹.

Thirty years ago, Browne² observed that the implantation of peristome tissue, or the material of a regenerating hydranth, or tissue from a bud in *Hydra viridis* resulted in the outgrowth of a new hydranth. Grafts of tissue from other regions of the *Hydra* body and wounds gave negative results. These results were confirmed by Rand, Bovard and Minnich³ for *Hydra oligactis* (fused).

Child⁴ has produced supernumerary hydranths in another hydrozoan, *Corymorpha*, by lacerations and by the grafting of various regions of the stem. Santos⁵ has produced supernumerary heads in planarians by the implantation of cephalic ganglion region. Supernumerary heads have developed in planarians following such diverse stimuli as laceration, faradic stimulation and cautery⁶.

In view of the reactions of *Corymorpha* and of the planarians, and since *Hydra* is known to possess an extremely high regenerative potency, it was believed that supernumerary hydranths could be produced by some means other than the transplantation of the tissues noted by Browne (*loc. cit.*). The techniques which had yielded successful results on planarians were used on *Hydra oligactis*.

A toothpick, the tip of which had been sharpened to a very fine point, was dipped into 70 or 80 per cent ethyl alcohol and the tip was then applied to the tissue of the mid-region of individuals of *Hydra*. In others, the tissue in the same region was lacerated with a finely pointed ophthalmic knife, and in a third group a heated micro-cautery needle was lightly touched to the *Hydra* tissue. Supernumerary hydranths did not develop in any of the 150 treated animals which continued to live after the injury without any apparent ill-effects.

Why *Hydra* should react only to a specific stimulus is not clear to me. Other agents which have been used successfully on other forms will be tried on *Hydra*.

Presence of Cancer-producing Substances in Roasted Food

A SERIES of mice was painted every second day for a long time in the ordinary manner in the occipital region with an alcohol or petroleum extract (a) of horse muscle, treated at a temperature of 275° C., (b) of browned butter, or (c) of roasted coffee. As controls we employed (a) a series of mice painted in the same manner with an alcohol or petroleum ether extract of horse muscle dried on a water bath or in a hot current of air, untreated butter and unroasted coffee, and (b) a number of untreated animals.

The experimental series have so far comprised 241 animals—149 males and 92 females. The spontaneous frequency of malignant tumours among the females is 10 per cent at most. Among the males this frequency is, as usual, much lower.

So far, no malignant tumours have been observed in the male mice painted with extract of either roasted or unroasted food. On the other hand, a giant-cell spindle-cell sarcoma was produced in the painted region in a series of mice which had been painted for a long time with pure cholesterol, treated at 275° C., emulsified in coco-nut fat. Further, certain chronic changes of great interest, which will be described later, were observed in the animals treated with roasted food.

Twenty-three of the female mice treated with extracts of roasted food survived a period of application of 11 months. In this period we observed nine malignant tumours in the mammary glands, all of the adenocarcinoma type (= 40 per cent), namely, two after the application of petroleum ether extract of roasted coffee, one after browned butter, two after petroleum ether extract of roasted muscle and four after the application of an alcohol extract of roasted muscle. The average time for the appearance of these tumours was 360 days. In the control series (26 animals) only one case of mammary cancer (= 4 per cent) was observed during an observation period of 378 days.

The statistical probability of such a distribution of the tumours (9 tumours in 23 animals treated with an extract of roasted material and 1 in 26 animals in the control series) occurring simply by chance is not more than 0.0026, that is, the chance of this occurring in such series is only one in 380. Moreover, as the tumour frequency has increased to 40 per cent, as compared with the maximum expected incidence of 10 per cent, the probability that chance has played a part is much less, and on that account I consider that I am justified in concluding from the results of these experiments that extracts of roasted food contain one or more carcinogenic substances.

These substances may be thought to reach the mammary tissue by resorption from the skin. However, very little change was noticed in the skin during the entire period of application. Cramer and Horning¹ and Burrows² have produced mammary cancer in mice by the application of estrone. Attempts to demonstrate the presence of an estrogen factor in the extract, however, have not yet given any positive results. Another possibility is that the carcinogenic factor reaches the organism *per os*, as the animals very quickly lick off the painted extract. The isolation of the active substance is in progress. A full report will be published in the *Proceedings of the Royal Physiographical Society of Lund*.

The present investigation was suggested by the observations of Kennaway^{3,4} and Kennaway and

Sampson⁵ that heating human skin, muscle, yea and cholesterol in a hydrogen atmosphere to 700° 920° C. produces carcinogenic substances with local effect.

Influence of Lactate on the Absorption of Glucose from the Intestine of Adrenalectomized Rats

IN experiments designed to throw light on the mechanism of sugar absorption and its control by the adrenal cortex, it was previously found¹ that with adrenalectomized rats sodium pyruvate restore the normal sugar absorption from the intestine. Similar experiments using the same methods have now been carried out with sodium lactate which was administered continuously in doses of 15–20 mgm a day subcutaneously. It was found that it shows the same effect as pyruvate does, restoring the low glucose absorption of the adrenalectomized rats to the normal level. (Normal absorption in forty-five minutes, 80.0 per cent of the injected glucose, with adrenalectomized rats 42.3 per cent, after lactate administration 73.7 per cent.)

Relation between the Secretory Cells of the Pars Nervosa of the Hypophysis and Classical Neuroglia

GEMSH¹ has shown that the glial cells of the pars nervosa—the pituicytes of Bucy²—are responsible for the secretion of the anti-diuretic principle of the posterior lobe. I have presented additional evidence³ which demonstrates that these cells elaborate the pars nervosa hormones. By the use of silver carbonate methods for neuroglia, developed by the Spanish school, Bucy showed that the pituicytes, like neuroglial astrocytes in the central nervous system, possess cytoplasmic processes, one or more of which end on connective tissue either in the form of pia, of that around blood vessels, or of septa. The pituicytes, however, are impregnated most satisfactorily by methods which demonstrate consistently neuroglial oligodendrocytes (these have cytoplasmic processes but no vascular attachments in contradistinction to astrocytes) and mesodermal microglia. Astrocytes are usually not impregnated by these methods.

In order to establish a clearer concept of the relationship between pituicytes and neuroglia, I have compared the morphology, genesis, and cytoplasmic inclusions of pituicytes with those of neuroglia.

From this study it has become evident that (a) pituicytes possess the distinct, ovoid cytoplasmic inclusions (gliosomes) characteristic of astrocytes and oligodendrocytes, but which are absent from microglia; (b) pituicytes, like astrocytes and oligodendrocytes, are spongioblastic in origin, being derived from the ectodermal supportive spongioblasts which line the lumina of the infundibular cavity and its extensions in the pars nervosa. The same 'pituoblast' is proposed for those spongioblasts which have quitted the ependymal epithelium and are migrating out to, and implanting attachments (foot plates) on, the peripheral connective tissue. Since oligodendrocytes are derived from those spongioblasts which never acquire foot plates, it follows that pituicytes are more closely allied to astrocytes. They are totally unrelated to mesodermal microglia. It appears, then, that pituicytes,

astrocytes and oligodendrocytes constitute a closely inter-related morphological, but not functional, unit.

It is interesting to note that Nageotte⁴, Mawes⁵, and Achúcarro⁶ have attributed glandular functions to neuroglia. The evidence is not conclusive, but the fact that one group of the glial unit—pituicytes—has endocrine functions, renders the hypothesis more plausible.

Points from Foregoing Letters

FROM a study of the correlation between indexes of solar activity and the critical frequencies of the F_2 region of the ionosphere, W. M. Goodall concludes that a monthly average character figure based on radio observations gives a reasonably good measure of solar activity.

The position occupied by the activating atoms in the crystal lattice of certain impurity-activated phosphors has been studied by the X-ray method by H. G. Jenkins, A. H. McKeag and H. P. Rooksby. In the case of zinc orthosilicate, for example, the addition of manganese causes a displacement of the X-ray lines which corresponds to a lattice expansion, and the lattice change is of the kind to be expected from the replacement of zinc atoms by manganese atoms.

J. T. Randall and M. H. F. Wilkins describe experiments on the photoconductivity and luminescence of uranyl salts, tungstates, and a number of compounds activated by manganese. The results give direct evidence of the existence of excitation states in these solids.

S. S. Ballard reports the spectrographic analysis of the total ash content of three species of arthropods. Nineteen metallic and semi-metallic elements were encountered during the investigation. A correlation between metallic composition and the feeding habits of insects is suggested.

From the results obtained in three balloon flights, S. Ziemecki concludes that oscillations of ionization found by G. A. Suckstorff in the higher troposphere are due rather to instrumental faults than to substances of extra-terrestrial origin. The anomalies found by J. Juilfs in the lower troposphere are likely to be due to radioactive substances of terrestrial origin.

The variation with temperature of the specific heat of potassium dihydrogen phosphate shows, according to W. Bantle and P. Scherrer, a strongly marked anomalous increase at the upper Curie point.

By the method of trial and error, the crystal structure of diphenyldiacetylene has been roughly determined by E. H. Wiebenga. A refinement of the parameter values will follow by the application of Fourier synthesis.

A new technique for determining centrifugal stresses in rotating disks by means of the photo-elastic method is described by R. E. Newton. The disk is made of Bakelite (BT-61-893), heated to 115° and allowed to cool while rotating at constant speed. In this way the photo-elastic optical effects are 'frozen in' and can be observed in polarized light when the disk is at rest.

Holger Madsen confirms Morot's statement that rabbits form two sorts of faeces, one of which is formed during the night and swallowed like pills directly from the anus. The difference of consistency is due to an intestinal rhythm in the rabbit itself. E. L. Taylor also confirms Morot's statement that the pellets found in the rabbit's stomach are of faecal origin; he considers it to be an outstanding example of physiological refection and thinks that its function may be the digestion of cellulose. He also directs attention to the important bearing which the observation has upon the interpretation of metabolism experiments carried out in the rabbit.

L. Harrison Matthews and Bryan H. C. Matthews find that infra-red rays produce no response in the retina of the tawny owl, and that the cornea, lens and humours transmit so small an amount as to be opaque to the rays for visual purposes. From direct experiments on the eye, they find no confirmation for the suggestion that in darkness owls can see infra-red radiation from animals on which they prey.

E. D. Goldsmith points out that thus far he has been unable to produce supernumerary hydranths in *Hydra* by either laceration of the tissue, local applications of ethyl alcohol, or micro-cautery. These techniques had previously yielded supernumerary heads in planarians.

By painting mice with petroleum ether or alcohol extract of roasted food, E. M. P. Widmark found that adenocarcinoma of the mammary glands was produced in a much higher frequency than the total incidence of spontaneous mammary cancer.

L. Laest finds that sodium lactate restores the normal glucose absorption from the intestine of adrenalectomized rats in a similar way as was found previously for pyruvate.

Research Items

Anthropometry of Syrian Males

MEASUREMENTS, as well as other observations of 1483 Syrian males, have been made by W. M. Shanklin (*J. R. Anthropol. Inst.*, 68, 2, 1938). Syria has been a battleground of the nations from time immemorial. Of the invasions of the mountains less is known than of those of the coastal regions; but within historic times one large mountain group, the Druzes, has migrated into southern Lebanon and the Jebel Druze in the Hauran. Like the coastal plain, the desert border has been frequently invaded. Question is raised whether the living races of to-day show traces of their complicated ancestry, and if there is any correlation between the diverse geographical areas and population. In this study the material is examined from the point of view of the religions represented and geographical areas—Shiite Moslems, Sunni Moslems, Christians, and Alouite and Druze, secret sects with Moslem origins. The geographical areas are mountain, desert-border, and desert. Summarizing the results of 15 measurements and 6 indices, as well as the other observations, it is shown conclusively that there are significant differences between the mountain groups and the desert border groups, while both of these differ from the Syrian Bedouin. The major differences are a progressive lengthening of the head, and a decrease of the cephalic index (maximum, Mitwali, 87; minimum, Rwala, 75), in passing from the mountain region to the desert border and the desert. Other changes in the same direction are a progressive narrowing and lengthening of the face and a lengthening of the nose. Convex noses, rarely seen in the desert, are frequently found in the other groups. There is also a progressive darkening of the skin towards the desert, and an increase in the percentage of blood-group O. The line of cleavage for Syrian racial differences is thus along geographical and not religious lines. The nomadic peoples of the desert are clearly Mediterranean in the larger sense. The border peoples represent a transition to a brachiocephalic stock, which cannot be considered 'Armenoid'.

Boat Oculi, Survival

In a further study of the survival of oculi on boats, Mr. James Hornell records additional examples from Portugal, the coasts of the Mediterranean, Madagascar, Zanzibar, the Swahili coast of East Africa, and the Far East (*J. R. Anthropol. Inst.*, 68, 2; 1938). In Portugal its use, though lingering in the fishing centres, is on the decline. There are several distinctive substitutes for the oculus, the most common being a star, usually five-pointed. Apart from these substituted devices, the same type of oculus with minor variations occurs along the whole coast line of Portugal south of the Tagus. The custom was encountered nowhere on the Spanish coast except at Malaga. In Sicily and in Malta the oculus is in common use as a device against the evil eye. In the Adriatic the true oculus is rare, though it does occur; but a large red disk on each bow is common around Venice. At ports lower down the coast the oculus is supplanted by a comma-shaped wooden boss on each bow. No trace of the oculus is found in the Red Sea

or Persian Gulf, owing to observation of the precept of the Koran against representation of the human figure, or parts of it. It is only when the Swahili coast is reached that the oculus is again encountered. Here the *mitope*, the only indigenous sea-going craft and many of the small craft of Pemba and Zanzibar are 'eyed', and commonly the eyes are duplicated in the stern. In Mayotte, the island nearest to Madagascar, the oculus is common, both on the bows and the quarters. In Madagascar itself the oculus, not found on the outrigger canoes, occurs on vessels of typical Arab design and on two-masted coasters of lighter type. Omitting India, where the oculus has already been noted, it appears in Burma, but has disappeared in Indonesia and the Malay Peninsula, where the Mohammedan religion has spread. It appears to have occurred sporadically in Selangor and Sumatra, and continues to flourish in Bali. An old tradition is preserved with fidelity in Botol Tobago. The statement made previously that the oculus is universal on the Chinese junk is incorrect. It is never seen on the boats of northern China.

Population Problems in the United States

THE Population Association of America arranged a symposium on "Intrinsic and Environmental Factors in American Population Growth", which was held at the American Philosophical Society, Philadelphia, in November 1938; and the results have recently been published (*Proc. Amer. Philos. Soc.*, 80, No. 4) as a series of papers by leading American students of population questions. The contributions include "Agriculture and Current Population Trends" by Conrad Taeuber, "Social Environment and Population Growth" by Warren S. Thomson, "Intrinsic Factors in Population Growth" by Frank W. Notestein, "Psychological Factors and Fertility" by John C. Flanagan, "Childlessness" by Clyde V. Kiser, "Cultural Patterns in Rural America" by O. C. Taylor, "Reflections of an Anthropologist on the Future of Population" by H. L. Shapiro, "Population Study and Related Sciences" by A. J. Lotka. The whole constitutes a valuable survey of population trends and problems in the United States, supported by extensive statistics on many points. These statistics are frequently derived from special investigations. Among the conclusions which emerge are the importance of contraception in lowering the birth-rate and the fact that the birth-rate has declined below the replacement level. In the professional group the reasons for family limitation are mainly financial, the cost of higher education and the health of the wife. One writer concludes from results derived from questionnaires that contraception is not responsible for any major share of permanent childlessness. The population is expected to reach its peak by 1980. There was a considerable movement back to the land during the depression years 1930-35. Migration from farms has taken place not only in regions where agriculture is non-commercial, but also in areas where commercial agriculture is dominant. In the latter areas smaller families appear to be a part of the culture complex.

Phosphorylations in the Cell

H. KALOKAR (*Enzymologia*, 5, 365; 1939) has shown that accumulation of phosphoric acid esters takes place in fresh kidney extracts under aerobic conditions so long as suitable concentrations of sodium fluoride are present. These esters do not normally accumulate owing to the activity of phosphatases, of which a group—the 'acid' phosphatases—are poisoned by fluoride. Fluoride, however, diminishes the respiration and this must have an inhibitory effect on the synthesis of the esters, which depends partly on the respiratory activity of the tissue. The specificity of the enzymes involved is shown by the facts that addition of α -glycerophosphate inhibits only the phosphorylation of glycerol, whilst the addition of hexosediphosphate inhibits only the phosphorylation of hexoses. M. Silverman and C. H. Werkman (*Enzymologia*, 5, 385; 1939) observe that phosphorylation of vitamin B₁ to form cocarboxylase takes place when a suspension of propionic acid bacteria (*Propionibacterium pentosaceum*) is incubated for two hours at 30° C. in a medium containing hexosediphosphate and synthetic vitamin B₁.

Nitrogen-containing Substances of the Intestines

K. RI (*J. Biochem.*, 29, 265; 1939) examined the large intestine and duodenum of healthy adult dogs for nitrogen-containing substances with the following results. The amount of choline, humine, purine-nitrogen, arginine, leucine, valine, isoleucine, phenylalanine and aspartic acid contained in the muscle layer of the duodenum was found to be larger than that of the muscle layer of the large intestine. The amount of glutamic acid and serine, however, contained in the duodenum was less than that of the large intestine. The duodenal mucous membrane was found to contain more choline, arginine, histidine, tyrosine, glutamic acid and glycocoll than the mucous membrane of the large intestine, and more humin, alanine and isoleucine were found in the mucous membrane of the large intestine than in that of the duodenum. Experiments showed that the chemical constituents of the digestive organs were distributed quantitatively, differing somewhat according to the various regions. Histidine, for example, was found in abundance in the duodenal mucous membrane and isoleucine in the duodenal muscle layer and in the mucous membrane of the large intestine.

Hypoglycemia and Anoxemia

H. E. Himwich, S. J. Martin, F. A. D. Alexander and J. F. Fazekas (*Endocrinology*, 24, 536; 1939) studied the activity of the autonomic system of dogs during hypoglycemia and anoxemia. Electro-cardiographic changes showed that in both conditions an initial transitory sympathetic influence was followed by parasympathetic predominance. This increased activity of the autonomic nervous system was associated with a depressed metabolism of the brain, as indicated by diminished cerebral utilization of oxygen. It is concluded that with depression of the brain metabolism the predominant and ultimate effect on the autonomic nervous system was a release of parasympathetic influence.

Alimentary Canal of Molluscs

The structure and function of the alimentary canal in different groups of molluscs have already been dealt with in several accounts in recent years.

This work is continued in a communication by Dr. Vera Fretter who has investigated these problems in the Tectibranchs, *Philina aperta*, *Scaphander lignarius*, *Haminea hydatis* and *Actaeon tornalis* (*Trans. Roy. Soc. Edin.*, 1939). All these have radulae, but the last has no odontophore so that the method of feeding is similar. *Actaeon* also differs from the others in lacking a pair of salivary glands which secrete a fluid containing an amylase and a glycogenase. Again, this species lacks a crushing gizzard. The stomach of all of them has a bilobed digestive gland opening into it; this produces a proteolytic enzyme with an optimum of pH 6.3 and a diastatic enzyme and a glycogenase with an optimum between pH 6.3 and pH 7.0 and a lipase. These enzymes produce soluble products and small particles which are ingested by the digestive cells of the digestive glands wherein digestion is completed. The gland exhibits a cyclical series of changes which includes secretion, and in *Philina* and *Scaphander* the latter phase of activity is associated with the expulsion of excretory matter. This gives rise to a characteristic type of faecal pellet. As in Gastropods purines tend to replace urea, it is suggested that in this group a terrestrial mode of life is preceded by a uricotelic metabolism.

Neocomian Cephalopods of India

The Cephalopoda of the Neocomian Belemnite beds of the Salt Range are described by Dr. L. F. Spath (*Palaeont. Indica*, N.S., 25, No. 1, pp. 154, pls. 25; 1939). They are found condensed into the basal beds or lower part of the Belemnite marls, and include eighty-one species of ammonites and three of belemnites; of the former only seven can be definitely identified with species already known; the latter belong mainly to the genus *Hibolites*. The ammonites show that the deposit is of Infra-Valanginian and Valanginian age, and indicate the existence of six zones, but the succession does not appear to be complete. They belong mainly to the families Olcostephanidae, Berriasellidae and Neocomitidae, and their affinities are with the fauna of the great equatorial belt (Tethys and extensions). The author believes that the distribution of oceans and continents was already essentially the same as at the present day, except for the more extended Tethys, and he visualizes an equatorial zone extending 45° of latitude north and south of the equator. While the fauna of the Belemnite beds consists essentially of cephalopods, it includes also a few representatives of reptiles, fishes, brachiopods, pelecypods and one gasteropod.

Greenkeeping Research

The spring number of the Journal of the Board of Greenkeeping Research (St. Ives Research Station, Bingley, 3s. 9d. post paid, 1939) contains an account, by R. B. Dawson and N. L. Ferguson, of the production of the St. Ives strain of creeping red fescue grass. This strain is a propagation of a uniform population of *Festuca rubra genuina* var. *glaucescens*, selected from sea marsh turf at Cark in Cartmel, Lancashire. The new strain offers greater leafiness and density of growth than existing commercial strains of the same species, and it has also good winter colour and reasonable resistance to fungal disease. Much of the St. Ives Station's work has centred around the treatment of lawns with appropriate fertilizers; but R. B. Dawson and R. B. Ferro show that this is inadequate without mechanical aeration.

by scarification. A paper on the Belfast Airport, by S. P. Mercer and P. A. Linham, describes some fascinating ecological transformations from dredged mud to turf which can support a load of four tons per square foot. The original soil had a salt content of about 0.4 per cent, and its relative acidity was pH 8. Many species of grass were tried upon the drained soil, but a mixture of 40 parts by weight of perennial ryegrass seed to one part of yellow suckling clover gave the best results. Sowings of *Poa maritima* were also used for initial colonization of bare mud. The interesting and complex life-history of an oil beetle, *Meloe proscarabeus*, is also described by Miss B. Lovibond. The species does not seem to cause much trouble upon lawns, except the distaste for its occasional presence in large numbers.

Melanism in Pheasants

THE two inter-fertile species of pheasant, *Phasianus versicolor* and *P. colchicus*, are subdivided into about 42 subspecies. The origin of one of these, sometimes called *P. colchicus* mut. *tenebrosus*, the black pheasant, is uncertain. J. H. Bruckner (*J. Hered.*, 30, 45-52; 1939) has reported some interesting breeding results. Melanism is dependent on one incompletely dominant gene. The F_1 hybrids between melanic pheasants and the common ring-neck pheasant, *P. colchicus*, are remarkably similar in the distribution of markings to *P. versicolor*. Bruckner suggests that *P. colchicus* may be the older or 'wild type', and that natural selection has selected the least melanic types to produce *P. versicolor*. Modifiers of melanic distribution are known in *P. colchicus*, and hybrids between melanic forms and *P. colchicus* range greatly in the amount of melanism.

Earthquakes during March 1939

ACCORDING to E. Peterschmitt, of the Bureau Central Séismologique de Strasbourg, there were a hundred earthquakes and strong tremors recorded by people and instruments during March 1939. There was not a day on which no earthquake was experienced somewhere in the world, and the greatest number on any one day was eight, on March 17. Of the hundred shocks recorded seventeen were of sufficient strength to have the epicentre determined accurately either by isoseismal lines or from instrumental recordings. Probably the strongest was on March 20, on the Island of Kiou Siou, Japan, and the next in order of magnitude were March 1, strength V, near Ebingen, Jura Souabe; March 5, strength V, La Cote-Saint-Andre (Isère, France); March 12, strength V, Province of Aquila, Italy. These were closely followed by March 20, strength IV, Barcelonnette (Hautes Alpes, France), and Susa (Torino, Italy), epicentre Mont Viso, 44.8° N., 7.1° E.; and March 30, strength IV, in the Ossan Valley.

Coastal Fogs in Scotland

A COMPARISON between the frequency of fog in each month of the year at Scottish lighthouses and inland observing stations in the period 1925-34 and similar data for the period 1889-1900 discussed by Buchan, is the subject-matter of Professional Note No. 88 of the Meteorological Office, by P. E. Dixon. The procedure at lighthouses is to log the number of hours on each day during which, in the opinion of the lightkeeper, there is sufficient atmospheric obscurity to necessitate the sounding of a fog signal, and the personal equation is a factor. At the climatological

stations, on the other hand, a more important disturbing factor is the seasonal variation of the time of sunrise in relation to the morning hour of observation. As the period between sunrise and one or two hours after sunrise is a critical one in regard to early morning fogs due to cooling of the lower atmosphere by radiation, this disturbing factor is apt to give rise in fog statistics to a spurious seasonal variation due to the fact that in winter the common hour of observation of 9 h. G.M.T. is favourably placed for the observation of this class of fog, whereas in summer it is much too long after sunrise and will have allowed most of the fogs to have cleared away as a result of prolonged sunshine. It appears from a chart (Plate IV) showing the average annual fog duration at the lighthouses in 1925-34 as a percentage of the average for the earlier period, that 1925-34 was in most areas much the least foggy; but when considering the exceptions, it is clear that these arise mainly because of increased industrial activity, resulting particularly in an increase of winter fogs so great as more than to counteract the general tendency, due to meteorological causes, for the 1925-34 period to be less foggy. This is particularly well shown in the Firth of Forth, and the Moray Firth, where the prevailing winds carry atmospheric pollution from industrial areas out to sea. The tendency for fogs with clear skies to thicken just after sunrise owing to an increase in pollution is well shown by the observations at fixed hours at Aberdeen, where the average number of fogs in 1927-36 increased from 0.4 to 7.0 between 7 h. and 9 h., whereas in summer the corresponding figures were 2.6 and 1.1.

Mechanism of Formation of Polythionic Acids

H. Stamm and H. Wintzer have shown (*Ber.*, 71, 2217; 1938) that the primary product in Wackenroder's reaction (the reaction between hydrogen sulphide and sulphur dioxide in aqueous solution with formation of polythionic acids) is thiosulphurous acid, $\text{H}_2\text{S}_2\text{O}_3$. Although this compound cannot be isolated, its chemical nature can be investigated by the aid of the hydrolysis of dimethyl thiosulphite. In a further communication (*Naturwiss.*, 27, 317; 1939) the authors conclude that the reactions of this substance which are important as regards the formation of polythionic acids are the following: $\text{H}_2\text{S}_2\text{O}_3 \rightarrow \text{H}_2\text{S} + \text{SO}_2$ (1); $\text{H}_2\text{S}_2\text{O}_3 + \text{H}_2\text{S} \rightarrow 3\text{S} + 2\text{H}_2\text{O}$ (2); and $\text{H}_2\text{S}_2\text{O}_3 + 2\text{HI} \rightarrow \text{I}_2 + 2\text{S} + 2\text{H}_2\text{O}$ (3). These reactions proceed quantitatively under suitable conditions. Reactions (2) and (3) show that the thiosulphurous acid is a powerful oxidizing agent. In order to study the reactions of the acid without reaction (1) occurring, it is necessary to work in a non-aqueous solvent, and for this purpose anhydrous formic acid was chosen. It was thus possible to show that the first reaction is reversible. When dimethyl thiosulphite was hydrolysed by hydrochloric acid in the presence of sulphurous acid in the correct proportion, tetrathionic acid was formed quantitatively, the equation being $\text{H}_2\text{S}_2\text{O}_3 + 2\text{H}_2\text{SO}_3 = \text{H}_2\text{S}_4\text{O}_6 + 2\text{H}_2\text{O}$. With excess of sulphurous acid and at pH 8.9, trithionate and thiosulphate are formed in equal proportions: $\text{S}_2\text{O}_3^{2-} + \text{SO}_3^{2-} = \text{S}_3\text{O}_6^{2-} + \text{S}_2\text{O}_3^{2-}$. If in this reaction the sulphurous acid is replaced partly or completely by thiosulphuric acid, higher polythionic acids are formed, including hexathionic acid. Once formed, the polythionic acids do not react with the thiosulphuric acid. It will be seen that these reactions offer a satisfactory explanation of the formation of polythionic acids in Wackenroder's solution.

Photochemistry of Colour Vision

By Prof. F. Weigert and J. W. Morton*, University of Glasgow

SOME years ago¹, we prepared 'artificial retinas' by imbedding in thin gelatin films the pigments extracted from frog retinas. When such films were exposed to coloured light, they exhibited a typical phenomenon called 'colour selectivity', and it appeared probable that a similar process might account for colour vision in the living eye. As a result of colour selectivity, a preferential increase in transparency is developed for the wave-length of the exciting light, so that there is a minimum for this wave-length in a curve showing extinction plotted against wave-length. The effects are extremely small, and can be detected only by a special microphotometric device. This is based on the production of photodichroism in light-sensitive solid films which have been exposed to polarized light².

In the case of the artificial retina, the photodichroism is generally negative³. Its distribution through the spectrum can be measured very precisely by means of a good polarimeter with a monochromator. Colour selectivity occurs when the photodichroism has its minimum at the wave-length of the exposing light. It is of advantage to express colour selectivity diagrammatically as a maximum of negative photodichroism.

In previous experiments, solutions of sodium cholate were used for the extraction of the retinal pigments, but recent researches on the photochemistry of visual purple suggest that it is better to extract the pigments by solutions of digitonin⁴ or digitalin⁵. In the experiments here reported, crystalline digitalin (kindly presented by Mr. A. M. Chase) was used for preparing gelatin films from frog retinas. Since the dyestuff of the retina is imbedded in a film of large surface and small thickness its absorption is extremely small, but the change of absorption due to the exposure of the film to polarized light can easily be determined. The general technique of the preparation, exposure and inspection of the artificial retina was the same as described in previous papers^{1,2}.

*Strang Steel Scholar, University of Glasgow.

The main results of the new experiments agree with those published previously, with one exception. While the inspection of the artificial retina prepared with sodium cholate revealed unspecific after-effects which proceeded in the dark and destroyed the specific colour selectivity¹, these after-effects did not occur when digitalin was used for the extraction of the pigments. Accordingly, it is now possible to expose the same part of the film several times and to study the effects of increasing periods of exposure on the phenomenon. Its general feature can be described as an increase of photodichroism after a certain period of induction and a fading away after longer exposure. The phenomenon therefore is confined to a limited exposure interval on a time-scale.

The upper section of Fig. 1 shows the shape of the photodichroism curves which correspond to the illumination of the artificial retina with polarized light of narrow spectral range, purified by means of Christiansen filters. Because the maxima of these graphs coincide with the wave-lengths of the pure spectral colours which were used for the exposure, they may be termed 'colour graphs'. Each colour graph is qualitatively distinguished from any other colour graph. They cannot be transformed into each other by simple quantitative operations. The same holds true for the psychological sensation of colour. A colour graph therefore may be defined as an expression of the manner in which the artificial retina perceives coloured lights; for example, colour graphs with maxima at 650, 580 or 490 μ correspond to 'red', 'yellow' and 'blue' in common language.

The lower section of Fig. 1 contains colour graphs which are produced by light of mixed colours purified by ordinary colour filters which are transparent for a large continuous part of the spectrum. The wave-length noted in Fig. 1 is the dominant wave-length which matches the coloured light of the carbon arc used throughout the experiments, after passing through the filter. It is noteworthy that the colour graphs are nearly identical with those for pure monochromatic light although, for example, a yellow filter transmits the total spectrum except the blue. The graph for white light has its maximum at 530 μ .

This means that the artificial retina shares the inability of the eye to distinguish between different spectral compositions of light with the same dominant wave-length. On the other hand, the inspection of coloured light by a spectro-scope shows the spectral composition of the light, but it gives no idea of its 'colour'. The artificial retina has the colour system of a normal trichromat.

Further information about the artificial retina can be obtained from Fig. 2. Black lines

FIG. 1.

represent the limited time intervals of existence of the colour graphs for monochromatic lights (1-11) and mixed coloured lights against a logarithmic time-scale of exposure. λ (exp.) means the exposing wave-length or, in the case of mixed light, the dominant wave-length; λ (obs.) the wave-length for the maximum of the colour graph. The last column shows in hundredths of a degree the direct readings of photo-dichroism at the analyser of the polarimeter; 0.01° corresponds to a decrease of extinction by 0.00015 or to an increase of transparency by about 0.03 per cent. This means that the effect of colour selectivity is far below the limit of normal photometric precision.

Two time intervals of existence occur for the colour graphs, which are distinctly separated from each other, and are due obviously to a 'fast' and to a 'slow' photochemical process. The fast process accounts for the colour graphs from blue to orange and the slow process for orange to red, with some overlapping near 600μ . A provisional explanation is the existence of two photosensitive pigments in the retina which may account for the fast and slow processes. Both exhibit the property of colour selectivity, but up to the present, nothing can be anticipated as to whether these pigments are identical with rhodopsin and the recently discovered iodopsin*.

It can be seen from Fig. 1 that the values of the maxima of the colour graphs are invariably of the same order. This is obviously due to the fact that the pigments are highly diluted in the artificial retina and that they are completely exhausted even by weak radiation. The colour graph records, therefore, the hue typical of a coloured light. The effect of intensity and brightness is being studied. It appears probable that the existence in the retina of two light-sensitive pigments with the properties revealed by these experiments, plays a part in the 'Purkinje phenomenon' and certain colour vision anomalies.

The colour graphs corresponding to mixed lights (Fig. 2, 19-21) which the eye sees as mixed hues require some comment. Purple (19) which is always perceived as a dichromatic hue, produces a fast blue and a slow red colour graph. No. 20 corresponds to a pink which was produced from red (12) by adding some white light. The white and red components are recorded separately by the colour graphs. The mixture of red and green (21), which appears to the eye as whitish-yellow, produces at first a yellow colour graph at 585μ , a spectral range which did not occur in the exposing light. This yellow colour graph was followed by white and shortly afterwards by a red colour graph. The colour graphs for the single lights from which the yellow was composed correspond to the green (16) and the red (12), with the dominant wave-lengths 500 and 650μ . It is noteworthy that the red component in the pink light which contained some white light (20), appears as a 'fast' process, while pure red is typically in the 'slow' series. These experiments established the fact that the systems responsible for colour selectivity are not originally present in the films, but are produced by the light itself during the period of

FIG. 2.

induction. Further research is in progress and will be published in due course. The examples with mixed lights demonstrate that the artificial retina distinguishes between pure and impure lights in the same way as does the eye. A hue which appears to the eye as composed of two 'valencies', for example, red and blue for purple, is recorded by two separate colour graphs.

Pure dark or mixed red light of a spectral range, or of a dominant wave-length, longer than 650μ (Nos. 1, 2, 12) is followed on continued exposure by a graph with a maximum at 580μ which does not occur in the exposing light. This slow process is distinguished from the fast process for green or white to be expected at that wave-length. No physiological phenomenon corresponds to this colour graph, but there are indications that it has its origin in an unspecific bleaching of visual purple, which cannot be observed during the state of high light adaptation required for the perception of dark red hues.

Any hypothesis with respect to the part which colour selectivity may play for colour vision must be postponed until the photochemistry of colour selectivity is clarified. But it is evident that some psycho-physical phenomena can now be studied by purely physical methods which are quite independent of the colour sense of a human observer. Even the modern graphical representation of chromaticity makes use of tri-stimulus values which are based on human colour vision*.

We are indebted to Prof. Edward Hindle for his interest in the research, and to the Society for the Protection of Science and Learning, the University of Glasgow and Lanarkshire County Council for financial help.

The Royal Observatory, Greenwich

Annual Visitation

THE annual visitation by the Board of Visitors of the Royal Observatory, Greenwich, presided over by the president of the Royal Society, took place on June 8, when the Astronomer Royal, Dr. H. Spencer Jones, presented his report for the year ending April 30, 1939. The report includes the following sections: instruments and apparatus; astronomical observations; time service; Nautical Almanac Office; magnetic observations; meteorological observations.

Transit Circle Observations. The programme for laying the foundations of a system of right ascensions with the new reversible transit circle has been continued. Since its inception in 1937, 4,333 transits have been observed; 1,501 collimations and 1,975 levels were taken in the course of these observations. Intensive observations have traced the main cause of the diurnal changes of collimation to small temperature differences between the micrometer screw and the eyepiece box, amounting sometimes to 2° F. Similarly, changes of level appear to be due largely to temperature differences between the two piers of the instrument, arising from unequal shielding in the case of any wind that is not due north or south. The adopted collimation and level errors are now derived from smoothed curves drawn through the values given by the observations; drift in the clock error has thereby been practically eliminated.

The Airy transit circle has been devoted chiefly to the observation of the sun, moon and planets. The Greenwich observations of the sun from 1750, combined with observations made at other observatories and used in conjunction with observations of the moon and Venus and of the transits of Mercury, form the data for investigating the changes in the rate of rotation of the earth. The results are being communicated to the Royal Astronomical Society.

Cooke's Zenith Telescope. 283 plates were taken for the determination of latitude variation. A definitive discussion of the observations for the years 1911-1936 is in the course of publication.

28-inch Refractor. The new comparison-image micrometer continues to prove superior to the filar micrometer, especially for the measurement of the closer double stars.

Thompson Equatorial, 26-inch Refractor. 1,238 plates for parallax determinations were secured and 38 parallaxes entirely completed.

Yapp 36-inch Reflector. With the slitless spectrograph the colour-temperature programme was completed in September. The discussion and detailed results for 250 stars will shortly be in the press.

The slit spectrograph has now taken the place on the telescope of the slitless spectrograph. In addition to experimental work, a provisional programme has been started, consisting of one-prism exposures, for the ultra-violet, on yellow and red giant spectroscopic binaries, to see whether a hot companion can be detected in this region of the spectrum even though its lines are smothered at longer wave-lengths.

Photoheliograph and Spectroheliograph. A daily series of photographs (begun in 1874) has been secured, in collaboration with the Cape Observatory and Kodaikanal Observatory, for the measurement of sunspot positions and areas. There are indications

that the peak of the maximum phase of the 11-year cycle has been passed. Eleven very large spot groups appeared during the year; in seven cases, a magnetic storm occurred within a few days of the respective times of central meridian passage. Examination of the sun's disk is made in hydrogen light ($H\alpha$) to detect the sudden occurrence of bright eruptions which show a relationship with ionospheric eruptions. Observations also include photometric measures of hydrogen disk markings and of prominences at the sun's edge.

Time Service. The official time services have been regularly maintained. The principle of employing a number of clocks as a 'mean clock' has been further extended and has proved of great assistance. The astronomical determination of clock error was made on 114 nights with a reversible transit instrument. The quartz crystal clock constructed at the National Physical Laboratory has been installed. The performance of the Westminster clock ("Big Ben") showed that, while on 16 days the error was greater than 1s., on 188 days the error did not exceed 0.5s. During the year, 4,170 chronometers and watches were received and 3,662 issued. The stock of chronometers and watches now held at the Observatory is being decentralized.

Nautical Almanac Office. During the year, the work of the Office has been mainly devoted to the routine calculation and publication of the *Nautical Almanac*, the *Abridged Nautical Almanac*, the *Air Almanac* and the *Astronomical Navigation Tables*. A working unit is being organized to deal with special investigations that frequently arise. A special supplement to the *Almanac* for 1940 will give data required in the design of instruments and their final adjustment. The paths of the ionospheric and corpuscular eclipses of October 1, 1940, have been published.

Magnetic Observations. A set of La Cour instruments for quick-run recording (3 mm. to the minute) has been added to the equipment at Abinger. The mean values of the magnetic elements for 1938 are:

Declination West, 11° 1.4'

Horizontal Intensity, 0.18522 gauss

Vertical Intensity, 0.43050 gauss

Inclination, 66° 43.2'

Magnetic activity during the year was considerable, five great storms and twenty-three small storms being recorded. The disturbance of the earth's magnetic field at Abinger by artificial fields due to electric traction is stated to have become increasingly serious as the electrification of the Southern Railway has extended. Disturbances (5 γ to 10 γ) is continuous throughout the working hours and ceases only during the interval 1h.-5h. civil time. The complexity of the total effect makes identification of the separate origins ordinarily impossible. The installation of the La Cour quick-run magnetograph has provided evidence, however, that significant effects occur coinciding with the movements of trains in the neighbourhood of Guildford as well as of Dorking. In the last few months, field investigations of the effect of electric traction have been made near

Chichester, at Itchenor and at Selsey. At the latter site, seven miles from the nearest point of the railway, disturbance was quite distinct, although seldom amounting to 1 γ in vertical intensity.

Staff. The post of chief assistant, rendered vacant by the appointment in the previous year of Mr. W. M. H. Greaves to the post of Astronomer Royal for Scotland, has been filled by Dr. H. R. Hulme, fellow of Caius College, Cambridge.

In concluding his report, the Astronomer Royal states the concern he feels regarding the steady deterioration of observing conditions at Greenwich. Long-exposure photography is no longer possible owing to the increasing brightness of the sky at night. As a result of atmospheric pollution by smoke, programmes of work which used to be successfully undertaken at Greenwich are now impracticable. The actual definition of stellar images has also suffered. In addition, there are various forms of fouling, the two most serious being the deposit of grit and the destruction of aluminized surfaces. The pivots and Y's of the new reversible transit, although carefully protected, already show appreciable scoring. There is a permanent risk of damage by grit to the

objectives of all the Greenwich telescopes. "If the Royal Observatory is to continue to make important contributions to astronomy as it has done for the past 284 years, and to provide an efficient time service of high accuracy, it is essential," the report continues, "that it should be removed to a site where astronomical conditions are favourable. The present wasteful efforts to secure observations under increasingly bad conditions, and the restrictions of programmes that are necessitated by such conditions, would thereby be avoided."

Finally, as regards the Abinger magnetic station, the general level of artificial disturbance is now such as to render all observations difficult, and when the disturbances are at their worst the observations lose much of their value. The removal of the magnetic observatory to another site has therefore become a necessity. The choice of a new site for such work in the south of England appears limited to a few regions in Devonshire.

The report concludes with the statement that proposals for the removal of the whole of the astronomical work from Greenwich and of the magnetic work from Abinger to new and more favourable sites are under consideration.

Historical Survey of Mycology*

UNLIKE the treatment of flowering plants, so far as Linnaeus was concerned, the subject of mycology had scarcely begun before his time. It is true that many fungi were mentioned by the classical writers but most of the interest in them was derived solely from their gastronomic effects. Their origin puzzled certain writers who regarded them as the result of the fermentation of the earth; truffles, on the other hand, were supposed to be due to the action of lightning. Herbals were based on classical authority: in 1593 Cesalpino wrote suggesting that fungi were not plants and were spontaneously generated.

Towards the end of the sixteenth century, Porta recognised the spores of such dark-spored forms as *Coprinus* and possibly of the mycetozoon *Phlegma septica*; but he thought they were seeds.

The arrival of the microscope was necessary before any progress in mycology could be made; but even then progress was slow. Hooke, in his "Micrographia", devoted two sections to fungi, and his description of the rose blight, *Phragmidium*, was accompanied by an illustration which is the first known diagram of a microscopic fungus. Hooke's views on fungi were thus expressed: "First, that Moulds and Mushrooms require no seminal property, but the former may be produc'd at any time from any kind of putrifying Animal, or Vegetable Substance, as flesh, etc., kept moist and warm. . . . Next, that as Mushrooms may be generated without seed, so does it not appear that they have any such thing as seed in any part of them; for having considered several kinds of them, I could never find any thing in them that I could with any probability guess to be the seed of it, so that it does not yet appear (that I know of) that Mushrooms may be generated from a seed, but they rather seem to depend merely upon a convenient constitution of

the matter out of which they are made, and a concurrence of either natural or artificial heat." In spite of accumulation of knowledge, similar ideas on the fungi extended over the following century and a half.

Malpighi, writing during 1678-79, described certain fungi in which he interpreted the sporangiophore as an inflorescence and the spores as florets. Thus, Hooke favoured the spontaneous origin of fungi, whereas Malpighi favoured the origin from seed.

Apart from Leeuwenhoek's observations on yeast in 1680, the next step was the recognition of the mycelium or spawn of mushrooms. Tournesfort, in 1707, gave the first account of mushroom-growing, and described the mycelium. Still further speculative theories of the origin of fungi appeared, until in 1729 P. A. Micheli published what may be considered as the first real step in our knowledge of the fungi. He made many morphological observations of first importance, but was actually still looking for flowers and seeds in the fungi examined. He also proved that what we now know as spores gave rise to new fungi similar to the plants from which they were taken. But in spite of Micheli's work, most botanists gave up the fungi as hopeless, and even Linnaeus in his "Philosophia Botanica" of 1751 wrote: "The order of Fungi is still Chaos, a scandal to art, no botanist knowing what is a species and what a variety."

Mixed by the observations of Baron O. F. Munckhausen, Linnaeus, in the twelfth edition of his "Systema Nature" described a genus "*Chaos*" with six species; the species "*O. Fungorum*" showed the metamorphosis of zoophytes from vegetables into animals and vice versa. "*O. Ustilago*" is the modern *Ustilago* which infects grains of cereals, grasses and certain florets. "*O. infusorium*" contained various Protozoa. The genus was rightly named, and thus did Linnaeus sadly come to grief.

John Ellis, who had a long correspondence with

* From the Presidential Address delivered to the Linnean Society of London, by Dr. J. Ramsbottom, O.B.E., on May 24.

Linnaeus on the subject, carried out a series of observations and finally convinced himself that the spores of fungi, like seeds of flowering plants, were unrelated to the animalcules which appeared when they were placed in water. But others, including Sir John Hill, persisted with Munckhausen's theory.

Necker, in 1783, published a treatise expounding the view that fungi were like plants in their method of nutrition, development and growth, but that they differed in origin. He therefore regarded them as a new kingdom between minerals and animals and proposed for it the name *Regnum mesymale*—the intermediate kingdom. Villemont also proposed a new class for them, namely, pseudo-xo-lithophytes.

Discussion on the origin of fungi which had been rife ended in 1783, and the conception of spontaneous generation was finally exploded by Pasteur, whose forerunners in this field of thought were Redi and Spallanzani.

In 1784, Hedwig published his classic work on

cryptogams, in which he proposed the use of the name 'spore' for the reproductive structures of these plants. In 1837, L veill  announced that spores are essentially different from seeds since they do not contain embryos. Hedwig's work was incorporated in the general mycological structure by Persoon, to whom was due perhaps more than to anyone else the foundation of systematic mycology. During 1815-74, the recognized authority on the classification of the fungi was Elias Fries.

The highly complex pleomorphy of the rust fungi took a long time to unravel, although heteroecism was much to the fore because of the damage caused by the rust of wheat. Heteroecism was proved conclusively in wheat by de Bary in 1865, while Oersted, in the same year, independently proved heteroecism in *Gymnosporangium* on junipers and pears.

The important part played by fungi in causing diseases of plants was obvious so soon as it was realized that mildews, etc., were fungi.

Training of Teachers

A DETERMINATION that teachers, as a body, should not be inferior to other professions in respect of their education and training led the National Union of Teachers to undertake two years ago an investigation of the whole question of the training of teachers and the grants available for the purpose. The investigating committee, composed of six members of the Union's executive and six representatives of university training departments, of training colleges and of secondary schools, completed its work last February, and the report* has been published in the form of a book of 360 pages including a summary of the principal conclusions formulated in 95 articles. These range over a wide field, including recruitment and placing as well as training. Although a number of the recommendations concern the content of training courses, the committee regarded such things as internal matters for the training institutions. In a preliminary chapter a strong case is made out for requiring some actual experience of teaching practice before admission to a training institution, this being desirable less for its intrinsic value than as a test of aptitude for the career of a teacher, for it is notorious that many recipients of grants for training have no such aptitude nor even any serious desire to take up teaching as a profession. It is proposed to make an officer of the local education authority report on the teaching potentialities, personality and general suitability for the teaching profession of every applicant for a place in a university training department or training college.

The vital importance of teaching practice as part of the college or university course is also emphasized and it is mainly to provide adequate opportunities for this that the report recommends the lengthening of the course to three years as a minimum. The report is equally emphatic as to the influence of residential conditions during the years of training, and proposes that residence in a college or hostel should be compulsory for all and that funds should be provided for ensuring that hostels are run on the

right lines as recommended by the University Grants Committee in its last quinquennial review.

Above all, the committee was concerned to press on towards the ideal of "a unified profession to serve a unified system of education", implying for the teacher trained in a training college a status equivalent to that of the university graduate. To this end it is proposed to develop the connexion between training colleges and universities so that the former may eventually become integral parts of the latter. On the crucial question of the staffing of training colleges the report observes that salaries are inadequate and prospects of promotion relatively small but leaves it at that, the additional grants it proposes for training colleges being intended to enable them to reduce the fees payable by students, not to make possible a higher standard of qualification and status for the staffs. It quotes with approval a suggestion that the staffs might be strengthened by the addition of two or three experienced practising teachers seconded for a definite period of years.

The report concludes with a paragraph on the need for immediate investigation by the Board of Education. Should such an investigation be made, it is to be hoped that the fundamental importance in this connexion of the progress of science will be recognized. The progress of science and its application has brought about changes which should affect the training of teachers both in respect of science teaching and as calling for a change in the attitude of all teachers towards science. Progress is so rapid that science teaching in schools is bound to lag hopelessly behind and be correspondingly ineffective unless it is kept constantly under review by competent observers, and modified and readjusted whenever necessary, and unless examining bodies are compelled to take cognizance of such changes. On the other hand, the social and economic transformations resulting from it are so sweeping that it is of the first importance that science should form an integral part of the curriculum of the primary as well as the post-primary school and that all teachers should grasp the relations of science teaching to the teaching of other subjects. The question is discussed in Prof. Bernal's recent book on "The Social Function of Science".

* The Training of Teachers and Grants to Intending Teachers Being a Report of a Committee of Investigation appointed by the Executive of the National Union of Teachers and adopted by the Executive on 3rd March 1939. Pp. xxxi+328. (London: National Union of Teachers, 1939.)

Science News a Century Ago

Societies and Academies

Heating and Ventilation of Public Buildings

A CENTURY ago much attention was being paid to the heating of both domestic and public buildings, and stoves of many kinds were being placed on the market. Patents for steam-heating apparatus had been taken out in the eighteenth century, and at the same time the hot-water heating system had been adopted for various purposes. At a meeting of the Institution of Civil Engineers on June 11, 1839, the subject was dealt with by Charles Hood in a paper entitled "On Warming and Ventilating Public Buildings and Apartments, with an account of the methods which have been most successfully employed in insuring a healthy state of the Atmosphere". In this paper he described the constitution of the atmosphere, the artificial changes produced in it and the effect of those changes upon annual economy. He pointed out the consequences of heating by very hot iron surfaces, or by a 'hot air cockle', and said that the systems of Mr. Bernhart and Dr. Arnolt were open to the same objections. Referring to the use of the more moderate heat of steam or hot water in pipes, he said the latter was the more economical and simple plan. The amount of heating surface depended on the building, but an approximate rule for a public building was its cubic contents divided by 200 to give the square feet necessary to maintain a temperature of 55° to 58° in the coldest weather in Great Britain. When speaking of ventilation, he said that the amount of air to be changed was 3½ cubic feet per minute per person. Natural ventilation through openings in the ceiling was the best for ordinary purposes, but in all extraordinary cases ventilation by mechanical means was the only efficacious method.

Trigonometrical Survey of India

ONE of the papers read at the Astronomical Society on June 14, 1839, was entitled "Some account of the progress of the Trigonometrical Survey now carrying on in India, extracted from the Correspondence of Colonel Everest". During the earliest operations the stations were the highest points of the mountains or hilly land; but a new district was about to be traversed where such advantages did not exist. This district, described as the Doab, was a country devoid of all natural elevations, but having mounds which appear to have been raised by the native inhabitants. For the operations in the Doab, Col. Everest contrived masts 70 ft. high, from the top of which by means of a bamboo staff an ignited blue-light was raised still 20 ft. higher. The site he chose for a base line was at Dhera Dun, near Sisse Bara on the verge of the Asan River. He had a complete set of compensation measuring rods like those used by Colonel Colby in Ireland. During his observations he had encountered some extraordinary phenomena of refraction; in many instances the distant helioscope, instead of exhibiting a round disk, appeared in the form of a tall column. His possession of the compensation bars had induced him to re-measure the base line at Seronge which he had measured in 1825 with a steel chain, and his experiences led him to the opinion that it would be necessary to revise the whole of Colonel Lambton's work before it could be joined on to the series of triangles recently completed with the new instruments.

Paris

Academy of Sciences (C.R., 208, 1257-1368, April 24, 1939).

M. MOLLIARD: New researches on the production of tubercles on potato in an aseptic medium.

H. DEVAUX: Remarkable relation between cellular constitution and 'wettability' of mosses.

C. EHRESMANN: Topology of simple closed groups.

H. HOFF: Topology of closed Lie groups and their generalizations.

P. HERRONI: Linear differential equations in a ring of certain continued matrices (hyperbolic matrices) and their applications to certain integro-differential equations.

N. OBERCHOFF: Zeros of some polynomials.

J. MARCINKIEWICZ: Interpolation of operations.

L. BERG: An integral representation of biharmonic functions in domains possessing an observable boundary surface.

P. COUDREBO: Luminous aureoles of novae.

C. SALOMANU and H. MCCORMICK: New method for the determination of the surface tension of liquids, based on the weight of falling drops.

E. BAUMGARDT: Measurement of certain adiabatic elastic constants of crystals, by the ultrasonic method.

MILN. A. DAMMANN: Analysis of musical sounds. Sounds of different instruments have been recorded by a cathode ray oscillograph; the results have analysed by a Coradi harmonic analyser.

M. PARODI: A phenomenon of the propagation of waves. Application to thermodynamics.

O. TE-TCHAO and H. LE BOITEUX: Coefficient of absorption of small ions by neutral particles suspended in air.

M. ROUAULT: Fourier analysis of the diffraction of electrons by free molecules.

C. S. PIAT: Absorption spectra of salicylic acid and of its alkaline salts in aqueous solutions.

P. ROUARD: A phase change of 2π in [optical] metallic reflection.

S. S. LU, C. HUNG-CHI and L. TA-YUAN: Influence of pressure on photographic sensibility to X-rays.

G. DUPOUY and C. FERT: Magnetic rotatory power of heavy water. Dispersion and variation with heat.

MILN. C. CHAMÉ: Grouping of atoms of radio-colloids.

T. SAN-TSIANG: Groups of protons emitted during bombardment of hydrogenous substances by α -rays.

V. KOSTOMAROFF: Influence of 'chemical tensions' and size of grain on the magnetic properties of a pure iron and of a silicon-iron.

MILN. S. VAIL: Introduction of further solutes into aqueous potassium iodide, and electrostatic effects.

E. DARMOIS and MILN. M. THEODORSSON: Raman spectrum of neutral molybdates, in the crystalline state and in aqueous solution.

M. BALLAY: Properties of some aluminium bronzes with beryllium.

MILN. P. RAMART-LUCAS: Structure and absorption of hydroxylated colouring matters derived from triphenylmethane; existence of two coloured isomeric forms of phenolsulphophthaleins and of phenol phthaleins.

Dublin

Royal Irish Academy, May 8.

D. BODROUX and R. THOMASSIN: Some derivatives of *ortho*- and *para*-cyclohexylphenols.

R. QUELLET and J. DUCASSE: Chloroalcoholation of *para*-propylanisol; application to the synthesis of some derivatives.

R. PAUL: Action of Raney nickel on alcohols; probability of combination of the catalyst with hydrogen receptors.

R. LOMBARD: Contribution to the study of pyro-abietic acids.

Z.-C. GLAUNT: Condensing reductions [in organic chemistry].

J. H. BRUNN: New observations on the south-west border of the Albano-Thessalian fold in Greece.

J. LUGNON: An integrating altimeter for aerological sounding.

A. ARNULF, R. BERNARD, D. CAVASSILAS and G. DELIARDIN: New description of the spectrum of the night sky in the ultra-violet region.

G. DEFLANDER: The 'stephanoliths', representatives of a new type of coccoliths of the Upper Jurassic.

P. DANGEARD: Some new marine algae of western Morocco.

MLLH. M. FOURCROY: Non-continuity of the internal generating zone of young roots.

R. SOULGES: Embryogeny of the Polemoniaceae; development of the embryo in *Polemonium corulorum* L.

R. GAUTHERET: Measurement of the growth of tissues of carrot cultivated *in vitro*.

G. GUITTONNEAU and MLLH. S. HAAS: A *Sporotrichum* agent of normal maturation of certain cheeses.

M. RANGIER and P. DE TRAVERSE: Urinary glycuronic acid and urochrome.

L. DAUTERBRAND: An anti-gas filtering cannister of high neutralizing capacity and responding to the exigencies of respiratory physiology.

R. CATALA: Acceleration by shock of the metamorphosis of caterpillars of *Chrysidia madagascariensis* Cram. (Uraniidae).

A. VANDEL: Researches on the genetics of *Armadillidium vulgare* (Latre.) in relation to monogeny.

A. PHYRON: Homologies between the embryonic vesicles of the human ovum and those of the parthenogenetic *embryomas*.

J. LOISELLEUR: Mechanism of the action of diastases of the tryptic group.

J. LAVOILLAY and MME. F. LABOREY: Definition of the coefficient of action of magnesium for *Aspergillus niger*; its variations with the composition of the medium.

R. DUBCHINSKY and J. JEANNERAT: Obtaining natural amino acids, starting from the racemic forms, by means of the *D*-amino-acid oxidase.

MLLH. S. VILLENEUVE-BRACHON: Division and formation of the peristome of *Licnophora* (L. Chattoni n.sp.) [Ciliates, Heterotrichs].

MLLH. G. CORDIER: Adsorption of aphthous virus by bone charcoal and tricalcium phosphate; application to immunization of the guinea pig.

M. PIÉRY, J.-F. MARTIN, J. ENSELME and O. PASCHIERA: Experimental study of the biological influence of a prolonged stay at an altitude; pulmonary modifications. Geese and rabbits were kept at the Jungfraujoch station for six months; hearts of the former show no lesions; of the latter, variable lesions. Lungs are all congested, the iron content being greatest with much congestion.

KENNETH O. BAILLY: Retardation of chemical reactions. (9) Choice of retarders in liquid phase oxidations. The results of nearly two hundred investigations of oxidations in the liquid phase have been summarized in tabular form, and the cases in which particular groups of retarders have been found to be successful or unsuccessful have been noted. No substance is known to retard all types of liquid phase oxidation. Deductions have been made as to the retarders likely to be helpful for particular groups of oxidizable compounds, and samples are given of retarders which, having been found of value in certain cases, would repay further investigation.

Rome

National Academy of the Lincei (*Atti*, 28, 283-330, 1938).

E. BOMPIANI: Projective geometry of a homogeneous linear partial differential equation. (1) Classification of the quasi-asymptotics. (2) Invariant systems associated with a system of quasi-asymptotics.

M. VILLA: Quasi-asymptotic curves (2).

T. VIOLA: Limits of an integral in the ordinary form depending on equal and uniform Lipschitz functions with first derivatives.

G. SOORZA DRAGONI: Criterion of existence for a problem of limiting values.

L. GIALANIELLA: Heterochromatic photometry and colour index of the planets Neptune and Vesta.

Tokyo

Imperial Academy (15, No. 3, 69-100, March 1939).

RYOJI SAKATA: A problem concerning transformations of polyhedra to spherical surfaces.

YUKIYOSI KAWADA: Characters of linear groups.

KÔITI KONDO: A proof of Toeplitz of the normal matrix.

AKITUNE IMAMURA: Land deformations and seismic activity in the Mutu-Dewa district.

SHIGEHICO SUGAWA, KÔITI SAKURAI and NORIO SUGIMOTO: Synthesis of some 1,2-polymethylenetetrahydro-iso-quinolines. Analyses were executed by Mias K. Serikawa.

HISAKATSU YABE and TOSHIO SUGIYAMA: Discovery of a Mesozoic hexacoral in a green schistose rock of the Kamuikotan system of Hokkaidô.

HARUO KINOSHITA: Electrolytic 'washing' of *Paramecium*. Unlike most living cells, by this method, *Paramecium* can be repeatedly washed in distilled water practically indefinitely, provided that the water is free from oligodynamic impurities.

TADAO YOKOYAMA: Circulation of blood in the silk worm. The generally accepted circulatory course of the blood is disproved.

EIJI FUKUSHIMA: Acanaphthene as a polyploidizing agency. Young archesporial cells are affected by acanaphthene and produce polyploid pollen grains. The polyploidizing value on late archesporial cells and cells in the meiotic stage is much lower.

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

ASSISTANT CIVIL ENGINEER ADVISER to the Director of Ordnance Factories, India—The Secretary, Military Department, India Office, London, S.W.1, marking envelope "Ordnance Department" (June 12).

ASSISTANT WORKS MANAGER at the Cordite Factory, Aruvankadu, Madras—The Secretary, Military Department, India Office, London, S.W.1, marking envelope "Ordnance Department" (June 12).

ASSISTANT LECTURER IN GEOGRAPHY in the University of Sheffield—The Registrar (June 12).

WOMAN LABORATORY ASSISTANT at the Horton Malaria Laboratory, Horton Hospital, Bpsom—The Director of Establishments, Ministry of Health, Whitehall, London, S.W.1 (June 12).

DEMONSTRATOR (man or woman) in the DEPARTMENT OF ZOOLOGY at Bedford College for Women, London, N.W.1—The Secretary (June 12).

ASSISTANTS (III) for compilation and analysis of statistical data in the Directorate of Scientific Research, Air Ministry—The Superintendent, Bawdsey Research Station, Bawdsey Manor, Woodbridge, Suffolk, quoting Ref. O.800 (June 16).

ASSISTANT LECTURER IN ZOOLOGY at Chelsea Polytechnic, London, S.W.8—The Principal (June 16).

HEAD OF THE PHYSICS DEPARTMENT in the Swansea Municipal Technical College—Director of Education, Gulliford, Swansea (June 16).

JUNIOR LECTURER IN CIVIL ENGINEERING in Queen's University, Belfast—The Secretary (June 17).

LECTURER IN THE DEPARTMENT OF PHYSICS, University College of Wales, Aberystwyth—The Registrar (June 17).

LECTURER IN MATHEMATICS in the County Mining and Technical School, Nuneaton—The Principal (June 17).

HEAD OF THE DEPARTMENT OF ENGINEERING AND BUILDING in the County Technical College, Guildford—The Principal (June 17).

LIVERPOOL OFFICER in the Ministry of Agriculture and Fisheries—The Secretary of the Ministry, 10 Whitehall Place, London, S.W.1 (June 19).

LECTURER IN METALLURGY in the Technical College, Bradford—The Director of Education, Town Hall, Bradford (June 21).

LECTURER IN ORGANIC CHEMISTRY in University College, Bangor—The Registrar (June 24).

HEAD OF THE PHARMACY DEPARTMENT of the Central Technical College, Birmingham—The Principal (June 24).

TUTOR (Geography) and a **TUTOR (Mathematics)** in the Gordon Memorial College, Khartoum—The Controller, Sudan Government, London Office, Wellington House, Buckingham Gate, London, S.W.1 marked "Tutor (Geography)" or "Tutor (Mathematics)" respectively (June 25).

TWO RESEARCH OFFICERS (Farm Management and Agricultural Caring) in the Agricultural Economics Research Institute, Oxford—The Secretary of the Committee for Rural Economy, School of Rural Economy, Parks Road, Oxford (July 1).

UNIVERSITY PROFESSOR OF METALLURGY at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, W.C.1 (Jan. 31, 1940).

ASSISTANT ENGINEER (M/5731) for the Malayan Public Works Service and an **ASSISTANT ENGINEER (M/5765)** for the Drainage and Irrigation Department, Malaya—Crown Agents for the Colonies, 4 Millbank, London, S.W.1.

PROFESSOR OF MINING ENGINEERING and **PROFESSOR OF ORE DRESSING** in Laval University, Quebec City, Canada—The Secretary, Faculty of Science.

Discipline in Freedom

THE three lectures which Lord Baldwin delivered at Toronto in April last, inaugurating the lectureship founded in memory of Sir Robert Falconer, have distinct claims on the attention of scientific workers. His analysis of the ideals and dangers of democracy and of the opposing forces at the present time both clarifies the fundamental issues and sounds a call to service to which men of science will not wish to be indifferent.

The supreme task, Lord Baldwin asserted, is that of combining freedom and discipline; in these lectures he adds one more voice to the many that have summoned scientific workers and their fellows to the defence of freedom of thought and speech and to the necessity of self-discipline and spontaneous service in order to enable the survival of our ideals. Lord Baldwin also insists on the necessity for having regard to the trends of our modern industrial system, for a wide perspective and not partial or biased views, and for imaginative handling of the possibilities which physiological knowledge and medical science offer us of eliminating some of the fundamental causes of industrial unrest by minimizing the strain or stress due to speed or monotony.

Here indeed is scope for further investigation, and not even the immediate exigencies of national defence should be allowed to stand in the way of increased effort in such fields as those in which the National Institute of Industrial Psychology and the Industrial Health Research Board are working. The work of the latter Board, it should be remembered, owes its origin to endeavours to safeguard the health of munition workers and increase their efficiency. A national defence policy must have full regard to the health of those who answer

the call to national service, whether in working or in leisure hours. The careless destruction of amenities may have serious consequences to the national efficiency or morale in more ways than one. The protests against the proposal to erect a steel works in the Edale district find strong justification in the threat the proposal may well involve to the health of the industrial populations which have benefited so much from the availability of that district for recreation.

This is indeed a particular aspect of the problem of maintaining standards, which Lord Baldwin reminds us is an ever-present danger in a democracy. The coalition of paganism and machinery which makes the situation grave to-day challenges almost every one of the essential values cherished in a democracy—human personality, freedom and truth. Universities have their special responsibilities in maintaining those standards, and above all in supplying leaders who will be loyal to them and adamant in their service. The pursuit of intellectual truth is the chief object of university training, as the advancement of knowledge is one of the chief functions of a university.

The logical sequel to the pursuit of intellectual truth in the university is that the community is entitled to expect those leaving a university to have trained minds able to give dispassionate consideration to varied problems. This point was made by Sir Robert Pickard, vice-chancellor of the University of London, in addressing the new graduates at the annual degree-giving ceremony last month. He warned them that their academic distinctions were based mainly upon book learning, and gave them no claim to special consideration, except in so far as their training had taught them to develop unprejudiced minds able to weigh evidence. Such.

critical interest in world affairs is indeed the plain duty of all thoughtful men.

Sir Robert Pickard also referred to the attacks which have been made in recent years upon mental freedom. A constant desire for truth, a hunger for knowledge, a balanced judgment and earnest consideration for the views of others who might not share their views on different problems, these are the hall-marks of a truly educated man. This attitude can only be achieved in an atmosphere of academic freedom, wherein the mind can follow the pursuit of knowledge untrammelled by the dictates of State or other institutions. Without mental freedom, Sir Robert rightly said, humanity and civilization must surely perish. It is a precious gift, which all who cherish learning would wish to hand on undiminished in value to succeeding generations.

Nevertheless, the path to knowledge, as Sir David Munro pointed out in his rectorial address at St. Andrews, is a disciplined path. The freedom we still possess in Great Britain to think for ourselves, to study the particular fields of knowledge that interest us, to act fearlessly on the dictates of our opinions and ideals involves discipline of the mind as well as of the body. Lack of self-discipline, Sir David Munro asserted, is what most endangers freedom.

The discipline and freedom of our schools and universities are not always enough to develop innate qualities of leadership. Sir David Munro pointed out that sometimes neither school nor college life fosters the eagerness and zest for life without which freedom is an empty gift and there is little worth disciplining. Such failure does not always lie in missed opportunities or in the biological make-up of the individual. What is lacking is interest or desire, in default of which faculties lie dormant and the tide of life runs low. Zest, he contended, is what matters; but without discipline it is unbridled, and without freedom it is stifled.

Nor is this reminder one for youth alone. It may be that youth has its special advantages and opportunities to be experimental. One of democracy's greatest needs to-day is for creative minds, willing and able to experiment wisely and constructively. A root cause of our failure to develop the new technique of social control which Lord Baldwin desiderated is this lack of zest and lack of interest in the social consequences of scientific discovery on the part of scientific workers themselves. That indifference is passing, but until disciplined enthusiasm in such matters is char-

acteristic of the overwhelming majority of scientific workers, we can scarcely hope to progress at the rate desired.

What we have yet to take account of is the changed condition of the struggle. New social techniques are available for directing mass behaviour in obedience to one man's will; new economic techniques for the industrial regimentation of the workers; new financial techniques for the ruthless taxation of rich and poor, for the plunder of aliens and the enemy within the gates. Plans can be prepared in secret and applied overnight for the enslavement of a whole nation and for the swift incarceration of its leaders by the hundred or by the thousand as required.

Conditions such as these impose on all democracies the necessity of attaining new levels of technical efficiency for self-defence and in co-operation. Moreover, there must be a devotion to the ideals of social justice and individual freedom inspired by a passion and zest for life which more than match the idolatrous worship of the State and brute force in the totalitarian countries. Grave as may be the threat which the menace of war offers to the world at the moment, if those in whose hands the defence of truth and freedom still remains are inspired, not by academic loyalty, but by a passionate zest for life, the danger may yet be averted, and advances in the standards of life for multitudes which social and scientific progress have made possible may be realized.

This is above all a question of leadership. It is not to be achieved by the pursuit of academic freedom as a thing apart from life, but by unflinching devotion to whatever that service and quest may involve in the social and political world, no less than within the walls of a university or laboratory. It demands that scientific workers themselves be willing to seek out and deal with all that restricts the full freedom of investigation or exposition and interpretation, or retards the application of the results of their work in the service of mankind. It means in practice the close study or investigation of many problems or even whole fields as yet largely unexplored. It means the acceptance of responsibilities for leadership and service and the development of such capacities, no less than of technical or scientific qualifications. But it involves above all an enthusiasm, a zest for life, a vision and sense of values and loyalty to ideals implicit alike in real leadership and in that moral disarmament for which the call was issued with the appeal for national service.

Cylinder Seals

■Cylinder Seals

A Documentary Essay on the Art and Religion of the Ancient Near East. By Prof. H. Frankfort. Pp. xlvii+328+47 plates. (London: Macmillan & Co. Ltd., 1939.) 42s. net.

THE cylinder seal is the typical product of the civilization of those countries and periods where cuneiform writing was employed, as is the scarab in Egypt or the coin on Roman sites. Invented at some period well before 3000 B.C., at the end of what is now called the Uruk period, in the land of Sumer, by men who had already begun to write, it spread wherever writing on clay with impressed signs was adopted. During the long ages which preceded its final disappearance, when Alexander conquered the East, roughly some three thousand years, this type of seal was employed at different times in Elam and Persia, in Anatolia, Syria and Palestine, in Cyprus and the Aegean islands. In Egypt, too, the shape was common at an early date, and it has long been a subject of debate whether its use there was borrowed from Mesopotamia or independently invented; Prof. Frankfort is now able to show, in his fourth chapter, that some cylinders from Egypt actually must have been importations from Sumer in the Jamdat Nasr period, which followed the invention of the type in Sumer, and that those Egyptian seals which show no trace of foreign influence, when placed beside those that do, point to the way in which a foreign idea can be borrowed and developed independently. Later, the cylinder seal lost its popularity in Egypt, perhaps owing to the practice of writing on papyrus, and occurs only sporadically, though occasionally examples of true Babylonian cylinders, imported, occur.

The classification of such a quantity of material, for there are many thousands of these seals in European and American museums, has been the subject of large catalogues of public and private collections. Much still remains to be done in this essential ground-work. What Prof. Frankfort supplies in this book is a brilliant, comprehensive *aperçu* which serves as a most readable introduction to the subject and will also give the necessary background for the cataloguing which has still to be done.

The purpose of the essay is correctly described in the sub-title. Questions of form are mentioned, but discussed only briefly; little emphasis is placed on the materials employed and cutting is scarcely described apart from an account of the tools employed and mention of cases where drill holes

are left conspicuous. Yet these matters are peculiarly relevant when considering any individual seal, and even for whole classes. It is not unimportant to note, for example, that the statement that "the Kassites favoured chalcedony or agate" is not accurate, for these stones by no means predominate in collections of Kassite cylinders; mottled stones, chosen presumably for the magical virtues of the colours, and so to reinforce the simple designs common on this type, are in fact more usual. As to technique, it should have been clearly pointed out that impressions do not always, or necessarily, indicate the real depth of cutting, and that no judgment should be passed until the original seal has been closely examined.

The detailed studies of the designs are written from the point of view of a trained historian of art, and form a masterly analysis of the possibilities of such design and the actual achievement of the different periods. In disposing their space, the seal-cutters could adopt diverse treatments; they might arrange continuous bands, divide up the area between groups capable of repetition, secure symmetry around a central theme, such as the inscription giving the owner's name, or secure variety by dividing into two registers. Some covered all the surface, others depicted a single animal *bombinans in vacuo*. Geometrical patterns were used in many periods side by side with seals showing complicated, sometimes dramatic, representations of divine and human figures.

Prof. Frankfort is an excellent guide through this maze; he uses dated material to classify undated with admirable discretion, and applies sound general principles as the basis of his arrangement. That is not to say that the author will escape criticism, for sometimes a general principle is deduced from too limited a set of ascertained facts. It may be true, for example, that in Prof. Frankfort's own excavations seals representing mythological scenes were found only in buildings belonging to the time of the Agade dynasty. It does not necessarily follow that all seals with such scenes must belong to that period. That is an old error in the typological argument, and has, the reviewer thinks, led to the wrong dating of the famous seal in the British Museum representing the sunrise, Plate XIX *a*; style, cutting and detail point to a later date. Sometimes the author commits himself to aesthetic judgments not necessarily right. To speak of "decline" in the Jamdat Nasr period is surely arbitrary, for it was a time of most fruitful experiment which, at least in the opinion of some, produced some excellent, and some good work.

Again, in discussing the designs of Sargonic seals, the author has lost sight of an important fact, that these seals, like the early Sumerian, have to perform their function of producing a design to cover not a given, but any length; he is peremptory in deciding where a design begins and ends, but the user of the seal was not, and these well-spaced groups do in fact allow of repetition, as do the endless bands. Indeed the learned will no doubt spend much ink controverting details in this book, but the main lines will undoubtedly stand, a pleasant general introduction which will also be of great use to the student.

The other subject fully dealt with—the religious significance of the subjects—requires and receives very different treatment. The purpose of these designs was, in general, prophylactic; sometimes the seals merely served as amulets. The author very rightly stresses the connexion of many scenes with myth and ritual. His object in this matter has been to make fruitful suggestions and to advance the study of ancient religion even at the risk of error. For this effort the right-minded

will be thankful. Once again, criticism will come in no small measure. The author does not, for example, fully expound the curious duality which attached to all the composite creatures of Mesopotamian fantasy, their sometimes good, sometimes evil, character; his argument on pp. 200–201, though it refers to this duality, fails to apply it to the *shedû* and *lamassu*—typical examples, as are other creatures mentioned. Similarly, in his discussion of the scenes which depict a light-god, he finds no place for the moon-god and thinks only of the sun; when a light-god is in a boat, he must always be Shamash, though Sin had a boat too and some of the symbols clearly refer to the night sky, not the underworld. So controversy could be conducted over much of the ground covered in what is said about religion. It is more pleasant to end on a note of praise for a stimulating and in many ways pioneering contribution to learning.

The book is well printed, misprints are few, the format convenient and the plates excellent. The publishers deserve the thanks of scholars for producing such an admirable work.

1938 Recorded

Encyclopædia Britannica of the Year 1939

Being a Survey of the Principal Persons, Events and Developments in Various Spheres of Knowledge and Affairs during the Year 1938. Pp. xvi+760. (London: Encyclopædia Britannica Co., Ltd., 1939.) 45s.

THIS is the second of a series of yearbooks projected as annual supplements to the "Encyclopædia Britannica". The first of the series was reviewed in NATURE of June 25, 1938, p. 1120, when the reviewer regarded it as a step towards the realization of the World Encyclopædia of Mr. H. G. Wells. This second volume is a further step towards that ideal, for all branches of knowledge and culture and all political and social problems—national and international—are dealt with in an objective and dispassionate manner.

To the editors and contributors, the work must have been prodigious, especially in keeping to the objective policy throughout; but it is a wise policy since the value of such an important work lies in its being not only a source of information for present-day readers but also a true and well-balanced review of past events for the benefit of future readers.

Events have moved very quickly recently, not only in international relations but also in science

and other branches of culture. Consequence and fulfilment have trod so closely on the heels of cause and prophecy that the editors must have found it a difficult task to make this volume a contemporary survey of men and affairs during the year 1938. But they have persisted in this well-chosen policy, for since the volume is one of a series it is the only safe policy to adopt. We already know the consequences and sequels of many incidents of last year (especially in international politics); but here "the closing scenes [of 1938] especially are depicted, not in retrospect and with foreknowledge of what was to come, but as they appeared at the time to the audience then witnessing the performance". Reading many of the topics so far into 1939 thus makes them all the more interesting and intriguing. On the other hand—and this applies especially to certain branches of scientific activity—progress over such a short period as one year is so slow that in each volume is to be given a summary of the developments for a period of several years.

It is noticeable that nuclear studies are still claiming the attention of many leading physicists throughout the world. Nearly three-quarters of the section devoted to physics is taken up by a review of progress in research in nuclear physics and cosmic rays. The rest is devoted to studies of liquid helium, properties of thin films,

and mass spectrography. In accordance with the wise policy adopted, the work on uranium, which has excited the whole of the world of physics during the first half of the current year, is not mentioned, and the cyclotrons, some of which are now at work, are described as "being constructed" or "not yet complete". In a similar way, all branches of science are treated. In spite of very careful scrutiny, no omission of importance has been detected; but it is interesting to the present-day reader with the results of current scientific work fresh in his mind to see how events of 1938 have inevitably led up to what he knows now but could not even prophesy then. That point of view may not strike the reader of several years hence so forcibly; but he will be able to deem himself fortunate in having at hand such an authoritative survey of events from year to year.

Scientific personalities are treated in a way similar to that accorded to the subjects themselves. Although a man of science may have a comparatively full biographical sketch of himself in the "Encyclopædia", if his achievements since the publication of the last edition (1929) warrant it, he appears again here, and sometimes accompanied by an up-to-date portrait. For example, Bohr's more recent work on atomic structure is given in a biographical sketch, together with reference to his award in 1938 of the Copley Medal. For very obvious reasons, too, Sir William Bragg appears again. The same may also be said of such scientific worthies as Sir James Frazer, the British anthropologist, philosopher and student of comparative religions; Sir James Crichton-Browne, the British physician; Prof. Samuel Alexander, the British philosopher; Dr. George E. Hale, the

American astronomer (the last three of whom died last year); and several others. What portraits are inserted are strikingly good.

In the review of the publishing world, an informative table is given of all classes of literature published in Great Britain and Eire as new books, translations, pamphlets, and new editions. The totals of these are compared with those of 1937. It is interesting to note that not only science but also most other branches of knowledge and culture had decreased, with the exception of philosophy, which remained constant, and sociology, law, philology, business and literature, which showed slight increases. Science showed a decrease from 758 to 701 and other decreases of interest were: history (131), medicine (86), education (45), technology (28), agriculture and horticulture (22) and geography (30). These figures were, no doubt, a sign of the times, though probably little was lost by the decreases, at any rate where science and related subjects are concerned.

Only a few topics, of interest even to the most exclusive men of science, have been chosen for comment; but sufficient has been told to emphasize the value and interest of this newcomer to the world of yearbooks. Not a page lacks interest; in fact, this, like the "Encyclopædia" itself, makes the inquiring man of science realize suddenly (and sometimes inconveniently) how interested he can be in such diverse subjects as music and jazz, ballet and boxing, navies and armies, stock exchanges and communism. Thus does the present volume maintain the very high standard set by its predecessor and achieved by the "Encyclopædia" itself.

Distillation and the Phase Rule

The Elements of Fractional Distillation

By Prof. Clark Shove Robinson and Prof. Edwin Richard Gilliland. (International Chemical Series.) Third edition. Pp. xii + 287. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 18s.

THE expression 'fractional distillation' inevitably recalls the name of Young to the older generation, but his book was written before the days when the art was of industrial significance and viewed the subject almost entirely from the laboratory bench. Of recent years the use of modern and often very complex types of distillation apparatus is growing apace, and though there have been foreign works on the subject, due largely to the fact that the inception of such

plant was on the Continent, there was no work available in English for the use of engineers and operators until the first edition in 1920 of this book, of which the third edition is now in our hands.

As experience has progressed, many changes in method and design of distillation plant have been made; the present treatment is believed to represent the best general practice in distillation design, but it is an introduction to, and not a complete treatise on, the subject of distillation.

Fractional distillation is a very ancient art which has developed by the gradual accumulation of empirical knowledge: it has from the beginning been associated with alcoholic beverages; indeed it is well known that H.M. Excise still find it.

difficult to divorce the word 'still' from its contact with alcohol.

The art has become a science as the result of the application of the phase rule, which enables the prediction of the conditions under which all systems of equilibrium can exist. The authors begin with the phase rule in Chapter i and, proceeding from simple one-component to complex systems, clear the ground for the study of specific problems of technical import best indicated by their chapter headings, namely, ammonia, benzolized wash oil, methyl and ethyl alcohol. So far the text is relatively simple, but we come to real grips with the subject in long chapters on the rectification of binary mixtures and of complex multicomponent mixtures. A lot of mathematics

is introduced with useful phase diagrams and tables, and the treatment is advanced and essentially for the specialist.

The subsequent sections deal with the theory of topping stills and continuous distillation, and give data for the performance of columns and condensers.

The book is essentially one for the specialist, who will undoubtedly find it of great value, but it must be hard reading for the engineers and operators mentioned in the preface. This does give us the opportunity to pay tribute to the skill of the operator of a modern petroleum still; at first sight it seems quite impossible that one man working in front of a complex instrument board can exercise the control he does.

The Cytological Approach to Inheritance

An Introduction to Modern Genetics

By Dr. C. H. Waddington. Pp. 441 + 5 plates. (London: George Allen and Unwin, Ltd., 1939.) 18s. net.

IT is curious and unfortunate that an experimental embryologist should write a genetical book which represents the extreme mechanistic branch of genetical opinion. It would seem that Dr. Waddington has missed a golden opportunity of bridging the gap between genetics and botany and zoology as taught in British universities. Instead he has accentuated the importance of chromosome twists and genic acrobatics at the expense of morphological and physiological genetics. Sufficient accounts of the relationship between genetics and cytology and between genetics and mathematics are now available elsewhere, but there is little text-book writing which combines a knowledgeable appreciation of genetics with physiology, morphology and systematics. There is a large amount of information on these latter subjects in research papers which is comparatively unknown in text-books.

In the encyclopædic survey of genetics and allied subjects, the author has presented a condensed text full of precise and annotated data on many subjects which are of interest to those with cytological and mathematical tendencies. This is done by dividing the book into five sections: formal genetics, genetics and development, genetics and evolution, genetics and human affairs, the nature of the gene. Within these sections space has been found for plant and animal breeding, the ramifications of chiasma formation and the mechanics of the chromosome, the genetics of

man, the genetics of pattern, and many other problems.

It is obvious that an 'introductory' treatment of this vast body of data is not possible in 450 pages. Indeed the book has an unfortunate title, since it is neither introductory in form nor does it contain a balanced statement of modern genetics.

For those who require a book which contains an extended survey of current topics, results and theories of the subjects allied to genetics in the form of an encyclopædic reference book, this volume can be recommended. But no non-geneticist or student should be permitted to visualize genetics as exhibited by this book. The general reader will find that some chapters are rather perplexing in construction and specialists may cavil at the attitude, and phraseology used on their own subject. The reviewer, for example, dislikes the chapters on sex-determination, chromatid segregation and evolution mainly for the essential features which are omitted. This is highly regrettable, since the material which is presented has been carefully described and the author has kept a critical hold on himself when discussing rival cytological theories.

There are a useful index and a bibliography which has been well designed; but the illustrations are poorly reproduced. Further, the acknowledgments to the borrowed figures are vague and unsatisfactory. The author has spent much time and painstaking effort in compiling a heavily packed but readable text ranging in subject from chromosome hysteresis to artificial insemination in man. It is not, however, an introduction to modern genetics as understood by the reviewer.

F. W. SANSOME.

Weed Plates Series 3, Plates 61-90

By Prof. Dr. E. Korsmo. 84 cm. x 64 cm. With Text-book of 140 pp. (Leipzig: Koehler and Volkmar A. G. and Co.) 22 gold marks.

THE third set of Prof. Korsmo's weed plates completes a series of ninety plates which are unequalled by any previous publication anywhere in the world. They are bold, colourful and easily understood by the most elementary student, but only a trained botanist can appreciate the accuracy of delineation and the skill with which the salient points have been selected. The illustrations of each weed provide an epitome of the life-history from seed to seed. Germination, seedling stages, mature plants, methods of propagation and seed dispersal all find their place.

Unusual details which frequently escape observation often throw light on the ecological behaviour of various species. In *Cardamine pratensis*, for example, rooting from the base of the leaflets of the lower leaves provides for new plantlets and continuous propagation. In *Cuscuta* the process of attachment of the young seedling to the host, and the withdrawal of the dodder from the soil explains the apparent mystery of how such a total parasite spreads by means of seeds. Examples might be multiplied to show the great value of these charts for teaching purposes. Their usefulness is enhanced by the booklet of explanatory notes published in various languages, with direct reference to the drawings.

Prof. Korsmo is to be congratulated on a valuable piece of work brought to a successful conclusion with the co-operation of an able staff of draughtsmen, who achieved the difficult task of combining scientific accuracy with true pictorial representation of the living plant.

Reports of the Progress of Applied Chemistry

Issued by the Society of Chemical Industry. Vol. 23, 1938. Pp. 861. (London: Society of Chemical Industry, 1939.) 7s. 6d.; to non-members, 12s. 6d.

IT is, perhaps, scarcely necessary to remark that, although these excellent annual reports are written by chemists and chemical engineers, they find many readers beyond the confines of the profession. While much of the information which they contain is admittedly of purely chemical interest and value, one cannot easily divorce chemistry from physics, engineering, or biology, and there is much which cannot fail to interest medical men, economists, and indeed all who have a lively concern in the more important phases of scientific industry. Any one volume is much the same in form as its predecessor, but considerable variations in substance in fact arise from such changes in authorship as occur from time to time.

In the report for 1938 there are twenty-seven chapters, including a report on explosives covering the period 1937-1938, and one on plastics. Of these, comparison with the previous report shows that in seven cases there has been a complete change of author, whilst in several others the responsibility has been differently shared among joint authors. In

the present volume, plant and machinery are discussed by S. G. M. Ure and F. J. Bailey; pulp and paper by T. T. Potts; iron and steel by S. J. Kennett; soils and fertilizers by G. V. Jacks; sugar by H. C. S. de Whalley; fine chemicals, medicinal substances, and essential oils by T. M. Sharp and W. Solomon; photographic materials and processes by C. Waller; and explosives by J. Weir. A. A. E.

The Annual Register

A Review of Public Events at Home and Abroad for the Year 1938. Edited by Dr. M. Epstein. Pp. xii+498. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1939.) 30s. net.

AGAIN this volume gives a survey of the year's history. In spite of a troubled year, crowded with events of great significance, the volume maintains its usual compass and departs in no respect from the customary allocation of space. Home, Imperial and foreign history again occupy rather more than half the volume, and much skill has evidently been exercised in the narrative of European events. No fault can be found with the factual record; every event of significance is mentioned, and in the main the survey is objective, though here and there a party point of view is manifest. The second part begins with a chronicle of events and is followed by a retrospect of literature, art and science in 1938. The section on science, though short, is a most comprehensive survey of work and publications of the year. Finally, there are the usual résumés of finance, commerce and law and obituaries of eminent persons. The public documents printed in full are of unusual interest since they include the Anglo-Italian Agreement of April 1938 and the famous Munich Agreement of September last.

Observation and Protocol Statement

By Dr. Bent Schultzer. Pp. ix+161. (Copenhagen: Levin and Munksgaard; London: Williams and Norgate, Ltd., 1938.) 7s. 6d. net.

PHILOSOPHICAL discussions about our knowledge of the external world have drifted more and more towards linguistic considerations. This is mainly the case with logical positivism, which asserts the importance of the logic and language of science at the expense of metaphysics. In this line of thought, Dr. Schultzer asks himself the question, How can an observation be validly registered in language? A close analysis of the condition of observation and of the content and structure of the so-called "protocol statements" (elementary propositions about direct observations) shows him that the only possible way of answering it correctly is by stating explicitly the presuppositions of a valid linguistic formulation of observations tacitly recognized by every empirical observer. It is the discussion of these presuppositions which forms the object of this book. Even if the results obtained are not final, Dr. Schultzer's treatment of the problem, especially when he proposes alternatives to the narrow orthodoxy of the Vienna circle, is both refreshing and useful. T. G.

Fauna and Flora of the Inner and Outer Hebrides

King's College (University of Durham) Biological Expeditions

By Prof. J. W. Heslop Harrison, F.R.S.

SO long ago as 1934, the idea of exploring the Hebrides with the view of writing a comprehensive Flora of the Inner and Outer Isles was conceived by the Department of Botany, King's College, University of Durham, and with it, as a corollary, the notion of studying the evolution of local races in the same area. At the same time,

VOLCANIC VENT WITH BROOCHIL CASTLE, ISLE OF RAASAY;
CLIFFS AT SCHRAPADAL BEHIND.

too, the whole of the plans necessary for bringing our project to a successful conclusion were formulated.

In consequence, since our first visit to Raasay in 1934, a yearly average of eleven weeks, spread over various parts of the year, has been spent in working the islands. Thus, in 1935 we visited Skye, Raasay, Scalpay, Longay, Mull, Coll, Tiree, Barra, South Uist, Canna and Sanday; in 1936 Skye, Raasay, Scalpay, South Rona, Eigg, Canna and Sanday; in 1937, Skye, Soay, Raasay, Pabbay, Coll, Rhum, Eigg, Canna, Sañday, Barra, Berneray and Mingulay; and, finally, in 1938, Rhum, Eigg, Muck, Eilean nan Each, Hyekeir, Lewis, Harris, Taransay, North Uist, Baleshare, the Monach Islands, South Uist and Eriskay. From this it will be seen that our investigations, although incomplete, have covered most of the area to be explored, and that we are in a position to take

stock of our present results, and to assess the value of our work.

Almost at the very commencement of our researches, we encountered a remarkable and inspiring cliff flora growing upon the precipitous cliffs, towering a thousand feet above the sea, along the east coast of Raasay. This included not only plants of alpine predilections such as *Arabis petraea*, *Silene acaulis*, *Dryas octopetala*, *Oxyria digyna*, *Polygonum viviparum*, but, in addition, commoner plants such as *Gerum urbanum*, *Lychnis dioica*, *Geranium lucidum*, *Calamagrostis Epigeios*, so rare and local in, or formerly considered absent from, the islands. There, too, jutting out from the cliffs, the rare shrub *Sorbus rupicola* flourished. Moreover, elsewhere in Raasay, we encountered unexpected species in the form of *Juncus pygmaeus*, *J. capitatus* and *Cicendia pusilla*, the first-named hitherto only recorded in Britain from the Lizard, the second from the same district and Anglesey, and *C. pusilla* from the Channel Islands.

These discoveries naturally invited speculation as to the causes of the peculiar and discontinuous distribution of the plants concerned. At once, it was forced upon us that the problem and its solution depended upon the Pleistocene and early Holocene history and geography of the Hebrides. Similarly, the resemblance between the positions of the plants on Raasay and those so brilliantly studied by Fernald in Newfoundland and in the Gaspé Peninsula, Quebec, was too striking to be disregarded. Naturally, we concluded that the circumstances explaining the situation in one case accounted for it in the other. These, in Fernald's opinion, and in ours, lay in the view that many, if not all, of the species involved, had escaped, by virtue of their positions, or by the local failure of glaciation, the wholesale extermination due to ice action so often pictured for us by those of extreme views.

Thus we were compelled to add to the original items of our programme a study of the influence of Pleistocene glaciations upon the composition and distribution of the Hebridean flora and fauna. To aid in this, a new line of attack, involving tedious examination of the pollen contents of the various peat deposits available, was of necessity developed.

Later, as we passed from island to island, these

onvictions have been progressively strengthened. The Isles of Eigg and Canna, with the flora of their magnificent western cliffs, reproduce on a smaller scale the conditions of Raasay, whilst the Isle of Rhum, with its rugged mountain masses, yields much more weighty evidence. On the latter island, the American grass, *Festuca prolifera*, reported by Fernald from Newfoundland, Anticosti, Gaspe and New Hampshire, turned up. Further, the Alpine penny cress, *Thlaspi calaminare*, formerly supposed to be restricted in Britain to Derbyshire, was collected freely on Fionohra and on the seaward cliffs of Bloodstone Hill. In the same way, the southern mountain massif produced the Norwegian sandwort, *Arenaria norvegica*, once listed as occurring with us only in the Shetlands and in Sutherland. Other significant plants secured on the Isle of Rhum included *Carex dioica*, *Deschampsia alpina*, *Juncus capitatus*, *Filago gallica* and many others, generally possessing alpine habitats.

When we passed to the Outer Islands, the same tale was continued. There the plant novelties belonged more particularly to two groups: (1) those of western or south-western tendencies; (2) those of arctic or alpine preferences. The former are exemplified by *Carex verticillatum* and *Vicia Orobus* and the latter by *Alopecurus alpinus*, *Festuca prolifera*, *Carex Halleri*, *C. rariflora*, *C. rupestris*, etc. Here, more especially in the case of South Uist, the case for glacial survival becomes much more powerful, for the Hecla-Beinn Mhor mountain group reveals considerable areas free from evidences of glaciation. The presence of *Alopecurus alpinus* adds a fact of vital importance, for the grass does not appear on the continent of Europe at all.

On the animal side, although few groups have been ignored, our chief interests have lain in the Mollusca, Insecta and Arachnida—circumstances determined by the personnel of the various expeditions. Among the molluscs, our principal discoveries were the detection of the American species *Planorbis dilatata* on Raasay, and of *Clausilia cravenensis* on North Uist and Harris, both again suggesting that the species are glacial relicts.

In the Insecta our most striking captures have been among the aquatic Coleoptera. These included *Hydroporus foveolatus*, hitherto only known from high mountain lakes in the Alps and Pyrenees, and now taken in similar localities in the central mountains of Rhum, *Deronectes canariensis*, a Canary Island species, now recorded from Barra, and the Mediterranean *Aulonogyrus striatus* from Raasay. Again, the import of the evidence seems unmistakable.

Among the Lepidoptera, although some of

our additions to the Hebridean lists were to be expected, others stand out conspicuously; these are species like *Omphaloscelis lunosa*, *Pachnobia leucographa*, *Miana exposita*, *Selidosema ericetaria*, *Zygna achilleae* and *Z. purpuralis*. At this stage, one of our special quests, *Nyssia zonaria*, a moth possessing apterous females, needs strong emphasis. In the form of the local race *atlantica* (Healop Harrison), we took it on Canna, Sanday, Rhum, Muick, Coll, Tiree, Harris, North and South Uist, Baleshare, Taransay, Monach Islands, Eriskay, Barra and Mingulay—a very significant and informative series of islands.

The Hymenoptera, likewise, have their quota of evidence to supply. In this connexion we would

WATERFALL ON ALLT LIATH, ISLE OF SCALPAY, WITH *Osmunda regalis* (ROYAL FERN).

single out as specially instructive the two Bombs, *Bombus smithianus* and *B. jonellus* var. *hebridensis*. The former we encountered on the same islands as *Nyssia zonaria*, with Eigg, Hyskeir, Berneray, and Raasay, in addition, whilst the latter was captured on every member of the Outer Island group examined.

On the other hand, in the case of the Hemiptera, although they provided unexpectedly long lists, only one species needs comment and that is *Anihocoris pilosus* Jak., beaten from trees on Scalpay; it is new to the British Fauna.

The Arachnida simply continue the indications of the other arthropods; in particular, the southern element represented by the spiders *Drassodes pubescens*, *Zelotes latreillei*, *Z. apricorum* and *Xysticus pini* deserves mention.

It is impossible within the limits of the present article to set out the whole of the results, or the

deductions to be made from them; that remains for our final reports. Nevertheless, a few facts may be offered now, and a few deductions mentioned without providing full details of the arguments leading up to them. In the first place, referring to our original task of producing a Flora and Fauna of the Inner and Outer Hebrides, it can be reported that we collected no fewer than 639 forms of flowering plants and their closest

concluded that at least some of the plants observed have survived the Ice Age, both in the Inner and Outer Islands, in habitats in, or near, those where they now exist.

Further, taking due cognizance of the whole of the animals and plants, we have been forced to admit that present geographical divisions do not harmonize with those based in biogeographical facts. From the faunistic and floristic points of view, Skye, Raasay, Scalpay, South Rona and Soay belong undoubtedly to the mainland; no form is more emphatic in deciding this than the endemic rose, *Rosa Sherardi* var. *glabrata* (Ley) Heslop Harrison. On the other hand, in the same respects, Canna, Sanday, Rhum, Eigg, Muck, Hyskeir, Tiree and Coll, just as emphatically line up with the Outer Isles.

In turn, this points to a long-continued separation of the islands just named from the mainland, and their more or less recent connexion with the 'Long' Island. In leading to this conclusion, no evidence has been of greater value than the distribution of *Nyssia zonaria* var. *atlantica* and *Bombus smithianus*, coupled with the indications of the Hyskeir reef peats, as well as of the occurrence of the bluebell, tormentil, etc., of the common blue butterfly, *Polyommatus icarus*, and of the small dragonfly *Ischnura elegans* on the same islet. Both the Hyskeir peat, and its present flora and fauna, suggest very recent oscillations and subsidences indeed, as do the submarine peats west of Uist.

At this point also, we should make it clear that we have been driven to

EAST COAST OF RAASAY, INNER HEBRIDES.

allies from the islands lying to the north of Skye, 651 from the Rhum, Eigg, Canna group to the south thereof, and approximately 600 from the Outer Islands. Of these at least 150 are new county records. We see little scope for adding further to these lists in the case of Watsonian Vice-county 104, but we are certain that, judging from our last year's results in the Outer Hebrides, our 1939 work will add substantially to those from Vice-county 110.

Our results in the insect groups discussed above and in others, as well as in the molluscs, arachnids, birds, mammals, etc., are of the same order.

Now let us consider the remaining aspects of our work. As will have been made abundantly clear from various remarks made above, we have

conclude that such forms as *Nyssia zonaria* var. *atlantica* and *Bombus smithianus*, which display a so-called fringing distribution, do not supply, as is generally supposed, the extreme western limits of species driven in that direction by invaders from the east. On the contrary, we regard them as the present limits of species falling back eastward as the land (the "Tir-fo-thonn" of Gaelic legend) sank beneath the waves, or was fretted away by Atlantic storms. In these cases we believe that they survived the glacial period in lands far to the west of the limits of to-day. Link this up with the presence of the same insects in the western islands of Ireland, and it will be seen that the land connexion between Ireland and Scotland, and the date of its severance, become part of the same problem, and that its

solution is assisted by the presence of the moths *Zygaena purpuralis* and *Miana exposita* in the west of Ireland, and in Rhum. Moreover, the distribution of the two bees *Bombus smithianus* and *B. jonellus* var. *hebridensis* hints that the Shetland Islands cannot be neglected in the same discussion.

In our evolutionary studies, we have been struck by the unusual facies presented by many island species of animals and plants when they

are studied alongside representatives of ordinary English populations, and we have already described well-marked island races, for example, an Outer Island honeysuckle *Lonicera Periclymenum* var. *Clarki*, a new race of *Nyssia zonaria* and so on, the whole emphasizing the importance both of the local race, and of isolation, in evolution. From the very nature of this work, observation must be backed by experimental work, and this, in the case of some forms, is well in hand.

'Photochemical Reactions in the Gaseous, Liquid and Solid States'

By Dr. C. F. Goodeve, University College, London

PHOTOCHEMISTRY is concerned with processes in which light quanta are absorbed and chemical changes result. A molecular species is characterized by a certain spatial arrangement of atoms governed by forces due to electrons. The oscillating electric field of a light quantum acts on a binding electron and raises it to an energy-level where the bond is either loosened or broken. This permits the spatial rearrangements to take place which we observe as chemical change.

The photochemical process may be divided into two stages: the primary process which occurs more or less simultaneously with the absorption process, and the secondary process which occurs consequent to the first. These two processes can be studied separately and by different methods, the first by a study of the absorption spectrum and the second by the methods of reaction kinetics.

PHOTOSENSITIVITY

The dual nature of photochemistry is emphasized by a consideration of the velocity of photochemical reactions. This velocity generally follows the equation

$$-\frac{dn}{dt} = \gamma I_a \quad (1)$$

where n represents the number of molecules of absorbing species present at any moment, $-\frac{dn}{dt}$ their rate of decrease with time, and I_a the absorbed light intensity in quanta per second. γ is the quantum efficiency defined as

$$\frac{\text{No. of molecules changed}}{\text{No. of quanta absorbed}}$$

* Taken from a course of afternoon lectures given at the Royal Institution, February 16, 23, March 2. References to, and further details of, most of the work described here may be found in papers to recent Faraday Society Discussions, the third Report on Photochemistry (*J. Phys. Chem.*, June 1938), and recent papers by Bowen, by Norrish and by the author, each with collaborators.

If a beam of monochromatic light of intensity I quanta per second falls on a *thin* layer of absorbing substance the concentration of which is n/v molecules per c.c., the fraction of the light absorbed is proportional to the concentration and to the thickness, and is given by

$$\frac{I_a}{I} = \alpha \cdot \frac{n}{v} \cdot l \quad (2)$$

The constant of proportionality α is the *molecular extinction coefficient* and has a value usually between 10^{-18} and 10^{-22} cm.². It is the 'target area' that a molecule presents to the light beam, that is, the chance of it absorbing light.

We can combine equations (1) and (2) to give us the final equation for the rate of a photochemical change

$$-\frac{dn}{dt} = \alpha \gamma \frac{I}{v} = \alpha \gamma \cdot \frac{I}{A} \quad (3)$$

where I/A is the intensity per unit area. This is the simplest equation for the rate of a photochemical reaction, and it is to be noted that the rate-determining constant is the product $\alpha\gamma$. This combined quantity is obviously the *photosensitivity*.

We see therefore that the sensitivity of a substance to light is governed by two quantities: the chance of the substance absorbing a light quantum, and the efficiency of the process per quantum absorbed. For example, the well-known reaction which takes place when a mixture of chlorine and hydrogen is illuminated is a very fast one. The extinction coefficient of chlorine is comparatively low—about 10^{-21} cm.². This low extinction is, however, counterbalanced by the fact that the quantum efficiency in the reaction with hydrogen is very high, between 10^3 and 10^4 . The photosensitivity therefore has values from 10^{-18} to 10^{-16} cm.² per quantum absorbed. It follows from equation (3) that in bright daylight, the blue light

of which has a value of I/A of about 10^{14} quanta per sec. per cm.², chlorine reacts at a rate of about 10 per cent per second.

As another example, a very light-sensitive substance called visual purple can be extracted from the retinae of the eyes of animals which have been adapted to darkness before being killed. It has recently been shown that the high sensitivity of this substance arises from the fact that the extinction coefficient is high, while the quantum efficiency has a value of about unity; its photosensitivity is about 10^{-12} cm.². On the other hand, for reactions such as the photodecomposition of aliphatic nitroso compounds, the quantum efficiency is unity and the extinction coefficient very low, the value of the photosensitivity being less than 10^{-12} cm.². If a solution of a nitroso compound is exposed side by side with a solution of visual purple, it decomposes at a rate 1,000 times slower than the visual purple, although its quantum efficiency is about the same. In a further class, there exist many dyestuffs of a very high extinction but of a low photosensitivity arising from the fact that their quantum efficiencies are extremely small. The photosensitivity of a reaction varies greatly with wave-length, largely due to the variation in the extinction coefficient α .

Here, as in thermal reactions, it is more convenient to make observations on the number of molecules present after certain intervals of time rather than to measure the rate at any instant, and we therefore use an integrated form of equation (3). For a layer of any thickness we arrive at the equation,

$$\log_{10} \frac{I_t}{I - I_t} = \alpha \gamma \cdot \frac{I}{2.3 A} \cdot t + \text{constant}, \quad (4)$$

where I_t is the light transmitted by a substance at the time t . In practice, coloured products may be produced, impurities may be present, reactions independent of light may proceed, etc. Equations may be set up for all these types of photochemical change and in them the photosensitivity $\alpha\gamma$ is the major rate-determining constant, similar to the 'velocity constant' appearing in equations for first- and second-order reactions. The photosensitivity may be conveniently determined by plotting the logarithmic function against the time, when a straight line should be obtained the slope of which is equal to the photosensitivity times the light intensity, I/A . This analytical method has been called "the method of photometric curves".

THE PRIMARY PROCESS

The absorption spectra of molecules in the gaseous state are of two principal types—discontinuous (band) and continuous. The first type

can be further divided according as the bands can or cannot be resolved into lines by high dispersion instruments. The presence of bands indicates that the molecule on absorption of a quantum has vibration frequencies characteristic of the excited state, and indeed these frequencies can be determined from the intervals between the bands. The excited state must therefore be one that can vibrate—it must be a complete molecule although the valence bonds may be weakened.

Cases where the bands cannot be resolved have been interpreted as meaning that the molecule has a short life in the excited state—something of the order of 10^{-12} sec. This has been called *pre-dissociation*. Conclusions in these cases, however, are not so reliable as in the others, as lack of resolution may arise from a number of causes.

If, on the other hand, there are no bands and the spectrum is *continuous*, there can be no characteristic frequency for the excited state and at least one of the bonds is broken. The primary process in this case yields atoms or free radicals.

SECONDARY PROCESSES

Secondary processes following discontinuous absorption usually consist of one or other of the following:

(a) The molecule may fluoresce, that is, give out most of its excess energy as light and return more or less to its original state.

(b) The molecule may suffer a collision in which its excess energy is converted into thermal energy. It is thus deactivated and cannot fluoresce or undergo photochemical change. Usually a molecule of the same species is particularly effective in quenching fluorescence. This arises from the fact that it is attracted to an excited molecule.

(c) The collision may lead to a chemical change. In any system there is usually competition between these possibilities. Most molecules will fluoresce unless they are deactivated or undergo chemical change within 10^{-8} sec.

Considerable advance has recently been made in our knowledge of the mechanism of chemical changes occurring on collision. This advance has been based on a consideration of the potential energy of the system as a function of the distances between the atoms. For each chemical state, defined by the existence of chemical bonds between certain atoms, there is a 'multi-dimensional potential energy surface' which describes this functional relation. A change over from one state to the other only occurs at an intersection of these surfaces, as it is only here that the energy, position and momentum of each of the particles can best be conserved. We now know that these quantities need only be conserved within the limits

set by the 'uncertainty principle' of quantum mechanics, and that change can take place with decreasing probability a short distance on either side of the intersection. In addition, however, the spins of the electrons need to be conserved.

Secondary processes following continuous absorption can also be considered according to the methods of reaction kinetics. The atoms or free radicals, produced by the primary process, are very reactive as they have free valencies. The chance of their reacting depends on the chance of their suffering a collision with a species with which they could react, and on the chance of their having sufficient energy, E_0 , to overcome any repelling force that may be present. This latter chance is given by the simple exponential expression, $e^{-E_0/RT}$.

EXAMPLES IN GASES

Iodine and oxygen absorb discontinuously in certain parts of the spectrum; iodine has been found to fluoresce at very low pressures. The excited molecules formed by the primary (light absorption) process collide and react with normal molecules, forming $I_2 + I(^2P_{3/2})$ and $O_2 + O(^1D)$ respectively in conformity with the conservation rules of the previous section. I_2 is, however, unstable, but ozone is produced with an efficiency of nearly two molecules per quantum absorbed—the second coming from a reaction between the oxygen atom and an oxygen molecule.

The bands of formaldehyde are unresolvable below 280 mμ. It is easily shown that the potential energy surface of the excited molecule intersects that of a different state of chemical combination of the four atoms— $H_2 + CO$. A path therefore exists via which the formaldehyde molecule, on absorption of a light quantum, can change over spontaneously into hydrogen and carbon monoxide with good conservation of energy, position, momentum and electron spin, and indeed experimentally this change is found to occur with a quantum efficiency of unity.

Hydrogen iodide absorbs continually and therefore dissociates into two atoms. Energy considerations indicate that the hydrogen atom reacts on its first collision with an HI molecule to produce $H_2 + I$. On the other hand, a reaction between $I + HI$ would be *endothermic* by 35 kcal. The value of E_0 is therefore at least as great as this and of $e^{-E_0/RT}$ less than 10^{-8} . This reaction is therefore negligible and the iodine atoms accumulate until they can collide and combine together. A quantum efficiency of two molecules of HI decomposed per quantum absorbed is therefore to be expected and is found experimentally over a wide range of pressure and temperature.

Although the chlorine-hydrogen reaction has been known for nearly a hundred years, it has only recently been understood. Most of the quanta responsible for photochemical change are absorbed in the continuous part of the spectrum and therefore the primary process is the production of chlorine atoms. Each atom suffers frequent collisions with hydrogen molecules, and from independent experiments it is found that about one collision in 10,000 is effective in producing a hydrogen chloride molecule and a hydrogen atom. The hydrogen atom reacts readily with a chlorine molecule, producing hydrogen chloride and a chlorine atom, which in turn repeats the cycle. In other words, a 'chain' is set up which can carry on indefinitely unless something happens to stop it. Most of the disagreeing results obtained by different investigators are now attributed to varying effects of chain-stoppers such as oxygen molecules or the walls of the container. With poisoned walls, and gases free from inhibitors, quantum efficiencies of 10^4 have been obtained.

REACTIONS IN LIQUIDS

In passing now to examples in the liquid state, we have first to consider how far our conclusions with regard to the primary process, as judged from absorption spectra, can apply. Molecules in the liquid are in a continual state of collision. As a consequence of this there is a general smoothing out of the absorption spectrum, and it is impossible to resolve the bands into fine lines, as in the case of discontinuous absorption in gases. However, a continuous absorption band of a molecule in the gaseous phase is characterized by the fact that it has a smooth rounded maximum and that its threshold on the long-wave side has a gentle slope. These two characteristics are retained in the liquid state, and in fact whenever we find, in liquids, absorption bands with rounded tops and gentle sloping thresholds, we find that photodecomposition takes place. For example, the absorption spectra of nitroso-compounds and diazonium salts are of this type. On the other hand, the spectra of most dyes, such as the cyanine dyes, have sharp maxima and steep thresholds. The primary process undoubtedly leaves the molecule intact and in an excited state. In the case of most dyes we find that the secondary process is one of fluorescence or deactivation, but sometimes the substances react with inorganic ions. The mechanism of the nitroso-compounds is not fully understood, but apparently free radicals are produced which react with the solvent.

A large amount of work has recently been done on the photodecomposition of aldehydes and ketones. Gaseous acetone decomposes with a

quantum efficiency of about 0.3, and the reaction apparently proceeds by the following mechanism:

Pure liquid acetone, however, is completely inactive to light. Apparently on absorption of light the electronic energy is degraded to heat very quickly. We have already noted that molecules of the same species have a very powerful effect in deactivating one another.

Even in dilute solutions, however, this reaction, particularly with higher ketones, is largely suppressed. This is apparently due to the fact that the free radicals produced in the primary process, being caged around by solvent, very readily recombine with one another, thus reducing the quantum efficiency. This is a common type of phenomenon in photochemistry, and is due simply to the fact that the movement of molecules, or their parts, is restricted by the surrounding molecules. We could not get a permanent chemical change unless the parts of the molecules could stay apart long enough to enter into some other state of combination. Given sufficient thermal energy, however, they may react at once with caging solvent molecules.

On the other hand, the higher ketones decompose partially in another way.

The process is a curious one. Light absorption takes place without a doubt by an electron associated with the carbonyl group. This excitation energy by some means or other is able to move along the molecule and break it at a position several carbon atoms away (a similar process occurs in crystals). The products are not free radicals, but normal molecules, and even if they are caged around by other molecules, they should have no tendency to recombine. We should not expect the rate of this process to be different in solution from what it is in the gaseous phase, and in fact no difference is found.

Finally, there is an interesting class of photo-reactions in solution involving changes of the charge on an ion. On the face of it, these reactions should not involve movement of nuclei. For example, to change an iodide ion into an iodine atom requires only the removal of an electron. The same is true for the conversion of ferrous into ferric ion. These changes of charge, however, are accompanied by changes in the arrangement of the solvent sheath around the ions.

REACTIONS IN SOLIDS

So far we have seen that modern theories of photochemistry give a fairly satisfactory treatment of gaseous reactions, and, to some extent, of reactions in liquids. With solids, however, the theories are only in a very early stage of development. The chief difficulty is that, whereas in gases and in liquids we can deduce something about the primary process from the absorption spectra, parallel deductions with solids can only be made in exceptional cases. We know, of course, that the movement of an electron is involved, but we cannot deduce how far an electron acts alone and how far its movement is coupled with that of the nuclei. However, we should expect to find more deactivation and greater restriction to spatial rearrangement in solids. For example, *trans*-azobenzene on absorption of a light quantum changes over quantitatively into *cis*-azobenzene, and the latter on absorption is reconverted back into the *trans* form. Both these reactions involve a large spatial rearrangement of nuclei, a rearrangement which could not take place inside a crystal lattice. In fact, in the solid state, these substances are quite stable to light, the energy of the light being degraded into heat. Similarly, the quantum efficiency of the decomposition of ethyl iodide is reduced in the solid state.

On the other hand, we have reactions of the type such as the conversion of *o*-nitrobenzaldehyde into *o*-nitrosobenzoic acid. This reaction proceeds in solution with a quantum efficiency of about unity. It involves only an internal rearrangement of the position of an oxygen atom, a movement in no way obstructed in the crystalline state. The conversion is found to proceed in the solid at exactly the same rate as in solution. There are many phototropic effects in organic chemistry which are of this type.

Apparently the only well-established case where atoms may be rearranged inside an ionic crystal is that of the dissociation of potassium hydride dissolved in potassium bromide. Here hydrogen and potassium atoms are produced by the action of light; these at low temperatures simply recombine. At room or higher temperatures, however, the hydrogen atoms have sufficient thermal energy to escape from their lattice points, the remaining potassium atoms producing a blue colour in the crystal.

While spatial rearrangements are restricted inside a crystal, they are much less so on the surface. However, the quanta absorbed by the surface layer of a crystal are generally few compared with the total number absorbed by the crystal itself, and could not account for most of the photochemical reactions occurring with solids. It is therefore believed that a quantum may be absorbed

in the interior of a crystal and its energy passed on, more or less as a complete unit, to the surface.

There are two possible mechanisms by which this transfer might take place. The first is based on the fact that there is little restriction from a *spatial* point of view to the movement of electrons through a crystal lattice. Normally, in non-conducting inorganic crystals the most loosely bound electrons are attached to the negative ions. They cannot move about very much at ordinary temperatures, because more energy than is usually available at this temperature is required to move them from their position. At higher temperatures, of course, most crystals become conducting. When a quantum of light is absorbed by a bromide ion in silver bromide, the electron may be torn from its position and sent to another part of the crystal. There it settles on a silver ion, producing a silver atom. Very little energy is now required to move it from one silver to another, and in an electric field such a movement may readily take place, giving rise to the phenomenon of photoconductivity.

When the electron is removed from the bromide ion, it leaves it as a bromine atom. An electron from a neighbouring bromide ion can readily take the place of the original one, leaving in turn a bromine atom. In other words, the *position* of the bromine atom can move about through the crystal lattice. If it by chance comes to the surface it can, in the case of the photographic plate, readily oxidize an adsorbed gelatine molecule. The silver atom is then stabilized and its *position* moves about until it meets another silver atom,

preferably at a surface, where it starts the nucleus of a crystal. This forms the latent image of the photographic plate which, on development, is increased about ten millionfold. Crystals not already having nuclei of silver do not develop in the period of time in which the plate is immersed in a reducing solution. The whole question of the action of a photographic plate is much more complicated than this, but the above mechanism provides a good working hypothesis.

The second important mechanism for the transfer of energy through a crystal does not require even the movement of an electron. According to this, the primary process of light absorption results (as usual) in an electron with a higher amount of vibrational energy, but moving more or less in its original mean position. Such a vibrating electron produces an oscillating electric field which influences neighbouring electrons, and the *energy* of the electron, the 'exciton', is passed on from one electron to another as a complete unit. In this way the exciton 'diffuses' about until it reaches a surface where it may cause a chemical change, or until it reaches a potential radiator where it may result in fluorescence.

There are many examples similar to the photographic plate in which light absorbed in the interior of a crystal leads to a reaction on the surface. Most inorganic oxides, such as zinc, titanium and antimony, which absorb in the near ultra-violet, can cause a photochemical change with certain organic compounds adsorbed on their surface. In no case as yet has it been established whether the transfer occurs by free electron diffusion or by exciton diffusion.

Obituary Notices

Prof. S. L. Loney

SIDNEY LUXTON LONEY, whose death at the age of seventy-nine years occurred on May 16, belonged to the older generation of Cambridge mathematicians, whose training was broad as well as specialized, and his position as third Wrangler in the then undivided Tripos justified the high opinion formed of his abilities at Tonbridge School by his teacher, Mr. Hilary, one of the most remarkable mathematical teachers of his generation.

On leaving Sidney Sussex College, Cambridge, Loney was faced with the choice which so often confronts the ablest young graduates—the choice between the advancement of specialized learning by research, or the advancement and diffusion of sound knowledge by direct teaching. His exceptional gifts of clear exposition and fertility of illustration led him towards teaching, and he devoted

himself wholeheartedly to his chosen profession, as professor of mathematics at Royal Holloway College, London. Before the establishment of the internal side of the University of London, many students of Holloway College took the Final Honour Schools of the University of Oxford, and the mathematical class lists of the years 1891–1907 afford evidence of the high standard of mathematics at the College at that time. After the College became one of the internal colleges of the University of London, a correspondingly high standard was maintained in the London honours lists, and this tradition has been continued under his successors, Prof. Jolliffe and Prof. Bevan Baker.

It was during his tenure of the College professorship of mathematics that Loney's text-books on applied and pure mathematics were written; and for nearly fifty years they have been established as

standard text-books, well known throughout the educational world. In addition to these books, he also actually wrote a popular "Arithmetic", although he himself considered that he "knew no Arithmetic".

Besides being a first-rate teacher, Prof. Loney was an excellent man of business, with a genius for committee work; and for many years he was one of the most influential members of the Senate of the University of London. His capacity for strenuous work, his thorough grasp of business, and his intuitive knowledge of men and women, were given full scope during the Great War, when for a considerable time he carried out many of the duties of Principal Officer of the University in addition to his other work. As chairman of Convocation since 1923, and deputy chairman of the Court since 1929, he rendered greatly appreciated services. These services were all the more valuable because of his dual position in the University. As a former professor in one of the internal colleges, he was a warm supporter of the teaching side; on the other hand, he was also an active and enthusiastic representative of the external side; and he was strongly of opinion that there was ample room for both internal and external sides in a great Imperial university, and that harmonious co-operation was the desirable ideal. Now, thanks largely to his efforts and those of other like-minded members of the Senate, this ideal has been to a large extent realized.

After retiring in 1920 from his professorship at Royal Holloway College, Prof. Loney continued to render valuable services as governor and trustee; and he had the satisfaction of seeing the College, with which he had been so long and honourably connected, established in its present position in the University and in the educational world.

E. C. HIGGINS.

Dr. J. G. Lipman

We regret to announce the death, after a brief illness, of Dr. Jacob Goodale Lipman, the well-known director of the New Jersey Experiment Station, New Brunswick, N.J. Dr. Lipman was born in Friedrichstadt, Russia (now in Latvia), on November 18, 1874, and received his early education first in Moscow and later in the *gymnasium* of Orenburg. In 1888 his family emigrated to the United States and soon settled on a farm at Woodbine, New Jersey. Here he became interested in agriculture and the scientific principles underlying it, and when in 1894 he entered Rutgers College, he came under the influence of Prof. E. V. Voorhees, one of the earlier American leaders in research on soils and fertilizers. He proceeded to Cornell University for advanced training in chemistry and bacteriology, and in 1901 was appointed to the Agricultural Experiment Station at New Jersey in charge of the Department of Soil Chemistry and Bacteriology. Shortly afterwards he was appointed, first instructor and afterwards professor, in agricultural chemistry at the neighbouring Rutgers College. His whole life was spent between the two institutions, and in 1911 he became director of the Experiment Station.

Lipman was one of the leaders in soil bacteriology and the study of fertilizers in the United States, and his writings did much to direct the attention of the public to the need for providing adequate support for studies of these subjects. Among his well-known publications were many reports of considerable technical interest, and in 1908 he published his book "Bacteria in Relation to Country Life".

Lipman was a great organizer and will long be remembered by all who took part in the First International Congress of Soil Science, held in 1927 in Washington, D.C., followed by a special scientific excursion throughout the United States and Canada. The whole Congress was a brilliant success, a model of what such functions should be.

Lipman was also editor of *Soil Science*, a journal which first appeared in January 1916 and owes much of its success to his enthusiastic and devoted labours. He was a man of unbounded kindness and geniality, wise in counsel, and a delightful host; he attracted and kept together a brilliant band of scientific workers and he made the New Jersey Experiment Station one of the leading agricultural institutions in the world. His death removes a great figure from among us.

E. J. R.

Mr. H. E. Wroot

We regret to announce the death of Mr. H. E. Wroot at the age of seventy-one years.

Herbert E. Wroot went to Yorkshire from St. Albans in 1890 to join the staff of the *Bradford Observer*, with which he was associated for thirty years. He then joined the staff of the *Yorkshire Post* and later became an assistant editor and, until illness overtook him in 1933, he was of great assistance to natural history workers by his knowledge and facile pen; the extent of this work is only known to those who were in touch with him at this time. He joined the Bradford Scientific Society, acting on the council, and as secretary and president.

Mr. Wroot was a member of the executive of the Yorkshire Naturalists' Union, president of its Geological Section and president of the Union in 1929. His address from the chair on "The Pennines in History" (*Naturalist*, 45-60, 105-115; 1930) is proof of his knowledge and interest in the county of his adoption. As a member of the council of the Thoresby Society he contributed a study of J. M. W. Turner's wanderings in Yorkshire. He did much work for the Yorkshire Dialects Society and the Brontë Society.

Mr. Wroot will be best remembered for his work in connexion with Prof. P. F. Kendall, "The Geology of Yorkshire". This work illustrates how a trained journalist, interested in the subject, can place in the reader's hands the knowledge and insight of the scientific worker with whom he collaborates. His reports of the meetings of Yorkshire naturalists and geologists were valued and always eagerly awaited. He enlisted a body of naturalists to aid him in a weekly column of Nature notes, and in these ways his pen greatly helped the local societies and increased their membership and usefulness.

Mr. Frank Corner

MR. FRANK CORNER, antiquarian and naturalist, died in London on April 22, at the age of seventy-seven years. Although he contributed little to the printed proceedings of antiquarian and natural history societies of London and of the home counties, yet his unfailing presence at their meetings and his enthusiasm helped greatly to their welfare. He succeeded to his father's extensive medical practice in the East End of London in the early nineties of last century after qualifying from the London Hospital, and his burly figure and warm heart made him hosts of friends in Poplar.

Mr. Corner had as a near neighbour at that time Sir Arthur Keith, who was teaching anatomy at the London Hospital. Although immersed in practice, Mr. Corner was then making a large rather than discriminative collection of fossils and stone implements of the Pleistocene period of south England. Among the specimens he succeeded in acquiring were the much-discussed fossil skull and skeleton of

the Galley Hill man. This he placed at the disposal of Sir Arthur Keith for examination, and afterwards gave it on loan to the British Museum (Natural History). His collection of Pleistocene animal remains was also freely accessible to the expert.

The case of acromegaly which Mr. Corner presented to the Museum of the Royal College of Surgeons in 1910 is one of the most instructive as well as one of the best worked out cases on record.

We regret to announce the following deaths:

Prof. Edwin Linton, formerly professor of biology and geology in Washington and Jefferson College, Pennsylvania, an authority on helminthology, on June 4, aged eighty-four years.

Prof. David Todd, formerly professor of astronomy and navigation and director of the observatory in Amherst College, Massachusetts, aged eighty-four years.

News and Views

King's Birthday Honours

THE following names of men of science and others associated with scientific work appear in the King's Birthday Honours List: *Baronet*: Dr. R. Hutchison, president of the Royal College of Physicians; *K.B.E.*: Prof. W. B. Benham, emeritus professor of biology, University of Otago, Dominion of New Zealand; Prof. T. A. Hunter, professor of philosophy and psychology, Victoria College, University of New Zealand; the Hon. P. H. Rogers, judge of the Supreme Court, and chancellor of the University of Sydney. *Knight Bachelor*: Dr. E. J. Butler, secretary to the Committee of the Privy Council for Agricultural Research and secretary to the Agricultural Research Council; Mr. F. Carnegie, chief superintendent of Ordnance Factories, War Office; Dr. R. E. Kelly, professor of surgery, University of Liverpool; Prof. J. Graham Kerr, M.P. for the Scottish Universities since June 1935, formerly regius professor of zoology in the University of Glasgow; Prof. O. W. Richardson, Yarrow research professor of the Royal Society, University of London; Prof. J. F. Thorpe, chairman of the Smoke Sub-Committee, Chemical Defence Committee, War Office, emeritus professor of organic chemistry in the University of London, and in the Imperial College.

O.I.E.: Mr. C. E. O. Cox, chief conservator of forests, Central Provinces and Berar; Mr. H. R. Stewart, director of agriculture, Punjab; Mr. E. A. Smythies, chief conservator of forests, United Provinces; Mr. W. J. Jenkins, officiating director of agriculture, Bombay. *O.B.E.*: Mr. A. S. Cox, assistant comptroller, Patent Office, Board of Trade; Mr. Seton Gordon, for services to literature and

natural history; Mr. C. E. Legat, for services to the Empire Forestry Association; Mr. G. M. Mathews, a prominent ornithologist, for services to the Commonwealth of Australia; Mr. J. P. Mead, director of forestry, Straits Settlements, and adviser on forestry, Malay States; Prof. E. J. Salisbury, Quain professor of Botany, University of London; Mr. R. J. L. V. Sukuna, district commissioner and chief assistant, Native Lands Commission, Fiji.

O.B.E.: Mr. E. J. Bruen, livestock expert to the Government of Bombay; Dr. G. P. Douglas, assistant superintendent (research), Royal Aircraft Establishment, Farnborough; Dr. W. E. Fisher, principal, Wolverhampton Technical College; Prof. W. G. R. Paterson, principal and professor of agriculture, West of Scotland Agricultural College, Glasgow; Mr. H. F. Mooney, forest officer, Eastern States Agency, India; Mr. J. Sinclair, for services to agriculture in the Nyasaland Protectorate; Mr. A. A. Topp, manager of the Government Explosives Factory, Maribyrnong, Commonwealth of Australia; Mr. J. Turner, forestry officer, Department of Natural Resources, Newfoundland. *M.B.E.*: Mr. B. M. Cameron, manager, Government Stock Farm and Agricultural Station, Acre, Palestine; Mr. A. P. Dodd, chief entomologist to the Prickly Pear Board, Commonwealth of Australia; Mr. W. M. Findlay, superintendent of experiments and lecturer in seed testing, North of Scotland College of Agriculture; Miss E. A. Leighton, accountant, Building Research Station, Department of Scientific and Industrial Research; Mr. A. F. MacCulloch, advisory chemist, Medical Store Depot, Madras; Mr. T. K. Mirchandani, officiating deputy

conservator of forests, Bombay; Miss U. F. M. Morton, principal, Women's Medical School, Agra, United Provinces; Mr. K. R. N. Pillai, extra assistant conservator of forests, Jubbulpore, Central Provinces and Berar; Mr. H. G. Smith, statistician, Agricultural Department, Uganda Protectorate. *I.S.O.*: Mr. J. M. Dumbur, assistant and office superintendent, Department of Agriculture, Gold Coast.

Dr. George Senter

DR. GEORGE SENTER, principal of Birkbeck College, University of London, since 1918, retires at the end of the current session. He became head of the Department of Chemistry at the College in 1914 and retained that position until 1932. His principalship has been a memorable one. In 1920 the College was recognized as a school of the University of London and in 1926 a Royal Charter was granted. The College thereby realized an ambition which existed so far back as 1863, when courses of instruction for University of London examinations were instituted. Further, Principal Senter has played a major part in the elaboration of the scheme for new buildings which are to be erected on the University site at Bloomsbury. His sound judgment and wide administrative experience have been of the greatest value in University affairs. Principal Senter first became a member of the Senate in 1912, was for many years chairman of the University Extension and Tutorial Classes Council and chairman of the University Scholarships Committee, and held the office of deputy vice-chancellor in 1933-34. To this record of distinguished service must be added the profound influence which Dr. Senter has exerted as investigator, teacher and writer in the realm of chemistry. He has contributed many important communications to scientific journals on physico-chemical and biochemical subjects and his "Outlines of Physical Chemistry" (17th Edition, 1933) and "Text Book of Inorganic Chemistry" (14th Edition, 1934) bear witness to his distinction as a writer and teacher. Recently the staff of Birkbeck College made a presentation to Principal Senter, which in the words of Prof. Dame Helen Gwynne-Vaughan, the chairman on that occasion, "will be a frequent reminder of the affectionate regard—the enduring respect—of those with whom he has worked so long".

The late Prof. E. B. Wilson, For.Mem.R.S.

REFERRING to Prof. E. W. MacBride's obituary article on Prof. E. B. Wilson in *NATURE* of April 1 "a gracious appreciation of the work of an eminent fellow biologist", Prof. G. N. Colkins and Prof. J. H. McGregor write that the statement that "His ill-health and subsequent death were due to a tragic accident which befell him when he was conducting a body of students, men and women, on a cruise up the Pacific coast of Canada" is incorrect. On the return journey the boat struck a rock and foundered. They write that they were members of the Columbia University party referred to and have been closely associated with Prof. Wilson ever since until his death. It is true that the ship struck a submerged

rock and sank, but no one suffered the slightest physical injury and no one was in the water. The sea was calm, there was no panic, the transfer of passengers and crew to the lifeboats was conducted in an orderly manner and more than two hours elapsed after striking the rock before the ship finally disappeared. This occurred on August 5, 1897. By far the greater part of Wilson's cytological research and much of his work in experimental embryology were done after the shipwreck. His last contribution to cellular biology was published in 1937, when he was eighty years of age, and his last visit to the laboratory was one week before his death.

Colonial Administration and Progress, 1938-39

IF a certain complacency noted by critics was not indeed entirely absent from Mr. Malcolm MacDonald's review of the year's activities in the debate in the House of Commons on June 7 on the estimates for Colonial and Middle Eastern Services, 1939, he no doubt derived justification from the substantial progress made. Further, the increased interest and understanding of Colonial problems on the part of the public warranted a certain optimism in forecasting increased activity on the part of the administrative authorities in applying the resources of scientific research to the solution of the varied problems which have arisen, especially in Africa, from the contact of backward peoples with the, to them, new standards of a more advanced civilization. Among the more notable features, indeed, of a statement which as a whole can in truth be described as gratifying, was Mr. MacDonald's announcement of the consideration being given, both by the local administrative authorities and the Colonial Office in London, to the recommendations of Lord Hailey's "African Survey" and of Lord Bledisloe's Rhodesia-Nyasaland Commission, and especially to the manner in which effect can be given to the main proposal of the former for the development and co-ordination of research. In dealing with the varied range of problems with which research in Africa is now concerned, Mr. MacDonald was able to speak only in most general terms; but this was of less moment as the annual report was already available ("The Colonial Empire: Statement relating to the Period 1st April, 1938 to 31st March, 1939, to accompany the Estimates for Colonial and Middle Eastern Services, 1939". H.M. Stationery Office. Pp. iv + 97. 1s. 6d. net), in which the activities of administration are set out in detail under headings such as "Research", "Social Progress", "Development of Natural Resources" and the like.

IN opening his statement, Mr. MacDonald emphasized the responsibility of British democracy in government of the Colonial Empire—a field, as he said, of every kind of variety in which "we were still to a greater or less degree the trustees, the guardians, and the tutors of the various peoples". As was said by Sir Edward Grigg on another occasion a few days later, criticism of our ability to make the best for all men of the vast territories under our control is a moral challenge which is by far the most

serious we have to repel. In Africa, which at present is our gravest responsibility, the touchstone of our policy, whatever efforts may be expended in social or economic advancement, must be the opportunities afforded the native by our administrative system to train himself towards adjustment with the changed conditions which must result inevitably from the impact on tribal institutions of a system and civilization in which personal responsibility and personal liberty of thought and action, with certain recognized and admitted limitations due to the rights of others, are the corner-stone. Under the present administration of the Colonial Office, faith is implicit in indirect rule, or local government by traditional chiefs and native councils. The report records with a note of enthusiasm that while local government is regarded as a great experiment, "the year under review affords encouragement for continuing that experiment in high hope of success". The number of local administrations has been increased in several of the African colonies; but is there a subdued note of cynicism in the remark of one of them, that under its administration, extensions "tend rather towards improving the native tribunals than towards setting up native treasures"?

Down House

It is just ten years ago since the British Association threw open to the public Down House, Charles Darwin's home, at Downe in Kent, which had been presented to it by Sir Buckston Browne as a memorial to be held in custody for the nation. The memorial rooms and the grounds are open without charge throughout the year except on Christmas Day, and the number of visitors during the past year is stated to have been 7,362. This figure is very close to the average annual attendance of 7,300 during the ten years since the opening, and since the village of Downe, four miles from a railway station and on an infrequent omnibus service, is probably less easily accessible than almost any other place within the radius of twenty miles from London, it cannot be felt that the number of those who make the pilgrimage to Darwin's house is unworthy of his memory. It has, in fact, always exceeded the expectations of those who are responsible for the maintenance of the house. The collection of Darwinian relics, remarkably complete from the first, is still receiving additions from time to time. The British Association, by means of an appeal to its members and others, is now acquiring the nucleus of a collection of books, magazine articles, and other studies and critiques of Darwin's views, such as appeared in large numbers especially after the publication of the "Origin of Species" in 1859. The Association will gratefully acknowledge any appropriate gifts to the collection.

An Oxford Expedition to Peru

THREE members of the Geology Department of the University of Oxford, Dr. J. V. Harrison (Christ Church), Mr. J. D. Weir (University College), and Mr. C. H. Kearny (Queen's College) and Mr. M. H. Donald are leaving on June 17 for Peru to study

and map the geology of a part of the Central Andes of Peru, a triangular area the apices of which are Tarma, Cerro de Pasco, and Canta, the centre being about eighty miles north-east of Lima. Besides doing the work of mapping and survey, the expedition will collect fossils and specimens of rocks from this region for the British Museum. Dr. Harrison has a wide knowledge of Peru. Mr. Weir, a Rhodes scholar from the University of Saskatoon, has served two summers with the Canadian Geological Survey and Mr. Kearny, a Rhodes scholar from Princeton, has collected archaeological material in north-western Mexico. Mr. Donald of Cumberland has previously collected for the British Museum. How much this expedition will do depends largely upon the weather it experiences. In the high altitudes where it will be, the weather in August and September is capricious and may be very stormy. The plans have been approved by the Royal Geographical Society. The expedition hopes to return to Oxford in October.

Accessions to the British Museum (Bloomsbury)

A serious gap in the archaeological material available for study in museum collections in Great Britain has been filled by accessions to the British Museum (Bloomsbury) reported at the meeting of the Trustees held on June 10. Representative specimens have been received of the antiquities found at Mohenjodaro in the Indus Valley during the years 1925-28 in the archaeological excavations carried out under Sir John Marshall, formerly Director of Archaeology in India. The collection consists of 247 pieces, which have been acquired by exchange from the Director General of Archaeology in India. It is of especial value to archaeologists not only on account of the fact that the Indus Valley civilization, one of the major archaeological discoveries of the decade following the Great War, was almost completely unrepresented previously in English museum collections, but also because of the extent to which it throws light on the relations between this civilization and that of Mesopotamia in the course of the third millennium B.C. The list of accessions to the Museum also included a remarkable archaic Sumerian figure of a seated mountain goat in gold, about 1½ inches long, which has been given by Mr. J. A. Spranger. It is dated approximately at about 2500 B.C. Roughly it is contemporary with, though larger than, similar objects found at Ur by Sir Leonard Woolley. From Mr. M. E. L. Mallowan's excavations in northern Syria of last year come a group of Chalcolithic pottery from the Balikh Valley and antiquities from Brak, among which are the remarkable series of amulets, seals and necklaces of beads and coloured stones, as well as the frieze from the pedestal of the statue found in a sanctuary, consisting of rows of different coloured stones or artificial material, fired at top and bottom with gold bands and gold nails. It is dated approximately at 3000 B.C. A gold figure of a weather god of Hittite origin from Anatolia, dating from the fourteenth or thirteenth century B.C., was acquired by purchase.

Early Man in the Somme Valley, France

A SCOTCHMAN similar to that to which Mr. J. Reid Moir referred in his recent Huxley Memorial Lecture in reviewing the evidence for the existence of man in Pliocene times, has appeared among French archaeologists, in attacks on the authenticity of the evidence which would associate the Abbevillian industry, formerly known as pre-Chellean, with an early type of mammalian fauna with Pliocene affinities in the Somme valley. The evidence is derived from the observations of Ault du Mesnil on a quaternary site at Porte du Bois, Abbeville, between 1875 and 1896. He recorded the association there in the lower horizons of implements with a fauna, which included relics of *Elephas meridionalis*. This site was further investigated by Commont from 1906 onward; but although he confirmed the existence of a fauna such as Ault du Mesnil had described, with the addition of two early types of rhinoceros, no implements were found in association. In view of this, doubt has been cast on Ault du Mesnil's testimony. It is said that he was misled as to an association, of which, in default of a categorical statement, it is assumed that he had no direct and personal ocular evidence. It is well known that early investigators, including Boucher de Perthes, suffered much from fraud on the part of workmen. The whole matter is thoroughly discussed by the Abbé Breuil in the current issue of *L'Anthropologie* (49, 1-2; 1939), where he shows that not only was Ault du Mesnil too careful an observer to make a statement for which he had not good ground, but also that the records of the finds occur in unpublished memoranda still extant, though many of his notes have been destroyed. Further, a closely reasoned archaeological argument by Breuil supports the authenticity of the evidence, as well as shows the impossibility that such implements as these could have been introduced from another source to be foisted on Ault du Mesnil by fraud. Further argument is rendered unnecessary by the discovery, after this paper was written, by Breuil, accompanied by the chief critic, of implements in the strata in which their existence is in dispute.

Climatic Conditions and Living Things in 1938

THE spring of 1938 was remarkable in Britain for a long dry period with varied temperature. January and the first ten days of February were warm, following a December with a temperature about 2.5° F. below normal; but a colder spell in late February was succeeded by a March which broke all records in a warm spell, accompanied by drought, which extended into April. The dry spell continued into April and May, but then it was associated by coolness during the day and frosts at night (Phenological Report, 1938, in *Quart. J. Roy. Meteor. Soc.*, 65, 1939). These conditions had a marked effect upon vegetation. At most of the recording stations plant life was brought forward with a rush, so that by the end of March early stations were recording a precedence of 20 days, while at the highest station, Braemar in Aberdeenshire (1100 feet), rather more than 20 days advance was noted. This precocity, restrained to some extent

by the drought, was eventually checked by the weather of April and May, which caused widespread damage to blossom and foliage. Insects made an early response, as plants did, and suffered the same check, the recorders sharing an impression that, over all, butterflies and moths were scarce throughout the season.

MIGRATING birds can scarcely be expected to regulate their coming by conditions at the end of their journey, but although they arrived in season or even earlier than usual in the southern areas, this earliness was reduced, disappeared or was changed to lateness by the time they had reached their northern quarters in April-May. The report makes reference to the profound effect over an extensive area of the invasion of the Norfolk Broads by the sea, which destroyed the freshwater fishes and many other creatures, but the total results of which have not yet been assessed. The Phenological Report is not an easy document to read or understand, owing largely to the mass of statistics which it summarises and the system of symbols used in the discussion, but it is of great interest, and its band of recorders now numbers 446. Additional observers would add to the trustworthiness of the conclusions, especially in certain areas where records are sparse; for example, no insect observation is listed from Scotland. Any qualified reader of NATURE may obtain the forms necessary for contributing to this team work by applying to the Secretary of the Royal Meteorological Society, 49 Cromwell Road, London, S.W.7.

The Science Museum

THE report of the advisory council of the Science Museum to the President of the Board of Education for the year 1938 opens on rather an ominous note, for it appears that the suggestion has been made that to provide the badly needed further accommodation a building should be erected with "four or more floors". Miniature skyscrapers may be quite suitable for offices and flats, but there will be very general agreement with the opinion that it is unwise to erect a museum with several storeys. "The Council," says the report, "deem it right to mention that the site area they request for the Science Museum in the future falls short of the areas now occupied by our other major national museums." As the Science Museum represents the very activities on which our national prosperity depends most, it surely is against the country's interest to fetter it by unnecessarily limiting its possibility of serving wide educational purposes, and we trust the views of the Advisory Council will prevail. The various sections of the Museum hitherto known as 'Divisions' are now named 'Departments'. Of these there are now five, namely, the Department of Physics and Geophysics, the Department of Astronomy, Mathematics, Optics and Chemistry, the Department of Civil and Mechanical Engineering and Land Transport, the Department of Industrial Engineering, and the Department of Air and Water Transport. These various titles at once suggest the names of great

pioneers, all of whose work is represented in the Museum. Recent acquisitions, special exhibitions, lectures, attendances, staff are all referred to in the report, which contains information also of the Library, testimony being paid to the initiative and resource of Dr. S. O. Bradford, who last year retired after being in charge of the Library for thirteen years. The record of the Museum is one of steady progress.

*Vocational Education in India

AMONG the many baffling problems confronting the authorities responsible for education in India are the prevalence of unemployment among ex-students of high schools, intermediate colleges and universities, and the scarcity of young people trained for practical work in industry. Mr. A. Abbott was invited as an expert in vocational education to bring his special knowledge to bear on these problems, and delivered a lecture on the subject at the Royal Society of Arts (*Journal*, March 10). His lecture is largely based on observations in the Punjab, the United Provinces, Delhi, and the States of Hyderabad and Baroda. It outlines a scheme providing for vocational schools of three grades: the vocational high school, the technical college and the postgraduate stage. The first and, for the time being, most important would be open to students who had completed eight years of 'general' education. As an exception, prospective artisans of the small-scale industries would be admitted to industrial schools if qualified in arithmetic, reading and writing by six years of general schooling. These would devote a third of their time in the industrial school to general subjects, including drawing, and spend the remainder in workshop exercises. But the keynote of the lecture is 'planning'. The first step must be the establishment of machinery for effective consultation between industry and educational organizations. This would take the form of advisory councils, provincial and local. The former would in the first instance survey the needs of industry and plan a provincial scheme. On the local council would devolve the critical function of estimating the number of recruits needed annually for each calling, a consideration too often ignored in the provision of opportunities for advanced literary education. Entry to the technical colleges would be restricted to students who had not only gained the leaving certificate of a higher secondary school with credits in mathematics and science, involving ordinarily eleven years of schooling, but also had already a prospect, more or less assured, of finding employment.

Indian Statistical Conference

ALTHOUGH the desirability of holding an Indian Statistical Conference was realized by the Indian Government in 1934, it was not possible to hold the first meeting until January 1938. The Proceedings of the Conference were published in December (Calcutta: Statistical Publishing Society; London: P. S. King and Son, Ltd., 1938), and contain, besides the official speeches, some twenty research papers in

full and abstracts of many others; it will probably surprise many English statisticians to learn how vigorously the subject is being developed in India. The Conference was divided into four sections dealing respectively with theoretical statistics, agricultural statistics, medical and public health statistics, and economic statistics. There was a symposium on agricultural field experiments, and a special discussion on standardization in industry. The Conference was presided over by Prof. R. A. Fisher. Among the supplements is a biographical sketch of Prof. Fisher, pointing out how deeply he has influenced statistical work in India. Other supplements give the sixth annual report of the Indian Statistical Institute, and an account of the work of the Calcutta Statistical Laboratory, with a list of 128 original papers produced there.

The Art of Pyrometry

THE growth of the science of matter at high temperatures in the last century has been largely determined by the perfection of methods of measuring high temperatures. Prior to that time manufactures at high temperatures were of necessity empirical and dependent on the unaided skill and judgment of craftsmen. It was impossible to measure furnace temperatures much more exactly than in the time of Shadrach, Meshach, and Abednego. The progress can be realized by comparing the symposium on "Gas Temperature Measurement" (*J. Inst. Fuel*, March 1939) with the modest and pioneering classic of Le Chatelier "Les Mesures des Températures Elevees" published only so recently as 1900. This report, with its discussions, covers more than 100 quarto pages and forms an excellent summary of the art of pyrometry as it exists to-day—an art which makes use of almost every branch of physics. In the symposium all pyrometric matters were considered, but considerable attention was directed to the suction pyrometer for measuring temperatures of gases flowing through flues. Dr. G. Naesser described a recent introduction to pyrometric technique—a colour brightness pyrometer—which makes use of colour instead of the intensity of radiation. Advantages are claimed in connexion with the measurement of the temperature of melted metal.

The Ross Institute Industrial Advisory Committee

AT a meeting of the Ross Institute Industrial Advisory Committee held on April 21 with Mr. G. H. Masefield in the chair, reports were presented upon malaria control in Ceylon, and upon housing and air-conditioning in the tropics. Sir Malcolm Watson spoke on anti-malarial oil for treating water in order to destroy mosquito larvae. An almost perfect anti-malarial mixture has been compounded, but it is very necessary to employ the right kind of oils, which are not always available. The conveyance of disease by aircraft was another subject discussed, particularly by transmission of infected mosquitoes, and it was mentioned that an apparatus had been recently devised for disinfection during flight.

Directory of British Health Resorts

THE British Health Resorts Association, Tavistock Square, W.C.1, has just published its official Handbook entitled "British Health Resorts: Spa, Seaside, Inland" (2s. 6d. net). The volume, which is edited by Drs. Fortescue Fox and Wyndham Lloyd, is a guide to the spas and health resorts, seaside and inland, of the British Isles and British Dominions and Colonies, giving particulars of their climate and rainfall, the characteristics of their baths and waters, if any, and indications of the conditions for which they are suitable. The Minister of Health contributes a foreword, and chapters are included on the science of waters and baths and on climates, with maps, charts and many illustrations.

Recent Earthquakes

THE recently enhanced seismic activity has continued. Several strong earthquakes and tremors have been experienced in many widely separated places. On May 6, violent tremors were felt in Chile, especially in the neighbourhood of the epicentre of the destructive shock of January 24. Many buildings damaged previously in Chillan, San Carlos and Parral collapsed, but there was no loss of life. Port of Spain, Trinidad, experienced a severe tremor on the evening of May 7, but no damage was reported and there were no casualties. On the morning of May 8, a severe tremor occurred in the neighbourhood of Athens but again no damage is reported. The strongest shock, however, was on the morning of May 8. Provisional readings of the initial pulses (*P* waves) of seismograms and calculated epicentral distances are as follows: Kew, 1h. 51m. 48s. (compressional), Δ , nearly 23° ; Paris, 1h. 51m. 55s., Δ , $2,540$ km.; Uccle, 1h. 52m. 11s. (compressional), Δ , $2,700$ km.; Hamburg, 1h. 52m. 50s., Δ , $3,100$ km.; De Bilt, 1h. 52m. 21s., Δ , about 24.5° . The shock was also recorded at West Bromwich, and at Selfridges in London the maximum double amplitude was nearly $6''$. These readings point to an epicentre in the Azores at approximately latitude 37° N., longitude 24° W., with normal depth of focus, and initial time approximately 1h. 46m. 50s. G.O.T. Reports from Ponta Delgada state that at about this time a severe earth tremor lasting about twenty-five seconds was experienced on Sao Miguel Island in the Azores but no damage was caused. The shock was preceded by unusual heat and terrifying underground rumblings. It is known that a definite band of epicentres lies near the Dolphin or North Atlantic Divide on which the Azores are situated, although earthquakes are not so numerous on this band as in the Mediterranean or circum-Pacific regions of instability.

Physical Society's Rutherford Memorial Lecture

It is right and fitting that we should, in due season, praise the work of famous men, and no man has left the impress of his work and personality more deeply graven on the structure of modern physical science than has Ernest Rutherford. It has been said with truth that he was on the crest of the wave

of scientific advance; it has been said, with deeper truth, that he made the wave. A memorial lecture is a useful and appropriate form of homage, which has been adopted by the Physical Society, it was announced at the summer meeting of the Society held at University College, Southampton, on June 9. The Society's Rutherford Memorial Lecture is to be given annually between October and March, and to be devoted to an address on some topic concerning recent advances in atomic and nuclear physics. The first lecture will be given in the session 1939-40.

International Congress of Biology

THE first International Congress of Biology will be held at Brussels on July 9-12 under the presidency of Prof. E. Sphel. Discussions have been arranged on the role of diet in the output of muscular work, introduced by M. Bigwood; physiology of muscular contraction (M. Bouckaert); muscular work and circulation of the blood (M. Heymans); physiological mechanisms during training (M. Brouha). Further information can be obtained from the secretariat, 96 Avenue Paul Janson, Anderlecht, Brussels.

Physics of Metals

THE University of Pittsburgh, Pennsylvania, is organising a summer course during July 6-August 11 on the "Physics of Metals", which will deal with the fundamental structure of metals and other solids. An attempt will be made to understand the nature of the forces which make pure metals and alloys hard or soft, ductile or brittle, good or bad conductors of electricity, etc. The lecturers include: Dr. John C. Slater, head of the Department of Physics, Massachusetts Institute of Technology; Dr. M. F. Manning, University of Pittsburgh; Dr. W. Shockley, Bell Telephone Laboratories; Dr. Frederick Seitz, University of Pennsylvania; and Dr. E. U. Condon, associate director, Westinghouse Research Laboratory. Further particulars can be obtained from Prof. E. Hutchison, University of Pittsburgh.

French Association for the Advancement of Science

A PROVISIONAL programme and a list of sectional presidents (twenty-two in number) have now been issued for the Liège meeting on July 17-22 of the French Association for the Advancement of Science. Arising out of the formation at Cambridge of the new Division for the Social and International Relations of Science of the British Association, an exchange of views between the British and French Associations was arranged, as a result of which it was decided to elect to honorary membership of the Association the president, vice-president, secretary, deputy-secretary, treasurer and secretary of council of the French Association. The latter has now elected to honorary membership the president (Sir Albert Seward), general treasurer (Prof. P. G. H. Boswell), general secretaries (Profs. F. T. Brooks and A. Ferguson) and secretary (Dr. O. J. R. Howarth) of the British Association. The offices of the French Association are at rue Sapperte 28, Paris VI^e.

International Congress for Experimental Cytology

THE sixth International Congress for Experimental Cytology will be held at Stockholm during July 25–August 1, 1940. A preliminary programme has been arranged by the Swedish organization committee (President, Prof. John Runnström; Secretary, Dr. Sven Hörstadius; address: Wenner-Grens Institut, Norrtullagatan 16, Stockholm). It has been developed from the point of view of cellular physiology. The conventional distinctions between physical chemistry, biochemistry and cellular physiology have at present no sharp borders. Therefore place has been reserved for physico-chemical discussions of the behaviour of the components of protoplasm. Opportunities will, however, be provided for the arrangement of informal afternoon sessions wherein smaller groups may enjoy unrestricted discussion. Membership fee for the Congress is 25 Swedish crowns.

Lady Tata Memorial Trust

THE Trustees of the Lady Tata Memorial Fund announce that, on the recommendation of the Scientific Advisory Committee, they have made the following awards for research in blood diseases with special reference to leukaemia, in the academic year beginning on October 1, 1939. Grants for research expenses: Dr. Jørgen Bichel (Aarhus, Denmark); Dr. Julius Engelbreth-Holm (Copenhagen); Dr. Maurice P. J. Guérin (Paris); Prof. Karl Jármai (Budapest); Prof. James McIntosh (London); Prof. Eugene L. Opie and Dr. Jacob Furth (New York); and Dr. Joachim Wienbeck (Breslau). A part-time personal grant and grant for research expenses has been made to Dr. Werner Jacobson (Cambridge), and a whole-time scholarship awarded to Dr. Edoardo Storti (Pavia).

The Colonial Service: Recent Appointments

THE following appointments and promotions in the Colonial Service have been made: F. E. Reid, chemist, Institute of Medical Research, Federated Malay States; Dr. W. Rintoul, assistant analyst, Straits Settlements; A. Huddleston, geologist, Gold Coast; L. H. Lester, veterinary officer, Uganda; B. E. Webb, utilisation officer, Forestry Department, Tanganyika Territory; G. K. G. Campbell (agricultural officer), botanist, Nigeria; E. F. Martin (agricultural officer), senior agricultural officer, Uganda; R. O. Williams (chief horticultural officer, Palestine), deputy director of agriculture, Trinidad; W. D. MacGregor (conservator of forests, Nigeria), conservator of forests, Sierra Leone; J. N. Oliphant (director of the Imperial Forestry Institute, Oxford, and formerly department director of forestry, Malaya), chief conservator of forests, Nigeria; Captain R. L. Creery (veterinary officer), senior veterinary officer, Kenya; W. G. Emerson (veterinary officer), senior veterinary officer, Kenya; W. Fotheringham (veterinary officer), senior veterinary research officer, Kenya; F. H. Geake (assistant analyst, Straits Settlements), chemist, Customs and Excise Department, Federated Malay States.

Announcements

Viscount Nuffield and Mr. John Davison Rockefeller have been elected fellows of the Royal Society in accordance with the terms of Statute 12, which provides for the election of persons who, in the opinion of the Council, "either have rendered conspicuous service to the cause of science, or are such that their election would be of signal service to the Society".

DR. W. BOWIE, formerly chief of the Section of Geodesy of the U.S. Coast and Geodetic Survey, has been given the first Bowie Medal of the American Geophysical Union. The medal was established to commemorate his work for geophysical research, and will be awarded annually for outstanding achievement in related work.

A PORTRAIT of James Watt was unveiled by Sir Nigel Gresley at the Institution of Mechanical Engineers during the course of a reception held on June 9. The portrait represents Watt at fifty-seven years of age; it was painted in 1792 by Charles Frederick von Breda, and was acquired by the Institution from the family of John Rennie in 1936. During the reception, a formal announcement was made of the award of the James Watt International Medal to Mr. Henry Ford, and an address was delivered by the American Ambassador.

THE new laboratories at Mill Hill, London, N.W.7, of the Imperial Cancer Research Fund will be opened officially on June 27 by Lord Halifax, president of the Fund. Sir Frederick Gowland Hopkins will deliver an address on "Scientific Aspects of Cancer Research".

THE ninth General Conference of Weights and Measures will meet in Paris and Sèvres early in October.

AN International Exhibition against Air Attack will be held at Brussels on July 8–29 at the same time as the second International Salon of Aeronautics. Further information can be obtained from La Ligue de Protection Aérienne, 182 rue de la Loi, Brussels.

THE sixth Pacific Science Congress will be held at Berkeley, Stanford and San Francisco during July 24–August 12, under the auspices of the U.S. National Research Council. Programmes and further information can be obtained from Dr. Roy. E. Clausen, Room 205, Hilgard Hall, University of California, Berkeley, California.

WE are informed by Prof. C. Daryll Forde that his work on the tribal customs in the Obubra Division of Southern Nigeria, referred to in NATURE of May 13, p. 816, was carried out while he held a Leverhulme Research Fellowship for field work in Nigeria, and not, as stated in AFRICA, a Rockefeller research fellowship of the International Institute of African Languages and Cultures.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 1027.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Photo-oxides of Carcinogenic Hydrocarbons

SUGGESTIONS have sometimes been made that the biological action of carcinogenic hydrocarbons is preceded by conversion, probably by oxidation, into water-soluble derivatives which may more readily be conceived as able to exert a direct action on the cells which eventually become malignant than the water-insoluble parent hydrocarbons. The photo-sensitivity of solutions of some of the more potent carcinogenic hydrocarbons (namely, 3:4-benzpyrene and 20-methylholanthrene) is apparent to those accustomed to work with them; moreover, Boyland¹ found that alkaline extracts of photo-oxidized carcinogenic hydrocarbons arrest the activity of certain enzymes, and Maisin and de Jonghe² observed that light accelerates the production of skin tumours in mice by 3:4-benzpyrene. Most of the known carcinogenic hydrocarbons are anthracene derivatives and are therefore related to the group of compounds which have been shown by Dufraisse and his collaborators³ to undergo facile photo-oxidation to oxides which are peroxidic in character.

With the view of determining whether oxides of this type are involved in the biological action of carcinogenic hydrocarbons, we have attempted to isolate the photo-oxides of some of these hydrocarbons. Such photo-oxides would naturally be insoluble in water and hence would represent merely one stage in the oxidation process envisaged as a prelude to biological action. During the earlier stages of our work, Vallux⁴ reported that no absorption of oxygen occurred when solutions of 1:2:5:6-dibenzanthracene and 20-methylholanthrene were exposed to sunlight. We have ourselves been unable to obtain photo-oxides from 1:2:5:6-dibenzanthracene and 3:4-benzpyrene; in the latter case, dark-coloured unidentified products were obtained. With 1:2-benzanthracene we found indications of the formation of a photo-oxide; but contamination with dark-coloured by-products hindered its isolation.

The most rapidly acting carcinogenic hydrocarbon now known is 9:10-dimethyl-1:2-benzanthracene⁵, and the superior *meso* additive reactivity of this hydrocarbon towards maleic anhydride⁶ suggested that a photo-oxide might be more readily formed than in the case of the hydrocarbons previously mentioned. This has proved to be so. Oxygen was passed through 500 c.c. of a 0.05 per cent solution of 9:10-dimethyl-1:2-benzanthracene in carbon disulphide, exposed to the light of a 200-watt gas-filled lamp. The solution was kept cool by immersion in a bath of running water. After some four hours, the blue fluorescence had disappeared, and the solvent was removed under reduced pressure, in the dark. The resulting photo-oxide crystallized from carbon

disulphide in colourless needles, m.p. 193–194°. Photo-oxides having the melting points given in parenthesis were also obtained with approximately equal facility from the following related hydrocarbons: 5:9:10-trimethyl-1:2-benzanthracene (212–213°); 6:9:10-trimethyl-1:2-benzanthracene (205–206°), 5:6:9:10-tetramethyl-1:2-benzanthracene (228–229°), and 9:10-dimethyl-1:2:5:6-dibenzanthracene (222–223°). Two of the hydrocarbons have not been described (6:9:10-trimethyl-1:2-benzanthracene, m.p. 157–158°, and 5:6:9:10-tetramethyl-1:2-benzanthracene, m.p. 132–133°) and their synthesis, and also full descriptions of the photo-oxides, will be published elsewhere.

The compounds thus made available should suffice to show whether oxides of this nature are intermediate products in carcinogenesis by the hydrocarbons, although the lack of correspondence between the carcinogenic activity of a compound and its ability to form a photo-oxide does not support this view.

The ultra-violet absorption spectrum of the photo-oxide of 9:10-dimethyl-1:2-benzanthracene has been examined. It is intermediate between a benzene and a naphthalene type of absorption as shown by their complex derivatives. That is, the bands are similar in position to those of a *meso*-dihydro derivative of 1:2:5:6-dibenzanthracene, but have only about half the intensities. On irradiation with the mercury arc, a hexane solution of the photo-oxide is decomposed and the spectrum of the parent hydrocarbon with its long wave-length band system (3200–4000 Å.) reappears. Prolonged irradiation results in further change in the spectrum leading to a continuous absorption rising towards the region of shorter wave-length, and the same change is observed when the parent hydrocarbon, 9:10-dimethyl-1:2-benzanthracene, is similarly treated. The spectrum of 9:10-dihydroxy-9:10-dimethyl-9:10-dihydro-1:2-benzanthracene, examined for comparison with that of the photo-oxide, shows bands of the same order of intensity as the photo-oxide, but shifted about 180 Å. towards the far ultra-violet.

Variations in the Inhibitory Power of Carcinogenic Hydrocarbons according to the Solvent

PRACOCK¹ has noted a difference in the carcinogenic power of certain hydrocarbons injected subcutaneously, according to the solvent used. This potency reaches its maximum in the case of lard or olive oil, and its minimum with fats obtained from the same species.

We judged it useful to find whether by varying the solvent any difference would be produced in the inhibitory action, possessed by carcinogenic compounds², on the growth of transplantable tumours. In the first tests, made on rat tumours, we used as solvent a fat obtained from this species by successive extractions with acetone, hot and cold alcohol and ether. In the final ether solution, small quantities of undissolved substances were filtered off. The action of the hydrocarbon dissolved in this lipoidal mixture was compared with that of the same substance dissolved in lard, or in colloidal suspension. In a first series of tests, rats in which Walker carcinoma had been grafted 4 days earlier were subdivided as follows: (a) 14 control rats injected twice with 1 c.c. of untreated lard with an interval of one week; (b) 14 rats injected twice with 3 mgm. of 3:4-benzopyrene dissolved in 1 c.c. of rat fat, with an interval of one week; (c) 14 rats injected twice with the same quantity of hydrocarbon dissolved in 1 c.c. of lard, with an interval of one week.

In a second series of tests, rats bearing Walker carcinoma were treated as follows: (a) 12 control rats injected twice with 2 c.c. of untreated lard, with an interval of one week; (b) 12 rats injected twice with 3 mgm. of 1:2:5:6-dibenzanthracene dissolved in 2 c.c. of rat fat, with an interval of one week; (c) 12 rats injected twice with the same quantity of hydrocarbon dissolved in 2 c.c. of lard, with an interval of one week.

Lastly, in a third series, we have compared the inhibitory power of 3:4-benzopyrene dissolved in lard and injected subcutaneously with that of the same substance administered in colloidal suspension by intravenous injection (30 rats for each test).

The results proved that the highest inhibitory power was obtained by subcutaneous injection of the hydrocarbons in lard. The colloidal solution given intravenously showed a less constant activity. *In mixtures of homologous lipoids and fats (that is, fats obtained by extraction from rats and injected into animals of the same species) there is a total suppression of the inhibitory power for 3:4-benzopyrene and a distinct diminution for 1:2:5:6-dibenzanthracene.*

This last fact cannot be easily ascribed to a more rapid elimination of the compound due to easier absorption of the solvent. In fact, when the animals died on account of the tumour, autopsy showed that most of the fat remained at the site of injection, where it determines a more rapid and more intense inflammatory reaction than is the case with lard. A formation of ulcers earlier than in the case of lard was also observed (10-15 days).

Tests are being carried out to explain this anomalous behaviour of homologous fat as a solvent of the carcinogenic hydrocarbons.

Permeability of Corpuscles and Muscle Cells to Potassium Ions

AN almost ideal method to study the permeability of corpuscles is to introduce into the plasma cations, for example, ions of potassium labelled by the addition of a radioactive potassium isotope, to separate after the lapse of a certain time the corpuscles, and to determine if and to what extent the latter contain radioactive potassium ions.

⁴¹K, which has a half-life time of 12 hours, was administered in the form of potassium chloride to a rabbit by subcutaneous injection. The active potassium was kindly prepared by Dr. J. C. Jacobsen and Mr. N. Lassen by means of the cyclotron in Prof. Bohr's institute. Blood samples were taken at intervals, the corpuscles were separated from the plasma by centrifuging, washed twice with inactive plasma and the activity of both the corpuscles and the plasma determined. After the lapse of twenty-four hours the animal was killed, and the activity of the different organs was also determined.

As seen in the accompanying table, a part of the labelled potassium resorbed into the plasma is present in the corpuscles; but, even after the lapse of twenty-four hours, the activity of 1 gm. corpuscles amounts only to 66 per cent of that of 1 gm. plasma. As 1 gm. corpuscles contains about twenty times more potassium than 1 gm. plasma, the above figure has to be divided by 20 to arrive at the figure representing the extent of equipartition of the individual potassium ions present in the plasma at the start of the experiment between the plasma and the corpuscles.

Thus, 3 per cent of all individual potassium ions present in the aggregate of the corpuscles at the end of the experiment were incorporated in the course of the last 24 hours. A part of this 3 per cent is due to the formation of new corpuscles, since corpuscles formed in an organism containing labelled potassium must certainly contain labelled potassium; furthermore, some of the ⁴¹K ions found in the corpuscle fractions may have been adsorbed on the surface, some may be penetrated into the corpuscles. From the above figures it follows that the permeability of corpuscles to potassium ions is certainly very minute, or more correctly, the bulk of the potassium ions present in the corpuscles is not replaced within the life-time of the latter. Incidentally, we can conclude that the formation of new corpuscles within twenty-four hours is restricted to 3 per cent of the total corpuscle content of the rabbit.

DISTRIBUTION OF ⁴¹K.

Time	Organ	Percentage of ⁴¹ K administered present in 1 gm. fresh substance*
16 min.	Plasma	2.0×10^{-3}
35 "	"	2.4×10^{-3}
61 "	"	2.7×10^{-3}
93 "	"	3.3×10^{-3}
93 hours	"	3.0×10^{-3}
7 "	"	3.0×10^{-3}
15.5 "	"	3.0×10^{-3}
19.5 "	"	3.1×10^{-3}
24.5 "	"	2.9×10^{-3}
24.5 hours	Corpuscles	1.9×10^{-3}
24.5 "	Muscles	4.2×10^{-3}
24.5 "	Liver	4.1×10^{-3}
24.5 "	Kidneys	4.7×10^{-3}
24.5 "	Brain	2.8×10^{-3}
24.5 "	Tibia epiphysis	3.1×10^{-3}
24.5 "	Tibia diaphysis	1.9×10^{-3}
24.5 "	Marrow	2.3×10^{-3}
24.5 "	Spleen	3.3×10^{-3}

* When evaluating the above figures due regard was taken of the activity of the tissue potassium due to ⁴¹K.

We also carried out experiments *in vitro*. Blood was shaken with labelled potassium chloride at 37° in an O₂-CO₂ atmosphere for a few hours; corpuscles and plasma were then separated. The corpuscles of rabbit blood were found to contain 35 per cent of the activity of the same volume of plasma. Taking into account, as above, the much larger potassium content of the corpuscles, we obtain 2 per cent as the extent of equipartition of the individual potassium ions between plasma and corpuscles.

We found the membrane of muscle cells to be somewhat permeable to potassium ions, as shown in the table. The ⁴²K content of 1 gm. muscle tissue was found to be 150 per cent of that of 1 gm. plasma. If we assume, as is generally given, the extracellular volume to be 16 per cent of the muscle volume, the ⁴²K content of the muscle cells after the lapse of twenty-four hours amounts to 1.8 as much as the ⁴²K content of the equal weight of plasma. Taking into account that the muscle cells contain about twenty times as much potassium as plasma of the same weight, we can conclude that in the course of twenty-four hours 8 per cent of the K⁺ of the muscle cells exchanged with those present in the plasma.

In an experiment in which labelled potassium chloride was injected into the lymph sac of a frog kept at 22°, no ⁴²K of any significance was found in the corpuscles after the lapse of sixteen hours, while 1 gm. of muscle tissue was found to be 2.4 times as active as 1 gm. plasma.

Colour Reactions of Lignin and Tannins

SEVERAL recent observations have led us to the view that the Mitchell colour reaction of gallotannins¹ and the chlorine-sodium sulphite reaction of hardwood lignin, which latter has been studied in this Laboratory^{2,3}, are essentially similar. The observation that ferric salts are among the oxidising agents which give a magenta coloration with gallic acid in the presence of such weak alkalis as sodium bicarbonate, sodium sulphite⁴ and Rochelle salt suggests that, in the Mitchell reaction, there is first oxidation of ferrous sulphate to the ferric state and then oxidation of tannin by the ferric salt. It would appear that all the observations of ourselves and others can now be explained by assuming that these reactions take place in stages as shown in the accompanying table.

Trimethylgallic acid and hardwood lignin	Gallic acid and tannins
(1) An excess of chlorine is required in order to break down other links and form a phenol.	Contain no other links.
(2) The necessary oxidation is carried out simultaneously by the chlorine.	A variety of oxidising agents may be used.
(3) The excess of chlorine must be removed whilst the system is acid since the coloured substance is specially sensitive to oxidation in alkaline solutions.	No excess of oxidising agent need be used.
(4) The system must be rendered weakly alkaline before the characteristic magenta colour develops.	The system must be weakly alkaline for the development of the magenta colour.

In the case of lignin, the importance of the third and fourth of the above steps is brought out as follows. Urea may be added to destroy excess of chlorine, and the coloration is given when the system is rendered alkaline. When sodium bicarbonate is added direct to freshly chlorinated wood, no colour is produced, even if urea is added afterwards. Sodium sulphite both removes excess chlorine and renders the system alkaline; but even in the presence of this reagent the colour is only transient, since it changes to brown on exposure to air. That atmospheric oxygen has little effect on the substance immediately responsible for the coloration when the medium is acid is shown by the observation that chlorinated beechwood, from which excess chlorine had been removed by sulphurous acid, still gave the magenta coloration, when alkali was added, after an interval of six days.

Lastly, we have observed that the colour develops when gaseous chlorine is passed into a dilute aqueous solution of gallic acid containing an excess of basic lead acetate in suspension. The colour disappears in the presence of excess chlorine and does not reappear on adding sodium sulphite. On the other hand, if either beechwood or trimethylgallic acid is treated in the same way, no colour is developed; but if, after using an excess of chlorine, sodium sulphite is added, the colour appears as usual. In the first case, a small amount of chlorine causes sufficient oxidation for the production of the colour in the presence of the weakly alkaline basic lead acetate. Then, while the liquid is still alkaline, the coloured compound is destroyed by further chlorine. In the second case, phenol formation is not complete until sufficient chlorine has been passed to make the medium acid so that the colour is developed by sodium sulphite in the usual way.

Ultra-Violet Chemi-Luminescence

A RECENT report by R. Audubert¹ on ultra-violet chemi-luminescence has provoked a good deal of discussion on the possible mechanism of the phenomenon. The phenomenon seems to be identical with the mitogenetic radiation², a fact which was emphasized in the discussion following Audubert's paper (S. I. Wawilow, P. Fringsheim). In this connexion it may be of some interest to report briefly on our recent results, which have a bearing on some points raised in the discussion (Polanyi), and which suggest an interpretation of the radiation occurring in chemical reactions as a kind of sensitized fluorescence. A detailed report is in preparation.

The starting-point of our investigation was Frankenburg's hypothesis on the origin of mitogenetic radiation, from which we quote the following extract³: "According to that interpretation [that of Haber and Willstätter] there may occur as

by-products of these reactions [fermentations] interactions between atoms and radicals, in other words, highly exothermic processes which may serve as sources of an ultra-violet radiation of very short wavelength. The ultra-violet luminescence could here either be caused directly by recombination of atoms with radicals, or indirectly by transferring the energy balance to 'molecules capable of radiating'. Evidence in favour of the latter alternative is supplied by the emission spectra of specific metabolic processes (glycolysis, proteolysis, oxidation, &c.) as found by Gurwitsch¹ (our italics).

The passage in italics suggests a possibility of experimental verification, which leads to unambiguously positive results. If one adds to a source (*S*) of chemi-luminescence of which the emission spectrum is known, a substance (*K*) which does not radiate spontaneously, and does not take any part in the reaction *S*, the emission spectrum of the mixture contains new bands, which must therefore be due to the mere presence, and not to any chemical action, of the substance *K*.

If radiation from the substance *K* can be excited by other means (for example, by fermentation) the spectrum in the first case (*K* + *S*) and in the second (*K* + ferment) are found to be identical.

The following case may serve as an example: The source *S* is a 0.5 solution of glycine, which has been irradiated mitogenetically (source $K_2Cr_2O_7$ + $FeSO_4$) and continues to emit for several hours. As we have shown elsewhere² the process is the excitation of a fermentative reaction (desamination of glycine). The emission spectrum was examined in repeated experiments, and contains only one band at 2290–2300 Å. After adding 0.1 per cent of glucose, the emission spectrum contains the bands 1900–1905, 1915–1920, etc., which are typical of glycolysis, in addition to the original glycine band³.

EMISSION SPECTRA OF THE THREE COMPOUNDS, USING YEAST CULTURES AS INDICATORS (OF. REF. 5).

The spectra of glycine and of the PO_4 radiation (denoted by 'P') were measured with greater precision (monochromator band width of 10 Å.), the rest of the spectra less accurately (monochromator slit of 2 mm., corresponding to 10 Å. for short waves and 45–50 Å. for longer waves). The PO_4 spectrum as found here is identical with that of the fermentation of nucleic acid; the latter is also a case in which the phosphate radical is set free (cf. ref. 5, p. 23).

We investigated a number of substances, which may be divided in two groups, 'fluorescent' substances and 'non-fluorescent' ones. The second group contains all the high-molecular compounds we have so far investigated (glycogen, pure albumin, nucleic acid). The first group contains several monosaccharides (glucose, levulose, mannose), sucrose, peptides, tryptophane phosphate radical, the ions of sodium and chlorine. For the last two, the fluorescent

spectrum was obtained by comparing the emission spectra of the systems glycine plus sodium chloride and glycine plus sodium dihydrogen phosphate. The accompanying diagram shows that some bands are common to both spectra, whereas others occur only in one of them. The former belong to the sodium ion, whereas the latter must be due to the chlorine ion, or to the phosphate ion, respectively. The extension of the spectra is, of course, limited by the properties of the biological detectors, which, according to measurements made by us recently, respond only up to waves of about 2800 Å.

Structure of Benzil

C. C. Caldwell and R. J. W. le Fèvre¹, by a comparison of the dipole moments of benzil and of phenanthraquinone in various solvents, are able to suggest that the former molecule has a maximum stability when the two $Ph - \dot{C} = O$ units lie in planes which are mutually perpendicular.

We have been engaged for some time in an analysis of the structure of crystalline benzil, based on complete X-ray measurements and on a new determination of the magnetic anisotropy. Benzil crystallizes in the D_2^h and D_2^d (enantiomorphous) space-groups, the unit cell containing three molecules. Each molecule has a dyad axis, normal to the central carbon-carbon bond². Starting with the plane *trans*-configuration, possible molecular arrangements may involve either a rotation of the two $Ph - \dot{C} = O$ groups about the central single bond, or a symmetrical rotation of the phenyl groups about their single bonds, or both of these. Seven main molecular types are being investigated:

(1) The plane *trans*-form: all the atoms must then lie in the {1120} planes. An exhaustive comparison of calculated and observed X-ray intensities of reflection over a complete range of parameters has eliminated this form.

(2) The plane *cis*-form: this is ruled out both by steric considerations and by the X-ray intensities.

(3) The form suggested by K. Banerjee and K. L. Sinja³, in which the two phenyl groups are normal to the plane central $O = \dot{C} - \dot{C} = O$ group, which is of the *trans*-type. This is contradicted by a careful comparison with experimental intensities, all parameters being systematically varied.

(4) A molecular arrangement intermediate between (1) and (3), the phenyl groups being symmetrically rotated out of the plane *trans*-configuration about their appropriate single bonds. No structure based on such a molecule could be found to give agreement.

(5) A molecule obtained by rotating the phenyl groups symmetrically out of the plane *cis*-configuration about their appropriate single bonds. This also has been eliminated.

(6) A skew molecule in which there has been rotation of the $\text{Ph}-\text{C}=\text{O}$ groups out of the plane configuration about the central single bond only, each phenyl group being co-planar with the adjacent $-\text{C}=\text{O}$ atoms.

(7) A skew molecule in which, in addition to the rotation about the central single bond, there has also been symmetrical rotation of the phenyl groups about their single bonds.

The investigation of possible crystalline structures based on skew molecules of types (6) and (7) is, unfortunately, both long and tedious, and is not yet complete. The elimination of the simpler molecular structures shows, however, that the molecule must be of such a skew type, in which case it can of course exist in a right-handed or a left-handed form. The crystals will contain spirals of oxygen atoms somewhat similar to those found in quartz. The optical rotatory power of crystalline benzil is even larger than that of quartz.

Preparation of Grease-free Polished Surfaces

POLISHED surfaces of metals and minerals, completely free from grease, are frequently required for scientific purposes. Adam¹ has discussed the difficulties encountered in their preparation, and the complications that ensue, for example, in electron diffraction work, if there is a surface film of grease. Del Giudice^{2,3} and Wark and Cox^{4,5} have discussed the matter from another point of view. The four main sources of contamination in polishing mineral or metal specimens are: (1) the polishing materials, that is, the abrasives and the laps of soft metal or cloth; (2) grease from the fingers used to hold the specimen during polishing or in otherwise handling it; (3) the water under which the mineral is polished and stored before use; and (4) air-borne grease.

The abrasives can be cleaned by ignition, but the polishing cloths present greater difficulties, because of a film of grease acquired during weaving. In this Laboratory, the cloth is refluxed with benzene for some hours, next boiled for three hours with 4 per cent caustic soda solution, and finally boiled in several changes of distilled water until the alkali is removed. Thereafter the cloth is kept under water.

To prevent contamination from the fingers, the operator should wear surgical rubber gloves or finger stalls, cleaned thoroughly in a fresh chromic acid-sulphuric acid mixture. Though contamination from the sides of a specimen is rare, because of the lack of mobility of most adsorbed films, it is a wise precaution to grind, under water, all faces of the specimen. After polishing, the specimen should be handled, face downwards, by cleaned glass forceps: it should never be allowed to dry.

Contamination by air-borne grease is prevented by conducting the polishing operations on wet polishing cloths, using a liberal supply of abrasive. The abrasives and finely divided metal or mineral that

tend to cling to the specimen (del Giudice² and Wark³) may be removed by wiping the surface with a pad of cleaned linen tied over the flattened end of a glass rod. In this Laboratory, aluminium oxide abrasive has been used for the final step in polishing: its known adsorptive power (upon which depends its use in vitamin extraction processes) tends to take care of any surface-active contaminants that find their way into the system. Freshly ignited magnesium oxide is a more rapid polishing agent, but because of its alkalinity it is unsuitable for some purposes.

A sensitive test for contamination is⁶ available. With the polished specimen still under water, a small bubble of air is brought into juxtaposition with the surface and pressed against it for a few minutes. In the absence of a grease film, the bubble will not spread, and comes away cleanly when it is raised. A still more stringent test is obtained by using a drop of grease-free benzene or 'Nujol' in place of the bubble of air. A convenient apparatus for these tests has been described by Taggart, Taylor and Ince⁷ and by Wark and Cox⁴; but if isolated tests only are required a simpler form could be used.

The readiness of contamination by water or the atmosphere is obviously dependent upon location. Taggart⁶ states that the New York water supply contains sufficient iron, and Talmud and Lubman⁸ state that the Moscow supply contains sufficient calcium, to alter the surface reactions of quartz. Distilled water, while free from dissolved salts, is usually found to be less free from grease.

The readiness of contamination from the atmosphere and/or the water supply is well illustrated by difficulties encountered in this Laboratory following severe bush-fires in the catchment area for the Melbourne water supply, distant about fifty miles from the city. Clean specimens could not be obtained for several days. Within a week, the difficulty disappeared for pyrite and calcite, but it was almost a month before clean specimens of chalcopyrite were consistently obtained. It is possible that the inability of some Continental investigators to obtain clean surfaces—judged by the bubble test—is due to their having to work with atmosphere or water always contaminated by some local industry.

Lamellar Structure of Potash-Soda Felspars

In an extremely interesting paper, Ito¹ has recently described the results of an X-ray examination of a Korean moonstone which he assumes to be similar to a specimen (described by E. Spencer²)

containing approximately equal amounts of potash feldspar and soda feldspar, showing a blue schiller, and resembling sanidine in its glass-clear appearance and in having an abnormally low¹ optic axial angle. It concludes that this crystal is an intimate intergrowth of a (monoclinic) potash feldspar having the sanidine structure, and a corresponding high-temperature monoclinic form of soda feldspar.

We have carried out by X-ray methods a preliminary general survey of potash-soda orthoclase feldspars with micropertthitic structures, and (with D. L. Smae) have described the results of our investigation in a paper read before the Mineralogical Society in January last, and to appear in the *Mineralogical Magazine* of June 1939.

More recently, we have examined in greater detail specimens representing each of the two types of structure the existence of which was suggested by our previous survey. One of these structures occurs when the proportion of soda feldspar does not exceed 30 per cent approximately, the other when a greater amount of soda feldspar is present, and it appears that our data are most easily explained on the following hypothesis. The low-soda micropertthitic structure contains (i) a monoclinic potash feldspar component, and (ii) triclinic soda feldspar lamellae which are either actually twinned on the *pericline law* or arranged in the same mutual orientation. The high-soda structure contains (i) monoclinic potash feldspar, and (ii) triclinic soda feldspar lamellae twinned on the *albite law* (or arranged in the same mutual orientation). It is not yet certain whether the triclinic lamellae which occur in the low-soda structures are structurally identical with those which occur in the high-soda structures, nor is it certain that lamellae of either type are identical with ordinary albite, though all three structures are very similar if not actually identical. The experimental evidence on which this hypothesis is based, and its implications for the theory of micropertthitic structures, will be discussed elsewhere; but in the meantime we may note that there now appears for the first time a fairly definite prospect of obtaining by X-ray methods a structural classification of the micropertthitic feldspars.

We have also examined Spencer's specimen of Korean blue moonstone (from the same locality as Ito's material), and find to our surprise that it is structurally exactly similar to the low-soda micropertthites already described, that is, it contains monoclinic potash feldspar and triclinic soda feldspar twinned on the *pericline law* (or correspondingly oriented). The difference between our conclusions and Ito's with regard to the structure of the soda feldspar component may be due either to a real difference between Ito's material and ours, or to the fact that our suggested structural scheme is adequate to explain at least a part, perhaps the whole, of Ito's published data. (Some of our X-ray photographs are in fact identical with some published by Ito.) These points are also discussed in detail in a paper to be published elsewhere.

A New Method for the Conservation of Milk

THE conservation of milk without drastic heat treatment is perhaps the most important problem in the dairy industry. Numerous attempts have been made to solve this problem, mostly with only partial success and necessitating elaborate and expensive apparatus. It has been found possible to conserve milk for about a fortnight by the simple process of adjusting the pH to 5.2 and holding at a temperature of 36–38° F. During the first week the bacterial count actually decreases but rises abruptly in two to three weeks coincident with 'going off'. The following is a typical experiment:

Milk adjusted to pH 5.15	
Age in days	Colony count per ml.
0	2,500
2	460
7	210
21	∞

Milk requires about 4 ml. normal hydrochloric acid per 100 ml. to reduce the pH to 5.2. In practice it is sufficiently accurate to titrate a portion of the milk with *N* hydrochloric acid until casein precipitation is observed and then to add 95 per cent of this quantity *pro rata* to the bulk. The acid must be added with vigorous stirring and the milk later neutralized with an equivalent amount of normal caustic soda before use. The only effect on the milk is a slight dilution and the production of a very slight salty taste, not detectable by casual tasting. The micro-organisms ultimately responsible for the deterioration of the milk are coloured cocci and yeasts. Milk can be conserved for longer periods by holding under 'anaerobic' conditions at lower temperatures and adjusting to lower pH values. Although casein precipitates at pH values below 5.2, the milk sol can be reformed on neutralization by prolonged stirring.

The method would appear to offer possibilities for industrial purposes. The chief advantages are that no expensive plant is required and that the milk retains in full the original fresh milk flavour. Although enzymic changes are undoubtedly proceeding under these conditions, the rate is so small that they cannot be detected by taste.

Bacterial Antigens

THE results of recent work on the nature of certain of the bacterial antigens of gram-negative micro-organisms suggest that these substances are essentially polysaccharide-phospholipin complexes¹. A further component, however, which contains 10 per cent nitrogen, has also been found². Utilizing preparations of antigenic material which had been obtained by the trichloroacetic acid method of Boivin¹ or by the diethyleneglycol extraction method³, we have succeeded in removing the phospholipin component⁴ (N:P, 1:1) from the antigenic complex of *B. dysenteriae* (Shiga) without employing acid, alkaline or enzymic hydrolysis. The phospholipin component cannot be removed by extracting the complex with acetone, ether or ether-alcohol mixture, but is readily eliminated on treatment with a strongly polar solvent such as formamide (dielectric constant 34 at 20°). The antigen dissolves readily in this solvent to give,

clear, colourless solutions which can be used for the measurement of optical rotation.

The phospholipin-free material was found to be fully antigenic in rabbits and induced the formation of specific agglutinins and precipitins and 'Shiga' heterophile immune-body. It would appear, therefore, that the phospholipin component of the complex is not essential for the manifestation of antigenic properties or for the capacity of the complex to induce the formation of haemolytic heterophile immune-body*.

This work is being continued with antigenic material that has been isolated from selected strains of *B. typhosum* which are known to contain the characteristic 'O', 'Vi', 'O + Vi' or 'Rough' antigens respectively.

Binocular Stereoscopic Vision

WITH reference to a letter of mine in *NATURE* of December 10, 1938, Father William O'Leary, of Riverview College Observatory, Riverview, N.S.W., wrote to me shortly before his death, and, after mentioning that he also for many years past had been able to view stereoscopic pictures without a stereoscope, says: "The stereoscopic effect is also quite easily obtained by reversing the position of the pictures, putting the right to left and the left to right. If now, instead of focusing the eyes for parallel distant vision, we cross the eyes, the left eye then sees the right-hand picture and the right the left-hand picture. For some people this is rather painful, but I find no difficulty. The effect is a combination image, seemingly just half-way distant between the eyes and the two pictures, in fact, a miniature picture, but beautifully sharp in detail."

It took some practice before I was able to observe the phenomenon thus described by Father O'Leary, but I did succeed, and it has now become fairly easy. I hold the reversed stereo pictures in my left hand at about 18 inches distance and gaze at the tip of my right thumb placed in line with or a little below the lower edge of the pictures and about 6 inches from the eyes. This causes a squint so that the right eye sees mainly the left picture, and the left eye the right picture, as described by Father O'Leary. By some practice two of the four rather vague images coalesce, and the thumb can then be removed. The stereoscopic image is fairly easily held, and will survive short periods of closure of the eyes as in winking, but not much longer ones.

The most remarkable feature of the phenomenon seems to me to be the size of the image. It appears, as Father O'Leary says, about half the normal size, and, it is thus quite easy, holding the pictures at about the distance of ordinary vision, to see a normal size stereoscopic image by the commoner method, or an apparently half-size one by the cross-eye method. In the latter case, when the stereoscopic equilibrium is upset, the pictures appear to revert to their normal size.

Another curious point deserves notice. While observing this stereoscopic effect, I closed one eye, expecting to see the resulting two images resume their apparent normal size. There was, however, little or no noticeable change; it seemed only to come about on reopening the closed eye. This appears to involve the rather remarkable conclusion that an object appears to be smaller when seen by one eye than when seen by both. Perhaps the binocular image is really a little bigger than the monocular image, but this does not seem sufficient to account for the marked difference in apparent size between the two kinds of stereoscopic image. Since the phenomenon is entirely subjective it can scarcely be appreciated by those who have not observed it. In only one point does my observation differ from Father O'Leary's description. To me, by the cross-eye method (as by the other), the stereoscopic image is of the same size as the two adjacent images, and is in the same plane with them, not in a plane half way between them and the eyes; but here I may be misinterpreting Father O'Leary's meaning.

It follows from what has been said, that stereoscopic pictures can be observed by the cross-eye method when considerably separated, if viewed from a sufficient distance. At eight feet distance the pictures may be separated by two feet or rather more, and in this case the other two images fall each on the blind-spot of its receiving eye, so that the only image observed is the stereoscopic one. Father O'Leary suggests that stereoscopic pictures, suitably placed, and projected on a screen, could be observed by the cross-eye method, and this seems to be quite a practicable proposition, its only drawback being, perhaps, the reduced size of the image. I hope that someone will be able to explain this difference in apparent size.

Spectroscopic Power of a Human Eye due to Injury

WITH reference to Prof. Kerr Grant's recent communication on this subject¹, I wish to refer to communications on this subject by myself and others^{2,3} under the title "Conjunctival Halos".

In cases of this sort, it is important to note whether the centre of the ring-system is light or dark. Thus in that described by Mr. Barton⁴ it was light and "A very approximate measurement of the first red ring gave its angular diameter as 7°, in fair agreement with the value [radius 4° 49'] quoted in Mr. Melmore's letter". No agreement is possible, for in my case the centre of the system was dark. But taking the 'grating interval' equal to 0.0125 mm. and λ equal to 0.0007 mm., and applying the equation appropriate to a bright centred system the angular diameter works out at 6° 24'. This is in good agreement with the result of Mr. Barton's own measurement.

The value given by Prof. Grant for the angular radius of the first order red ring accords well with the value found by me for a dark-centred system.

Fission of Heavy Nuclei

PROF. O. HAHN has written to me pointing out that the translation of a passage from a paper of Curie and Savitch (*J. Phys.*, Sept. 1938) in my recent article on "Fission of Heavy Nuclei" (*NATURE*, May 27) might possibly be misleading.

Curie and Savitch wrote: "Dans l'ensemble, les propriétés de R3.5h. sont celles du lanthane, dont il semble jusqu'ici qu'on ne puisse le séparer que par fractionnement." I omitted the final qualification in my translation: "On the whole, the properties of R3.5h. are those of lanthanum, from which it appears that until now it has not been separated." It seemed to me that the qualification in question ("except by fractionnement") was unimportant from the point of view of the proof that R3.5h. was neither an isotope of actinium nor a trans-uranic element of the chemical type envisaged by Hahn, Meitner, and Strassmann. I did not wish to use the quotation for any other purpose than the establishing of these two conclusions.

Darwin's Geological Collection from Tasmania

A VISITOR to Darwin's home, Down House, recently put a question as to the whereabouts of his geological collection from Tasmania, made during the voyage of the *Beagle*. (The specific reference was to brachiopods.) We were unable to answer, either from records in our possession or after inquiries elsewhere.

It is well known that the *Beagle* collections, geological, botanical, and zoological, were widely distributed, and it is felt by the Down House Committee of the British Association that as full a record as possible ought to be made of the present location of all the material which survives, and that the Association, as the custodian of Darwin's house, should make it. I shall be very grateful to the authorities of museums, laboratories, or other institutions, for information as to any Darwinian collection in their keeping.

O. J. R. HOWARTH.

(Secretary, British Association).

Down House,
Downe, Kent.

Points from Foregoing Letters

It has been suggested that some of the insoluble organic compounds which produce cancer do so after they are oxidized to water-soluble derivatives. J. W. Cook, R. Martin and E. M. F. Roe have prepared photo-oxides of 9:10-dimethyl-1:2-benzanthracene and of related compounds as a step towards testing this view.

E. Morelli and A. Danzi have found that the inhibitory power of carcinogenic hydrocarbons on transplantable tumours diminishes or disappears if they have been inoculated dissolved in fat of animals of the same species.

By using radioactive potassium as an indicator L. Hahn, G. Hevesy and O. Rebbe find that the bulk of the potassium ions present in the corpuscles is not replaced within the life-time of the corpuscles; about 8 per cent of the potassium ions present in the muscle cells were replaced within 24 hours by ions previously present in the plasma.

W. G. Campbell and J. C. McGowan point out the similarity between the Mitchell colour reaction of gallotannins on one hand and the chlorine-sodium sulphite colour reaction of hardwood lignin on the other.

A. Gurwitsch and L. Gurwitsch report new experiments on the spectral distribution of ultra-violet radiation emitted during certain chemical reactions. It is found that the presence of other substances (taking no part in the reaction itself) introduces new lines into the spectrum; these are presumably due to molecules being excited by the energy liberated in the reaction.

I. E. Knaggs and K. Lonsdale, from an analysis of crystalline benzil based on X-ray and magnetic measurements, have deduced that the molecule must be of a skew type. This agrees with the recent suggestion of C. C. Caldwell and R. J. W. le Fèvre, who have measured the dipole moment in various solvents.

Ian W. Wark describes a method of obtaining grease-free polished surfaces of metals and minerals. He also discusses a sensitive test for cleanliness, based

upon the fact that the angle of contact between an air bubble and a clean solid surface immersed in water is zero.

S. H. Chao and W. H. Taylor report that the experimental data obtained in an X-ray examination of selected orthoclase-microporthites are most easily explained if it is assumed that in both the observed structure types the potash feldspar is present as a monoclinic component; while in the low-soda type the soda feldspar lamellae are triclinic and twinned on the pericline law, in the high-soda type the soda feldspar lamellae are triclinic and twinned on the albite law.

J. G. Davis states that it is possible to conserve fresh milk for about a fortnight by the simple process of adjusting the pH to 5.2 and holding at a temperature of 36-38° F. The original fresh-milk flavour is retained in full.

W. T. J. Morgan and S. M. Partridge have succeeded in eliminating the phospholipin component of the antigenic complex of *B. dysenteriae* (Shiga) by utilizing the dissociating properties of the strongly polar solvent, formamide. The phospholipin-free material is fully antigenic in rabbits, thus indicating that the phospholipin component is not essential for the manifestation of antigenic properties.

T. S. Patterson points out that stereoscopic effect can be obtained by reversing the position (left for right) of ordinary stereoscopic pictures, and viewing the left picture by the right eye and vice versa. The stereoscopic image thus observed appears, however, to be only about half the normal size.

The centre of the ring-system of interference spectra seen in cases of conjunctivitis may be bright or dark. S. Melmore directs attention to the importance of distinguishing between them and notes that Prof. Kerr Grant's determination of the angular radius of the first order red ring is in agreement with his own for a dark-centred system.

The Secretary of the British Association asks for information as to the whereabouts of collections made by Darwin during the voyage of the *Beagle*.

Research Items

Early Man in San Dieguito Valley, California

SOME unexpected archaeological features were revealed in an investigation carried out by Malcolm J. Rogers, chief curator of the San Diego Museum, in a field expedition and excavation in the San Dieguito River Valley, of which a brief report is given in the Year Book of the Carnegie Institution of Washington for the year 1937-38. A site was chosen for examination which seemed to offer the deepest accumulation of alluvium available. The choice proved to be exceptionally fortunate, as on excavation a complete record of post-pluvial river history was uncovered. After trenching in recent flood river silts to a depth of two to three feet, a Yuman camp level with a maximum depth of two and a half feet was uncovered. This had been built on three feet of lateral outwash soil of terrestrial origin. Beneath this were a two feet deep band of boulders and sand, deposited in a period of flash flooding, and a stratum two feet in thickness of stream origin, consisting of coarse sands and yellow clayish sand, while the lowest stratum was composed of boulders and sand strata, attaining a thickness of seven feet at the entrance of the trench. This last formation rested on a Tertiary sandstone, into which a Pleistocene channel had been cut. The lowest stratum was also implementiferous, the material consisting of factory debris or transported items. In the upper third was a camp level which produced many whole implements. Stream-transported implements occurred down to the very base, and in contact with the Tertiary surface, probably Phase I or Phase II, San Dieguito tools derived from camps up-stream. The camp level belongs to Phase III. The main trench section showed "splendid examples" of solifluxion, probably the first to be found in the New World. As a result, San Dieguito implements were even found on top of the horizon containing the Yuman implements, a result of the lateral outwash.

Fertility Rates of Scottish Married Women

IN a study of the fertility of Scottish married women, R. S. Barclay and W. O. Kermack make a further application of their 'diagonal law', according to which the birth-rates for each age group (excluding 15-20 years) decline regularly at a rate from year to year which is expressed by a diagonal line. It is found that in Finland the same general effect is apparent, and in England and Wales predictions based on this law are in general agreement with fertility rates calculated from census data. This law is now applied (*Proc. Roy. Soc. Edinburgh*, 59, 62; 1939) to Norway and is further developed for Scotland. In almost every county, fertility is found to be greater in landward districts than in the small burghs. Ross and Cromarty has the highest value, which progressively declines towards the north, south and east. There is no striking deficiency in the fertility of large towns compared with rural areas, and the large burghs are intermediate. The new Population (Statistics) Act will shortly provide information on various points at present uncertain.

Vitamin C and Poliomyelitis

A. B. SABIN (*J. Exp. Med.*, 69, 507; 1939) carried out experiments on 46 monkeys which showed that both natural and synthetic preparations of vitamin C had no effect on the course of experimental poliomyelitis induced by nasal instillation of the virus. Administration of vitamin C was begun immediately after the instillation of the virus, and if it were capable of exerting any effect on the virus or the tissues it could have done so before multiplication of the virus had begun. Monkeys whose store of vitamin C was depleted reacted in the same way as those receiving an adequate diet; 13 out of 25 monkeys on a scorbutic diet died of spontaneous acute infections, chiefly pneumonia and enterocolitis, while the monkeys receiving an adequate diet remained well. The surviving 12 monkeys on the scorbutic diet developed the osseous and other changes of human scurvy, and vitamin C was shown to produce healing and calcification in the bones as well as to check oedema and the hemorrhagic diathesis.

Primary Lung Tumours in Mice

J. ARGYLL CAMPBELL (*Brit. J. Exp. Path.*, 20, 122; 1939) has tested tarry matters from the following for carcinogenic potency, using the simple skin painting technique for mice; dust from tarred roads, cigarette smoke, chimney soot, soot from exhausts of internal combustion engines burning heavy oil, and a binding material in cardboard. The results were as follows: (1) The tarry matter from roads and chimney soot contain potent carcinogenic agents, but in ordinary circumstances the effect on the skin of the latter is somewhat mitigated by the presence of the carbon of the soot, while the effect of the former is aided by the presence of organic constituents. (2) Cigarette smoke under ordinary conditions gives rise to tarry matter which may occasionally produce hyperplasia and cancer of the skin after prolonged application. (3) Tarry matter from the motor exhaust soot and from the cardboard do not produce cancer. (4) Exhaust soot suspended in the atmosphere slightly increases the incidence of lung tumours in mice, while chimney soot does not produce any perceptible increase. The dust from tarry roads appears to be the most dangerous source of carcinogenic agents. Here, again, the inorganic constituents of the dust such as silica or iron enhance or aid the effect of the tar, whereas the carbon of soot tends to mitigate any effect of the tar in producing tumours of the lung. (5) Although some primary lung tumours in mice are simple adenomata, other tumours show typical malignancy with definite production of metastases.

Amine and Blood

IN an examination of the action of amine on the blood, F. Jung (*Naturwissenschaften*, 27, 318; 1939) has determined the solubility of the gas in water at various temperatures, in the absence of other gases. The solubility in electrolytes is less than that in water, but solutions of proteins dissolve considerably more of the gas. Fresh blood takes up 0.5-0.8

volumes of arsine at 20° in the absence of oxygen. In the presence of oxygen, arsenic, methæmoglobin, and hydrogen peroxide are formed. There is also an increase in the readily removable iron in the blood, supporting the view of Barkan (*Hoppe-Seyler's Z. physiol. Chem.*, 254, 241; 1938) that in addition to methæmoglobin another derivative of hæmoglobin ('pseudohæmoglobin') is formed in this reaction.

Relics of the Cave Hyæna of the Ice Age

In a preliminary announcement in the *Anzeiger der Akademie der Wissenschaften in Wien*, H. Zepfe describes some work he has carried out on the study of the fossil bone fragments of animals devoured by the cave hyæna of the Ice Age. In order to be able to form a satisfactory judgment of such fragments, an extensive study was made of the feeding habits of the spotted hyæna in the Vienna Zoo. The animals were fed with the bones of oxen, horses and deer. There was found to be a remarkable regularity in the manner in which each kind of bone was seized, and in the shape of the portions finally rejected. Thus, in the case of the humerus, it is the greater tuberculum that is first attacked. The head of the joint, after being isolated in this manner, is bitten off and the large marrow-filled diaphysis can then easily be opened. This is eaten up to near the distal end of the bone; the remaining fragments have a characteristic form. On the calcaneus, tooth marks are always found on the tuberosity. In the case of the pelvis, the portions round the acetabulum, with parts of the ilium and ischium, are rejected. On the basis of this information, the fossil bones discovered in the Teufelskucken at Eggenburg were studied and bones of *Tichorhinus antiquitatis* showing all stages in the hyænas' meals were found. Thus, in the case of the humeri, there was a continuous succession from those showing the initial bites on the proximal end to characteristic small fragments of the distal ends. It appears from this work that a number of remains of rhinoceros which have hitherto been regarded as the relics of palæolithic man are really relics of hyænas. It seems probable that further work on this subject will enable the presence of hyænas and other bone-eating animals to be deduced from remains of Tertiary mammals in a larger number of cases than has hitherto been possible.

Study of Xylem in Whole Plant Organs

WORKING on whole plants of *Phylloglossum Drummondii* and on flowers, seedlings and fern fronds, Miss E. M. Debenham has devised a modified technique for the microscopic examination of the xylem of whole plants or plant organs (*Ann. Bot.*, 3, New Series, No. 10, 369; April 1939). By this method, permanent preparations of whole cleared plants or organs could be obtained with the course and structure of the xylem clearly elucidated by staining. Material with abundant food storage or a deep pigmentation caused difficulty since the period of clearing exceeded a month, and then the lignin was so affected as to take the stain either feebly or not at all. Many successful results were obtained, however, and these are illustrated by photomicrographs. The method involves clearing in 70-75 per cent lactic acid at 58-60° C., bleaching in eau de Javelle at 40° C., staining the xylem with ammoniacal fuchsin, and mounting in euparal or Canada balsam.

Effect of Seed X-radiation on Cotton Leaves

B. N. Singh, R. S. Choudhri and S. L. Kapoor have recently studied the structural abnormalities in cotton leaves following exposure of the seed to X-radiation (*Ann. Bot.*, 3, New Series, No. 10, 307; April 1939). Irradiation of seeds for five minutes induced a certain amount of leaf-modification which increased with increasing exposure. The effect on soaked seeds was greater and that on germinated seeds still greater. Petioles of normal leaves are cylindrical, those from dry, irradiated seeds were thicker and those from irradiated soaked and germinated seeds were grooved. Heavy irradiation induced dorsiventrality in the petioles, of which the bundles instead of being arranged in a ring in cross-section formed a single crescent-shaped mass associated with a greater development of wood. The lamina from a dry irradiated seed showed no modifications, but those from soaked and germinated seeds were asymmetrical and variegated and showed puckering and tumour-like structures. The vascular system was markedly affected and injurious effects were more pronounced in the palisade tissue.

'Take-all' Disease of Wheat

THE fourth of a series of papers by S. D. Garrett on parasitism of the 'take-all' fungus, *Ophiobolus graminis*, has recently appeared (*Ann. App. Biol.*, 26, No. 1, 47-55, February 1939). Ascospores of this fungus are liberated into the air, but all attempts to infect wheat seedlings with such spores on natural soils have failed. Inoculation of ascospores in sterile soils, however, is invariably successful. It is considered that inhibition of infection in unsterilized soils is due to competition of other micro-organisms, rather than their antagonism, for infection can be accomplished in unsterilized sand, where nutrients for the micro-flora are practically absent and their numbers are low. The general micro-flora of most soils apparently uses all the available nutrient material, and it is only under sterile conditions that any such material is available for the ascospores of *Ophiobolus*. It seems unlikely that the ascospores of this fungus play any part in its natural distribution under field conditions.

Intracellular Bodies of Plant Viruses

CERTAIN types of intracellular inclusions have been found in the cells of many virus-infected plants. The inclusions appear to be specific to the disease rather than to the host, and they are usually considered to be aggregates of virus particles. Much recent work upon the physico-chemical nature of these particles has shown that they are proteins of high molecular weight, and their relation to inclusion bodies is discussed in a paper by F. C. Bawden and F. M. L. Sheffield (*Ann. App. Biol.*, 26, No. 1, 102-115, February 1939). Insoluble complexes which are similar to inclusion bodies have been formed when viruses are combined with protamines, histones and proteins *in vitro*. Properties of the virus are compared with those of the corresponding inclusions, and possible explanations for the formation and disappearance of the inclusions within infected plants are suggested. Some viruses produce only amorphous inclusions in their host cells, but others form crystalline and amorphous bodies.

Elastic and Viscous Properties of a Certain Kind of Rock

KUMIZI IIDA has made a thorough study of this problem, using for experimental purposes a pumice from the island of Niisima cut into cylinders about 48 cm. in height and 5 cm. in diameter (*Bull. Earthquake Res. Inst.*, Tokyo Imp. Univ., 17, Part 1, 59-78; March 1938). The work was carried out by both static and dynamic methods, and separate sets of results obtained. The relationship between the properties of the rock and its water content were especially sought. It was found that the velocities of waves propagated in the rock and also the solid viscosity coefficients diminished with increase in water content. Young's modulus and the modulus of rigidity obtained by static measurements diminished somewhat rapidly with increase in water content, whilst Young's modulus obtained dynamically increased with increase in water content, the modulus of rigidity remaining almost unchanged. These results are considered by the author to show that in sponge-like materials such as pumice, the skeleton alone reacts to torsional vibration, the included water being scarcely affected, whilst in the case of longitudinal vibration the effects of the water content are very marked. The coefficients of normal solid viscosity were found to be greater than those of tangential solid viscosity. The ratio of the viscous coefficients λ'/μ' increased with increase in water content, and λ'/μ' is greater than 0. The quantity η , determined by the above in connexion with the ratio of the

Lamé elastic constants by the relationship $\frac{\lambda'}{\mu'} = \frac{\lambda}{\mu}$, diminished with increase in water content. The simple relationships such as

$$\frac{\lambda'}{\lambda} = \frac{\mu}{\mu'}; \lambda' + \frac{2\mu}{3} = 0, \frac{Y_I}{Y_t} = \frac{2.3K}{\mu}$$

were found not to hold in the experiments. The elastic constant of the rock was found to be of the order of 10^9 c.g.s. units, and the viscosity coefficient of the order of 10^{14} poises. The values of Young's modulus, modulus of rigidity, and Poisson's ratio obtained dynamically all exceeded those obtained statically.

Water Supplies and River Pollution

THE annual report of the Water Pollution Research Board for the year ended June 30, 1938, has been issued by the Department of Scientific and Industrial Research (H.M. Stationary Office, 1s. net). It has been found that acids, bases and salts can be removed from solution in water by means of certain synthetic resins, and the process has been applied for the removal of dissolved salts in water, and for the removal of metals and of objectionable substances, such as fluorides, present in water in low concentrations. Investigations, in collaboration with the milk industry, have been carried out on the treatment and disposal of waste waters from dairies and milk products factories, which have in the past caused serious pollution of streams into which they have been discharged. It has been found that these liquids, which are difficult to treat by ordinary methods of sewage disposal, can be satisfactorily purified when passed at a controlled rate through two percolating filters in series. The investigation on the River Mersey, begun in 1933, has been completed. Its object was to determine the effect of the discharge of crude sewage into the Estuary on the amount and hardness of the estuarine deposits. This work is summarized in the present report, and it is

concluded that the crude sewage discharged into the estuary of the River Mersey has no appreciable effect on the amount and hardness of the deposits in the Estuary.

Fluorescence of Natural Silicates

A BLUE fluorescence is obtained when certain natural silicates, including some specimens of potash felspar, potash soda felspar and datolith ($\text{HCaBSi}_2\text{O}_6$), are illuminated with ultra-violet light. The spectral similarity of this fluorescence with that given by specimens of fluorite known to contain small amounts of europium has led Haberlandt and Kohler (*Naturwiss.*, 27, 275; 1939) to carry out experiments with the object of determining whether the fluorescence of the silicates is also due to europium. Synthetic silicates with the composition of the above minerals were prepared with the addition of small quantities of europium. When these were exposed to ultra-violet light the blue fluorescence was excited. The addition of 2.5×10^{-4} gm. of europium per gram of synthetic felspar was sufficient to produce a fluorescence considerably brighter than that of the mineral itself. The europium was added in the form of the trivalent oxalate, which itself gives a fluorescence spectrum consisting of sharp, narrow bands in the red. As the fluorescence spectrum of the synthetic mineral containing europium consisted of a broad band spectrum in the blue, it is considered that the trivalent europium was reduced to the divalent form during the fusion. It was found possible to give a rough estimate of the amount of europium present in a mineral by visual comparison of the brightness of the filtered fluorescence emission, and by an improved photometric method it is possible to determine traces of europium in a mineral so small as 10^{-6} gm. per gm. of substance.

Oscillation Clocks

At a meeting of the British Astronomical Association held on March 29, G. A. Tomlinson, of the National Physical Laboratory, gave an interesting lecture on the above subject. The oscillating clock, like the synchronous clock driven from the mains, depends on the fact that a small synchronous motor, driven by an oscillating current, cannot get more than 0.1 cycle out of phase without stopping. The usual frequency for oscillating clocks is 1,000 cycles upwards—about twenty times that of the mains clocks, and hence the possible lag of the motor of about 0.1 cycle is a very small amount. A short description was given of the three different oscillators in use, the tuning fork, the quartz crystal and the longitudinally vibrating metal bar. Excellent results have been attained when all possible precautions are taken, such as keeping the oscillator in a vacuum, avoiding temperature and pressure effects on the frequency, and even safeguarding against errors from secular effects. A test in Germany from three similar clocks running for more than a year showed maximum variations of only a few milliseconds per day. Similar results were obtained by tests in the National Physical Laboratory, a gain of one clock on another being about 1 minute in 2,000 years. It seems that clocks of this type may run with a precision greater than that of the earth, and indeed the Germans claim to have detected abrupt variations in the earth's rotation by means of these clocks. The possibility of thus solving the problem of lack of uniformity in the rotation of the earth must not be overlooked.

Metabolism and Salt Absorption by Plants

By Prof. D. R. Hoagland, Division of Plant Nutrition, University of California, U.S.A., and
Dr. F. C. Steward, Department of Botany, Birkbeck College, University of London

A SATISFACTORY physical theory of salt absorption by plants has been long awaited. The general reader might infer from the communication by Lundegårdh¹ that such is now available, but this conclusion should not be drawn without a full consideration of all the evidence. It is our view that Lundegårdh's explanation of the mechanism of salt absorption represents an over-simplification of a very complicated problem the ramifications of which are only just becoming evident. That this is so is shown by extensive investigations to which we shall refer.

Lundegårdh writes as though whole root systems, with their complex anatomy and inter-relations with the tissues of the shoot, could be reduced to very simple terms—anion-induced respiration and surfaces which in contact with an external solution absorb cations and exhibit potential differences. His speculative references to these ill-defined "surfaces", to bio-electric potentials the origin of which is uncertain and respiratory components (for example, anion respiration) the reality of which is still controversial, create an illusion of precision which is dispelled when the complexity of the system involved is adequately appreciated and the results of investigations made on a wide range of living cells, tissues and organs are contemplated.

Even when the problem is restricted to single cells, or groups of cells identical in their behaviour, it is difficult, if not impossible, to segregate those vital activities which are causally involved in salt absorption from concomitant metabolic processes. So apparently simple and uniform a system as that provided by thin disks cut from the interior of potato tubers—the surface cells of which constitute a very uniform tissue the behaviour of which can be accurately controlled—presents a far more intricate piece of metabolic machinery than Lundegårdh envisages¹. Without exaggeration, one may say that under the conditions conducive to salt absorption, such cells carry out all the vital functions and metabolic processes (other than photosyntheses!) of which parenchyma tissues are capable and that each and all of these thus far investigated are affected by the variables (temperature, oxygen concentration, nature and concentration of salt present, disk thickness, etc.) which determine salt absorption. Similarly an adequate description of the system concerned in salt absorption of barley roots² demanded the consideration of a wider range of variables and processes than Lundegårdh considers necessary. In green cells, whether of submerged aquatics or of the leaves of flowering plants, light is involved in salt uptake—not only because photosynthesis is the source of sugar, but also because light regulates their capacity to grow (especially for leaves of the broad-leaved angiosperms). Hence, although respiration is clearly the most outstanding vital process associated with salt uptake, it should not be considered to the exclusion of others

with which it is also linked. In potato disks aerobic respiration, protein synthesis and salt accumulation are all linked together in a manner yet to be elucidated. In barley roots aerobic respiration, organic acid metabolism and salt uptake are clearly inter-related.

Salt accumulation is pre-eminently a property of cells still able to grow, although this relation of growth and salt accumulation may be modified in the case of the root by the removal of absorbed salts to the shoot. From the evidence on disks of potato tuber, there is increasing reason to believe that protein synthesis is the essential property of growing cells which is involved, and it remains to be seen what part, if any, protein synthesis plays in the salt accumulation which may occur in roots, previously depleted of salt during subsequent brief periods of rapid absorption. Be that as it may, a single isolated monocotyledon root represents a composite system—grading from cells at the apex active in metabolism and absorption to those much less active farther back³—and the entire attached, or unattached, root system presents still further complexity.

Lundegårdh envisages a special component of respiration which is associated only with anion absorption and by which energy is made available for anion accumulation; that is, the movement of anions against activity gradients. The experiments of Hoagland and Broyer² on barley roots and of Steward⁴ and others on disks of storage tissue, have not led to a fundamental distinction between cation and anion accumulation. These distinct investigations are in agreement and indicate that aerobic metabolism is essential to the accumulation of both cations and anions and that a high temperature coefficient is characteristic of the accumulation of either type of ion.

It might appear from an earlier publication of Lundegårdh⁵ that the accumulation of cations depends indirectly on energy provided by the postulated anion respiration. However, on this basis, it would be difficult to explain the rapid accumulation of potassium from solutions of potassium bicarbonate which has been observed in the barley root experiments; since bicarbonate ions do not stimulate, they even suppress, the anion respiration of Lundegårdh.

In experiments on the effects of different salt solutions on the respiration of barley roots, the largest salt effects observed were not related specifically to anion absorption. The cation ammonium and the anion nitrate usually produced the most marked acceleration of respiration over that occurring in distilled water. These results of the barley experiments are not inconsistent with the conclusion derived from the storage tissue work that the salt effects on respiration are related to, and caused by, concomitant effects on nitrogen metabolism (protein synthesis from amino acids). Work on the

metabolism of storage tissues has shown that in its response to salts the effective ions are the cations, although their effect is modified by the anions present. The inter-relations between organic acid metabolism and salt uptake of barley roots, already referred to, are not explained by the theory of anion respiration. Further, Lundegårdh's conclusion that a "very effective aeration is a drawback for intensive anion uptake" is not supported by our experimental evidence.

It is desirable to stress the importance, in absorption experiments on roots, of the metabolic status of the roots studied and their initial salt content. In so far as comparisons may be made of the results of Hoegland and Broyer³ on young barley roots and of Lundegårdh on wheat roots of similar age, the indication is that the former material was so prepared that it had a much greater capacity for rapid salt accumulation than the latter, and thus some of the factors associated with salt absorption may have been more sharply defined. Items of technique assume considerable importance when general theories are proposed. Both in the barley root and potato disk experiments attempts were made to control the essential variables, biological and otherwise, and so to standardize the conditions and the absorbing system that clear-cut results emerged. This procedure, though laborious, is justified by results. Confidence in the principal conclusions is increased

because they have not only been repeatedly verified over a period of years but also because they apply equally to the quite diverse systems which have been investigated. The implications of this, we believe impressive evidence, have not been adequately considered by Lundegårdh. It is, therefore, legitimate to suspend judgment concerning the reality of the anion respiration coefficients—which purport to be characteristic of the anion species—until their reality is evident, not merely from the none too concordant sets of data from which this conception was originally derived, but also from investigations on other tissues by other investigators. It is our view that Lundegårdh's concept is not critically established.

Lundegårdh further cites in support of his theory certain measurements of electro-potentials which are thought to arise between the culture solution and the absorbing surface. The secure interpretation of these potentials would, however, require further understanding of the thermodynamic system involved. It has not been proved that the potentials do in fact have the origin suggested.

Modern Views on Magnetism

Conference at Strasbourg

A CONFERENCE on magnetism was held at Strasbourg during May 21-25 under the auspices of the International Institute of Intellectual Co-operation and of the Service Central de Recherche Scientifique de France. The discussions were directed by Prof. Pierre Weiss, to whom and to whose colleagues so much of the progress in the subject is due. As well as the members of the Strasbourg laboratories, there were some thirty specialists from other institutions.

The conference brought home the contrast between the positions of the theories of paramagnetic salts on one hand, and ferromagnetism and paramagnetism in metals on the other. Paramagnetism stands in rather the same relation to quantum theory as astronomy does to Newtonian mechanics, in being the field in which results in the most detailed agreement with experiment can be obtained. This happy state of affairs is due mainly to the theoretical work of Kramers and Van Vleck, and to the experimental work carried out at Strasbourg, Leyden, Madrid and elsewhere. Reports on the present state of the subject by Foex, Cabrera and by Van Vleck revealed, it is true, a number of unexplained facts, but the general atmosphere was one of agreement between theory and experiment. The same may be said of the results on magneto-optics presented by Becquerel, Bizette, Rabinovitch and Cotton, and Ollivier.

The discovery of the magnetic cooling method, discussed in a report by Simon, has given an added importance to paramagnetism of salts and suggested new problems for investigation, for

example, that of paramagnetic relaxation. A report on paramagnetic relaxation was presented by Gorter and Kronig. The question at issue is the time taken for the atomic magnets in a paramagnetic crystal to get into equilibrium when the field is switched on. For nuclear spins this time may possibly be so long as to prevent their use for reaching low temperatures. For atomic magnets, the authors quoted suggest two mechanisms by which the energy of magnetization can be dissipated. The actual magnetic interaction between the elementary magnets, small though it is, is capable of taking up some energy, and under certain conditions will absorb the energy of magnetization before this energy can be communicated to the lattice vibrations. The effect of applying a field will thus be to lower the temperature of the assembly of magnets below that of the lattice. If, however, the crystal is already in a field of more than about 2,000 gauss, this cannot happen; an elementary magnet can only come into equilibrium by giving up its energy directly to the lattice vibrations.

In metals, and especially in ferromagnetic metals, we are much further from being able to solve the equations of quantum mechanics than for paramagnetic salts. This is because we have here to do with exchange interaction between the atoms; since the electrons are continually changing places, one has to treat the whole assembly of electrons in the metal as one dynamical system, whereas a paramagnetic ion in a crystal can to a very good approximation be treated as moving in an electrostatic field. One starts from one or other of two models; the collective electron or Bloch model, in which the electrons are

treated as running through the lattice as a whole independently of each other, and the London-Heitler-Heisenberg model, in which the electrons are supposed to be bound to individual atoms and to move only by changing places. The relation between these models was discussed by Néel, Stoner, Mott and others, but remains by no means clear. It may, however, be of interest to give the description of a ferromagnetic metal or alloy which emerged from the discussions.

A metal such as nickel must be thought of as a mixture of ions in different states, $(3d)^{10}$, $(3d)^9$ and perhaps higher states of ionization. The conduction electrons move freely among the ions, and number about 0.6 to 0.7 per atom. The elementary magnets are the 'holes' or vacant places in the nearly completed shells of the ions. The holes in the ions are continually moving about from ion to ion; to this motion is ascribed the large electronic specific heats observed in iron, nickel, palladium and platinum at helium temperatures. If ions with the configurations $(3d)^9$ are present, then pairs of coupled spins with a moment of two Bohr magnetons will move through the crystal. The possible energy states for these holes, or pairs of holes, form bands with an energy spread of about 3 electron volts, as shown by experiments on soft X-rays (Farineau, Skinner). However, there may well be strong correlation forces which prevent more than one elementary magnet from ever being in one atom. If this is the case the correct model for a ferromagnetic material would seem to be of the Heisenberg type, modified to take account of the fact that the number of lattice points is greater than the number of magnets, a fact which allows the

free motion of the magnets (holes) already referred to. An interesting first step in this direction has been taken by Stoner, who has worked out the effect of introducing a Weiss intramolecular field into the collective electron treatment.

For nickel and nickel-rich alloys the total number of positive holes in the d shells is equal to the saturation moment in Bohr magnetons; the report of Néel showed very clearly that this cannot be the case for iron. Here the ions must be present in a large number of different states of ionization, and only some of them give a positive exchange integral and thus a contribution to the ferro-magnetism.

There were interesting discussions on what happens to the orbital moment in ferromagnetic materials, evidence being drawn from the gyromagnetic effect (Sucksmith, Barnett) and from the saturation moments of alloys (Forrer). From the theoretical point of view this problem remains quite obscure.

Becker, Sucksmith and Gerlach gave results bearing on the magnetization curves of ferromagnetic materials. A large number of facts seem to indicate that a small piece of material has a high coercive force. According to Becker, a magnetized material contains nuclei at which demagnetization can start, and such nuclei would not be present in a small specimen; but no explanation could be given of the nature of these nuclei.

The diamagnetism of aromatic crystals was discussed by Krishnan, in particular their magnetic anisotropy. As pointed out by F. London, the 'orbit' responsible for the diamagnetism in naphthalene, anthracene and so on must extend over the whole molecule.

Work of the Discovery Committee

Fifth Commission of the R.R.S. *Discovery II*

THE Discovery Committee's vessel R.R.S. *Discovery II*, built in 1929 for oceanographical research in the Southern Ocean, returned to London from her fifth voyage on May 9. Leaving England in October 1937, she spent the southern summer circumnavigating the antarctic continent, making observations along the northern edge of the pack-ice south of the Indian, Pacific and Atlantic Oceans, and running lines of stations across the antarctic, subantarctic and subtropical regions as she came northwards to Australia, New Zealand and the Falkland Islands for fuel.

In the subtropical and subantarctic regions a full station was worked every day: temperatures were measured and water samples taken at a series of depths between the surface and the bottom, and nets were fished to depths of at least 1,000 metres. In the antarctic zone extra nets were fished to obtain a more complete picture of the distribution of the small prawn-like krill (*Euphausia superba*) on which the whales feed, and a constant look-out was kept for whales. Near the ice-edge, and in regions where the krill are known to breed, the work was still more intensive.

A qualitative picture of the water circulation in the Southern Ocean and the distribution of factors that influence plant and animal growth had been obtained on previous voyages, and although this latest voyage extended the work whenever possible, its main object

was the collection of data for comparison with previous observations, particularly in regard to the contrast between summer and winter conditions. The circumpolar voyage was completed early in May 1938, and the remainder of the commission was devoted to the systematic survey, month by month, of a limited section of the Southern Ocean. Such repeated observations are of great assistance in the elucidation of oceanographical problems, and it is noteworthy that the International Council for the Exploration of the Sea is planning a similar though more concentrated survey of the Faroe-Shetland region.

The area chosen was the antarctic sector between the Greenwich meridian and 20° E.: this afforded a good opportunity for the examination of typical antarctic, subantarctic and subtropical conditions, and at the same time it allowed a continuous examination of the terminal region of the Weddell Sea current, a matter of great importance, since the Weddell Sea has been found to be by far the greatest centre of production of krill.

After refitting in Simonstown, the *Discovery II* steamed southwards along the Greenwich meridian as far as the ice-edge, and after a short cruise away from the ice to a point some 300 miles to the northward in 10° E., she returned northwards along 20° E. Between July 1, 1938, and March 19, 1939, this voyage, south and north, was made seven times, and

altogether within the last two and a half years the 0° line has been examined eleven times.

The preliminary examination of the repeated observations shows that there are important changes from month to month, particularly at the surface; but—and the discovery is a matter for great satisfaction—the changes in the deep water are not large enough to invalidate a qualitative picture of the water circulation drawn from observations made on only one or two occasions. It is hoped that a closer examination of the repeated observations will give reliable quantitative information, and that many problems—chiefly those connected with the speeds of the water and plankton movements—will be brought nearer solution.

The data and collections obtained, a valuable supplement to those of earlier voyages, have been brought to England, and the scientific staff are settling down to what it is hoped will be a very productive period.

The pressure of the scientific work on the fifth commission left little time for survey work, but charts have been prepared of the Balleny Islands, and of the antarctic coastline between the Greenwich meridian and 4½° E. Along this part of the coast there is a very narrow shelf, and in one place the ice-barrier was found to protrude beyond the 1,000-fathom line. One bay, however, that was entered was found to end in a low ice-shelf 10 feet high with a sounding of 60 fathoms within a distance of three cables; behind the bay snow-covered slopes rose gradually to 2,000 ft. The only exposed rock seen along the whole coastline was one snow-free boulder, and a small exposure at the foot of a shoulder.

The ship was commanded by Captain Hill, and Mr. Herdman was the senior scientific investigator on board. In addition to the Committee's own staff, Australian, New Zealand and South African scientific workers were carried for some parts of the commission.

Glass Technology at Sheffield

New Buildings

THE Department of Glass Technology in the University of Sheffield came into being as a result of a scientific advisory committee set up by the University of Sheffield in 1914. The Department was founded in June 1915 and existed by courtesy in various rooms in the University buildings. A small building to deal with experimental work was erected and occupied without any formality early in 1917, but growth and the need for returning borrowed accommodation to its rightful owners on the conclusion of the Great War compelled a move to other premises some distance from the University buildings in 1921. It was always felt that such a move could only be temporary, but not until 1935 was a suitable site found to house the Department in a worthy manner. This was acquired in 1936, the twenty-first anniversary year of the Department, and the appeal for funds called forth a most gratifying response. In addition to the subscriptions of more than £37,000 to the Glass Delegacy's fund, the Society of Glass Technology has contributed £2,600 towards the cost of the lecture theatre and adjacent rooms, and old students and staff have furnished the professor's room. The Frank Wood Library also was the subject of a special fund of some £1,150.

On Monday, June 12, the new buildings were formally opened by the Right Hon. Lord Riverdale of Sheffield, chairman of the Advisory Council for Scientific and Industrial Research, after dedication by the Right Rev. the Lord Bishop of Sheffield.

In his remarks, Lord Riverdale emphasized that one of the prime needs of the world to-day is confidence. Such confidence in the Glass Department has been felt by the industry that these new buildings are the result. What began as a local movement is now not only national but also international, for the Society of Glass Technology draws its members from all over the world and works in harmony with other similar bodies abroad.

The actual opening ceremony consisted of the drawing apart of curtains woven from glass silk

hung before the main doorway. Mr. Geoffrey Pilkington then unveiled a tablet in the porch commemorating the opening, after which a degree congregation was held in the Museum for the purpose of conferring the degree of LL.D. on Mr. S. B. Bagely, the chairman of the Glass Delegacy, and of Ph.D. on Mr. B. P. Dudding, who as president of the Society of Glass Technology that year launched the Society's Elmfield Fund. The vice-chancellor, Dr. Irvine Maason, said that the building is a monument to the good relations between the University and the glass industry. Its products would be two—new knowledge and scientifically trained men.

The president of the Society of Glass Technology, Dr. C. J. Peddle, next unveiled in the lecture theatre a tablet bearing the names of the donors to the Society's fund, and the ceremonies were pleasantly concluded by the presentation to Lord and Lady Riverdale of a glass rose bowl by Mrs. W. E. S. Turner, and a speech of thanks by Prof. Turner, to whom many tributes were paid during the day's proceedings.

Afterwards the Department was inspected by the guests. It is situated in two and three quarter acres of attractive grounds overlooking on either side small reservoirs and is about six minutes' walk from the main University buildings. The original stone-built house has been retained to form an administrative section. It contains on the ground floor an entrance hall with a pair of stained glass windows by Mr. S. M. Scott depicting glass makers at work and will house later a large tablet with illustrations of great achievements by English glass makers during three centuries and bearing the names of donors to the Glass Delegacy's Fund. In the porch is a glass-fronted niche containing a glass casket which holds historic records. Opening off the entrance hall are the conference room, the professor's room and the visitor's room. On the first floor is the Frank Wood Library, containing a stained glass window in memory of Mr. Frank Wood, a librarian's room,

records room and ladies' rest rooms, whilst the second floor contains a small classroom and various store rooms.

The new building runs on from the house to give a total frontage of 151 ft. 6 in., with a mean depth of 50 ft. It consists of Section A, separated by a second entrance hall from Section B. In addition, Section C runs off to form the limb of a letter L and contains the heavier practical equipment. Section A contains on the ground floor a central corridor opening into rooms on either side. These comprise the following: general office, refectory and kitchen, in which good use is made of glass for tiling and table tops, mechanics' shop, drawing office, and laboratories for the study of optical radiation and X-ray, mechanical and thermal properties, with a small dark room. On the same floor, Section B contains students' cloakrooms, a general physical and a high-temperature laboratory, and store rooms for apparatus and materials. On the first floor, the whole of Section A is taken up by a museum 60 ft. long and 31 ft. wide on one side, whilst the remaining space comprises a small lecture room, museum keeper's store, and a decorative processes laboratory. Outside the museum in Section B is the landing, with office, leading to the lecture theatre and preparation room. The theatre seats approximately one hundred and has a projection gallery, dimming device, and the usual services. On the second floor are the two laboratories, students and research, for work of a chemical nature, and two smaller rooms which are

equipped for special branches of research. There are also an office and store rooms and the projection room on this floor. A lift connects all floors with the basement, where the following are located: meter room and pipe duct, boiler room, battery room, dynamo room, and various store rooms.

Section C, only half of which is at present erected, is to have a length of 75 ft. It now consists of three rooms, one of which is built over an archway and is devoted to raw materials and mixing, whilst of the other two, 50 ft. by 36 ft., that on the ground floor is used for the storage, preparation and testing of refractories, two small laboratories being partitioned off for the latter purpose. The remaining room on the first floor is given over to glass melting and is equipped with a variety of furnaces, gas and electrically heated. Provision has been made for the building of large furnaces, and an adjustable stage has been built below an opening in the floor to accommodate regenerator or recuperator structures without taking up too much of the space in the refractories section below.

Throughout the building glass has been used as much as possible and Vitrolite, glass bricks, Thermolux and armour-plate glass, together with glass silk insulation have been effectively employed. Special mention may be made of the large glass dome over the stairway, the glass panels in the latter, the various stained glass windows, and the window to be erected in the museum depicting "Glassmaking through the Centuries".

The Royal Society and the Kaiser Wilhelm Gesellschaft Exchange of Visits

IN the autumn of 1938, following a suggestion of the president of the Kaiser Wilhelm Gesellschaft, arrangements were made by the president of the Royal Society of London, Sir William Bragg, and representatives of the Kaiser Wilhelm Gesellschaft, for an exchange of visits between these two bodies. The Kaiser Wilhelm Gesellschaft, founded in 1911 at the suggestion of the Kaiser Wilhelm II, has as its aim the encouragement of the natural and human sciences, primarily by establishing and maintaining research institutes for natural science in Germany.

This exchange of visits was welcomed by the Royal Society, which, since its foundation in 1662, has always sought to maintain, irrespective of race or politics, the liveliest interest in the work of men of science throughout the world. Consequently, arrangements were made for two fellows of the Society, Prof. F. G. Donnan, emeritus professor of chemistry in the University of London, and Prof. A. J. Clark, professor of materia medica in the University of Edinburgh, to visit Germany in March; at the express wish of the Kaiser Wilhelm Gesellschaft for a lecture on a non-scientific subject, Prof. Dover Wilson, the eminent Shakespearean scholar, was invited by the Royal Society to visit Berlin to lecture. The visits, which took place in March and April, were highly successful. The visitors were most hospitably entertained by their German colleagues and were afforded facilities for visiting laboratories and research institutes.

The Royal Society is entertaining during this month four German men of science. They are Freiherr von Verschuier, of the University of Frankfurt-on-Main, Prof. R. Kuhn, of the Kaiser Wilhelm Institut für Medizinische Forschung, Heidelberg, Prof. F. Wever, of the Kaiser Wilhelm Institut für Eisenforschung Forschung, Düsseldorf, and Prof. Otto Hahn, of the Kaiser Wilhelm Institut für Chemie, Berlin-Dahlem. Freiherr von Verschuier and Prof. Kuhn delivered lectures before the Royal Society on June 8 and 9 respectively; Prof. Wever will speak at the Royal Society on June 22 at 4.30 on metallurgical research, and Prof. Hahn at the Royal Institution on June 23 at 2.30 on the fission of uranium nuclei by neutrons.

RESEARCH IN TWINS

The first exchange lecture between the Kaiser Wilhelm Gesellschaft and the Royal Society was given on June 8 by Freiherr von Verschuier, professor of human genetics and eugenics at the University of Frankfurt-on-Main. This institution has devoted itself especially to the study of twins and the subject of the lecture was twin research.

Prof. Verschuier pointed out that Galton in 1875 was the first to recognize the importance of the study of inheritance in twins, distinguishing between monozygotic or identical, and dizygotic or fraternal, twins. The twin method dissociates the parts played

by heredity and environment in the development of the individual. A resemblance diagnosis has been established for determining the identity of similar sexed twins, and every case of identical twins is confirmed by identity of the blood groups. Examination of the after-birth of many twin births shows that identical pairs may have one chorion or two. Hair colour and eye colour are useful characters in diagnosing twins among Europeans, but not among Mongolian or African peoples, where these features do not vary appreciably. Identical twins are genetically identical persons, so that even skin transplantation can take place between them. All differences between such twins are therefore non-hereditary.

In a considerable study of tuberculous twins, extending over ten years, striking evidence has been obtained of the existence of an inherited disposition to tuberculosis. In several cases identical twins living for many years under very different conditions nevertheless sickened and died of the same form of the disease at almost the same time. In identical twins the number of concordant reactions to tuberculosis is very high compared with that of ordinary twins.

Inheritance in relation to numerous other diseases is being studied by recording all the twins in a given district and period, or by examining the twins among all the patients at certain clinics who are suffering from a particular disease.

CHEMICAL BASES OF THE BIOLOGICAL ACTIONS OF LIGHT

The second exchange lecture was delivered on June 9 by Prof. R. Kuhn, of the Kaiser Wilhelm Institut für Medizinische Forschung, Heidelberg, and president of the German Chemical Society. Prof. Kuhn said that the elucidation of the mechanism of the many living processes in which light is concerned involves the application of well-established photochemical principles and experimental technique. As only light which is absorbed can cause a photochemical change (Grotthuss-Draper law) one first looks for a photosensitive substance which absorbs light of the active wave-length. The correlation can often be confirmed by comparing quantitatively the 'action' (photosensitivity) curve with the extinction coefficient curve of the absorbing substance. In many cases the photosensitive substance is present in such minute amounts that careful extraction in the dark from a very large bulk of material is necessary in order to find it.

It is possible to make generalizations as to the types of organic structure which will lead to absorption in a certain part of the spectrum such as the

visible. There are, of course, many examples of these types found in plants and animals. Furthermore, associated with these organic structures, there are certain types of photochemical change, such as *cis-trans* transformations, shifts of the double-bond position, ring breaking, and production of free radicals.

It is a familiar fact that the higher green plants grow towards the light. The 'action' curve has recently been found to correspond to the absorption curve of carotene. The latter apparently photosensitizes the conversion of auxine-a, a growth-promoting substance, into an inactive lactone compound. On the sunny side of a plant the cell growth is therefore inhibited, while on the shady side it is not, hence the turning towards the light.

Gametes of *Chlamydomonas eugametos* in the light liberate a substance which sensitizes their copulation. This substance is found in high concentration in the stigma of *Orococcus sativus* and is called crocin. The gametes are extremely sensitive to this substance, 0.4 mgm. in 10¹¹ cm.² being sufficient to activate them when their concentration is 2 × 10⁶ per cm.². As the molecular weight of crocin is 978, this corresponds to one molecule per gamete. A concentration a hundred times stronger is necessary before fusion between males and females takes place, but such a concentration is still far below the limits of detecting this highly absorbing substance by means of the eye. The specificity for the male and female species has been correlated with the *cis* and *trans* forms.

In fishes, the liberation in the dark of a light-sensitive substance, 1,2,3,4,5,6,8 heptahydroxy, 7-ethyl-naphthalene, by the ripe eggs chemotactically attracts the spermatozoa.

The photo-activity of human skin was studied by projecting the spectrum of a carbon arc on a test area for four minutes. The usual erythema maximum at 300 mμ was found to develop after four hours, but a marked browning with maxima at 360, 380 and 408 mμ developed in a much shorter time. The erythema at 300 mμ disappeared in a few weeks, while that at longer wave-lengths persisted for some months. In a similar manner the 'action' curve of the ripening of a green banana skin was studied, and it was found to follow closely the absorption spectrum of chlorophyll.

Photosensitive substances, particularly visual purple, play a fundamental part in vision. The 'action' curve, that is, the luminosity curve, of scotopic vision follows closely the absorption spectrum of visual purple. A new colouring substance, astaxanthin, coupled to a protein, has been isolated from hana' eyes, and certain coincidences between its behaviour and phenomena occurring with colour vision may mean that it is associated with this visual process.

The S.S. *British Queen*

A CENTURY ago, no journal displayed more interest in the progress of trans-Atlantic steam navigation than the *Athenaeum*; and in its issue of June 22, 1839, it referred at length to the *British Queen*, which was built at the same time as the *Great Western*, but the completion of which had been seriously delayed. In June 1839, the *British Queen* was still in the Clyde, having her machinery

fitted by Robert Napier, and the *Athenaeum* said: "The completion of this vessel is looked forward to with much anxiety by all who take an interest in the improvement and extension of steam navigation and all who desire the peaceful and reciprocally beneficial intercourse of civilised nations. She will be most certainly a great experiment, in the theory of steam navigation, on many interesting points."

The journal promised to give an account of the voyage of the ship from the Clyde to the Thames, and added to its article some notes from a "Scientific Correspondent" who had visited the ship. "Every-one admits," he wrote, "that she is a very handsome vessel; and perhaps the greatest proof of her symmetry is that as she reposes her leviathan bulk on the level shore, she does not appear so enormous as she really is. . . . It was only when I gained the deck of the *British Queen* that I became thoroughly impressed with the truth of her enormous size. The deck is a long promenade, and the distance from stern to stem is a good rifle shot; her breadth on deck being some sixty feet. Descending to the engine room . . . looking up you perceive the men who guide the whole machinery and regulate and direct the combined strength and simultaneous energy of 500 horses, with greater success than the tyrant Philopater and his galley of 3,000 slave power, and feel that you are in the presence of one of the noblest of human creations. . . ."

The *British Queen* was built on the Thames at Limehouse by Curling and Young for the British and American Steam Navigation Company. This company had been founded through the efforts of the American lawyer and business man Junius Smith (1780-1853), who had been greatly assisted by Macgregor Laird (1808-61), the African explorer. She was 275 ft. long from figure-head to taffrail, 40 ft. 6 in. wide between the paddle boxes, and of 1,863 tons, being the largest steamship afloat. She had a two-cylinder side-lever engine, with cylinders 77½ in. in diameter and 7 ft. stroke, driving paddle wheels 31 ft. in diameter.

tenable at St. Mary's Hospital Medical School. Since 1930 he has worked at University College Hospital, being appointed as assistant in the Department of Clinical Research and, in 1936, as lecturer in cardiovascular pathology. In 1931 he was appointed a member of the permanent scientific staff of the Medical Research Council.

OXFORD.—The appointment of the first twelve fellows of Nuffield College, following on the appointment last year of its warden, Dr. H. B. Butler, marks the beginning of its corporate existence. The six faculty fellows, all of whom are fellows of existing Oxford colleges, are Mr. R. C. K. Ensor, Mr. J. Fulton and Miss Margery Perham, representing the political side, and Mr. G. D. H. Cole, Mr. R. L. Hall and Mr. R. F. Harrod, representing the economic. The six visiting fellows, whose task is "to assist those engaged in the University in research by giving them the fruits of their experience in practical affairs", are Lord Hailey, Lord Cadman, Sir Walter Citrine, Sir George Etherton, Mr. Claude Vickers and Mr. A. P. Young. In two years' time it is hoped that the buildings will be up and its gates open to the kind of persons for whom the College was intended. Apart from the fellows and the distinguished visitors for whom accommodation in the College will be provided, there will be forty students, all of whom will be reading for the degrees of D.Phil., B.Litt., or B.Sc., or engaged in some approved piece of research. These, if men, will be accommodated also in the College. It is expected that after 1941, Nuffield College will become the centre in Oxford for all those who are concerned with the practical or theoretical treatment of social, economic and political problems.

University Events

BELFAST.—The Senate of Queen's University has decided to confer the following honorary degrees, among others: D.Sc. on Dr. J. H. Smith, until recently head of the Department of Engineering in the Belfast College of Technology; Doctor of Laws on Prof. F. H. Hummel, until recently professor of Civil Engineering in the University; F. W. Ogilvie, formerly vice-chancellor of the University and now director general of the British Broadcasting Corporation.

CAMBRIDGE.—W. Campbell Smith, keeper of minerals in the British Museum (Natural History), has been approved for the degree of Sc.D.

GLASGOW.—The King has been pleased, on the recommendation of the Secretary of State for Scotland, to approve the appointment of Prof. J. W. Cook, professor of chemistry in the University of London (Royal Cancer Hospital), to be regius professor of chemistry in succession to the late Prof. George Barger.

HULL.—The following appointments and promotions, to date from October 1, have recently been made: P. G. Espinasse, to be lecturer (grade A) in the Department of Zoology; Dr. W. B. Orr, to be lecturer (grade A) in the Department of Chemistry; Dr. J. Bronowski, to be lecturer (grade B) in the Department of Mathematics; Dr. G. Tatham, to be lecturer (grade B) in the Department of Geography.

LONDON.—G. W. Pickering has been appointed, as from October 1, to the University chair of medicine

Societies and Academies

London

Royal Society (*Proc.*, A, 171, No. 945, 137-280, May 19, 1939).

SIR C. V. RAMAN and K. S. VENKATA RAMAN: Determination of the adiabatic piezo-optic coefficient of liquids.

R. G. W. NORRISH and E. F. BROOKMAN: The mechanism of polymerization reactions. (1) The polymerization of styrene and methyl methacrylate.

E. V. APPLETON and K. WEEKES: On lunar tides in the upper atmosphere.

K. G. BUDDEN, J. A. RATOLIFF and M. V. WILKES: Further investigations of very long waves reflected from the ionosphere.

P. S. H. HENRY: Diffusion in absorbing media.

J. F. ALLEN and E. GANZ: Influence of pressure on the thermal conductivity of liquid He II.

G. P. KANE: Influence of nitrogen peroxide on the two-stage ignition of hydrocarbons.

H. FRÖHLICH, W. HEITLER and B. KAHN: Deviation from the Coulomb law for the proton.

Edinburgh

Royal Society of Edinburgh, May 1.

P. M. S. BLACKETT (Bruce-Preller address): The mesotron: the new unstable cosmic ray particle. Recent work both theoretical and experimental has

shown that the penetrating cosmic rays consist of a new type of particle with a mass of about 160 times that of an electron. It has further been shown that this new particle (mesotron) is unstable and decays when at rest with a mean life of about 2×10^{-14} sec. This instability of the mesotron provides an explanation of many hitherto unexplained facts, such as the failure of the mass absorption law, and the temperature effect of cosmic rays. The mesotron must be produced in the atmosphere by some incident stable particles, but the mechanism of this is still uncertain.

I. M. H. ETHERINGTON: Non-associative combinations. This paper envisages an extension of the elementary theory of permutations and combinations by taking account of the way in which the elements of a combination are associated together.

T. M. MACROBERT: Expressions for generalized hypergeometric functions in multiple series. Various known formulae for the ordinary hypergeometric function are extended to generalized hypergeometric functions. This is made possible by the use of multiple series. Among the formulae discussed are the alternative forms of the hypergeometric function, Saalschütz's theorem, and Gauss's formula for well-poised series.

IAN SANDEMAN: The molecular spectra of the hydrogen isotopes (2). The assumption of a common potential function for the isotopic states. An analysis of one of the states of the isotopic molecules, hydrogen, deuterium hydride, and deuterium (the last two from the measurements of Dieke and Blue), has been carried out by the method of Dunham in order to test whether it is possible to represent the spectroscopic data for the three isotopes by an application of the ordinary mass-effect theory for molecular isotopes. The conclusions are (1) that the internuclear distance in the three isotopic molecules cannot differ very much and (2) that the potential functions of the three isotopes are different. The second implies that the electric field of the deuteron differs appreciably from that of the proton.

N. W. RADFORTH: Further contributions to our knowledge of the fossil Schizaeaceae (*Senftenbergia*). Using the transfer and oxidation methods in an analysis of the fructifications in two Carboniferous fern-like compressions of the plants *Senftenbergia pennsylvanica*, and *Dactylothea Sturi*, the dehiscence mechanism is revealed in detail, and the spores, preserved in different developmental stages are extracted. *Dactylothea Sturi*, having annulate sporangia, becomes a member of *Senftenbergia* although remaining specifically distinct. The comparison of the sporangia of both plants with those of *Senftenbergia plumosa*, and of the living Schizaeaceous type *Aneimia*, indicates a series in which progressive structural changes have occurred in connexion with the annulus, and in which spore output has diminished.

F. YATES: Tests for significance in the difference between regression coefficients derived from two sets of correlated variates. The test of significance for the difference between regression coefficients calculated from a sample involving one set of variates is known. The author considers the more general case, which also occurs in practice, of two sets of variates, and derives the appropriate testing formulae. The necessary computations are reduced to a systematic and easily calculable shape, which is illustrated by a worked example.

Paris

Academy of Sciences (C.R., 208, 1369-1444, May 1, 1939).

E. BOREL: An interpretation of virtual probabilities.

J. DRACH: Application of the method of Darboux to the equations $s = f(x, y, z, p, q)$: rational invariants.

J. CHAZY: Action of a circular ring on the perihelion and the node of a planet.

G. HEILBRONN: Construction of equations $s + f(x, y, z, p, q, r) = 0$ which have an invariant of the second order.

M. EGME: A characteristic property of some harmonic and biharmonic functions.

S. WACHS: Pseudo-conformal transformations admitting an invariant boundary point.

B. KWAL: Equations independent of the theory of the photon.

R. RUELLOS: The linear equation of the second order and the differential systems.

L. HERMAN and Mme. R. HERMAN: Existence of oxygen phosphorescence in the spectrum of the night sky.

F. PERRIN: Calculation relative to the eventual conditions of chain transformation of uranium.

H. VON HALBAN, JUN., L. KOWARSKI and P. SAVITCH: Simple capture of thermal neutrons and of resonance neutrons by uranium.

L. GIRAUT-ERLME: Theory of differential potentiometric titration (weak acids and bases).

J. LECOMTE and R. FREYMANN: Study of the infra-red absorption spectra by the powder method (acetates, formates, oxalates, acetylacetonates, sulphates).

H. JOLIVET and A. PORTVIN: Formation of granular structures in the upper transformation domain of steels.

R. VIELLEFOSSÉ: Partial hydrolysis of sulphoacetic dichloride.

R. CORNUBERT and G. MORILLON: Probable existence of three α - α' -dibenzoylcyclohexanones.

M. MOUSSEBON, R. GRANGER and M. RONAYROUX: Constitution of the essential and other oils of *Juniperus oxycedrus* L.

R. CALAS: A new example of passage of the C_2 cycle to the C_3 by pinacolic dehydration.

F. PRANTL: Silurian Bryozoans of the Black Mountains.

S. MAZLOUM: Propagation of some hydrometric components in the basin of the Orontes.

R. BURBAU, M. DOUGUET and Ph. WHEELÉ: Radio soundings in Australian seas. Data were obtained in February and March (Australian summer season) on the altitude and temperature of the stratosphere.

G. DUBOIS and Mme. C. DUBOIS: Micropalaeobotanical characteristics of a peat in Togoland.

M. CHADEFAUD: Active and inactive mitochondrial elements in diatoms of the genus *Fragilaria*.

J. and Mme. FELDLMANN: Alternation of generations in the Bonnemaisoniaceae (Algae).

M. SIMONET and M. GUINCHERT: Production by α -monochloronaphthalene and α -monobromonaphthalene of effects produced by colchicine on plant mitoses [namely, polyploidy].

H. PRAT: Study of the possibilities of submarine respiration.

A. POLACK: Interpretation of the Le Grand-Geblewicz phenomenon. A large brilliant flickering source of light, coloured or monochromatic, observed by indirect vision, appears continuous and colourless when

the flicker frequency is 40-50 a second. This can be explained on the basis of consecutive images.

MLLE. G. COUSIN: A graphical method for the analysis of hybridization applied to researches on different species of crickets.

MLLE. P. BERTHIER: Variation of the coefficient of specific magnetization of oxyhaemoglobin in the presence of soda and of hydrochloric acid.

P. MEYER: Relation between the concentration and colloid-osmotic pressure of blood serum.

M. DOLADILHA: Contribution to the problem of the extraction of haemolysin.

M. PIÉRY, J. ENSELME, C. PESCHIERA and P. DONJON: Experimental study of the biological influence of a prolonged stay at a great altitude [Jungfrauoch]: hepatic and muscular modifications. In geese, after six months exposure, there is a distinct lowering of muscle iron and slight lowering of hepatic iron. In rabbits, muscular iron is unaffected and hepatic iron increased.

Cape Town

Royal Society of South Africa, March 15.

J. L. B. SMITH: A surviving fish of the order Actinistia. The sub-class of fishes Crossopterygii is generally sub-divided into three orders, of which two, the Rhipidistia and the Actinistia, are generally stated to have no surviving members. Of the order Actinistia, fishes of the family Coelacanthidae originated in the mid-Palaeozoic and became very abundant over a wide range, but all were supposed to have become extinct by the close of the Mesozoic, some 50 million years ago. At East London there has recently been discovered a large living Coelacanthid fish, which is closely related to some of the Mesozoic forms. A general account, in not too great detail, of the specimen, and a figure, are given (see also NATURE of May 6, p. 748).

J. L. B. SMITH: Marine fishes of two families and two genera new to South Africa.

D. D. NIDDER: A hitherto undescribed industry from Mfongosi, Zululand.

F. G. CRAWFORD: (1) Some observations on the alleged succession of teeth in snakes. (2) Some observations on the arrangement of teeth in fishes.

R. GUHLKE: A method of correcting an objective noise meter for use on composite tones.

H. B. S. COOKE and J. DESMOND CLARK: New fossil elephant remains from the Victoria Falls, Northern Rhodesia, and a preliminary note on the geology and archaeology of the deposit.

Dublin

Royal Irish Academy, May 22, 1939.

T. THOMSON FLYNN: The egg of the rare marsupial *Sarcophilus*. *Sarcophilus*, the "Tasmanian devil", a polyprotodont marsupial, now exceedingly rare, agrees with *Dasyurus vicerrinus*, *Didelphys* and some other marsupials in producing more embryos than can be accommodated in the pouch. Twenty-two ova were found in the uteri, whereas the pouch has accommodation only for four. The egg is very similar in its structure, particularly in the distribution of deutoplasm, to that of *Phascogaster*, and in this way helps to confirm Caldwell's description of the egg of the latter marsupial, a description which has been the subject of criticism.

Vienna

Academy of Sciences, February 23

L. SCHMID and R. LANG: Colouring matter in the yellow spots on diseased potato tubers. The constituents are identified by their chemical properties and absorption spectra.

L. SCHMID and ANNEMARIE POLACZEK-WITTEK: Diffusion of glycogen in liquid ammonia. Glycogen dissolved in liquid ammonia does not pass through a cellulose membrane, and must therefore exist as a colloidal polysaccharide in this medium.

K. GRATZ: Grey cloud in the region β , α , 103 Tauri. Visual observation of this region reveals a grey cloud, while on photographic plates the same cloud appears black. This is probably due to the photographic technique commonly employed: the usual hard gradation photographs of the Milky Way certainly do not reveal all the objects present.

L. LÄMMERMAYER: Studies of underwood.

H. ZAPPE: Fossil relics of bone-eating animals, particularly the hyena.

G. GÖTZINGER: Drumlins in the Traun glacier region.

Moscow

Academy of Sciences (C.R., 21, No. 7; 1938).

P. A. CHERENKOV: Spatial distribution of visible radiation produced by fast electrons.

I. A. KHVOSTIKOV: Polarization of the green line of the luminescence of night sky.

J. LARIONOV, O. V. NOVIKOVA-MINASH and A. SEIDEL: Fluorescence and absorption of praseodymium salt solutions.

T. BOBOVICK-ROMANOVA: Effect of sodium, potassium and lithium salts introduced into the flame upon the intensity of the rubidium line.

A. IMSHENETSKY: Sugar fermentation of cellulose by thermophilic bacteria.

V. N. NIKITIN: Lower limit of the bottom fauna and its distribution in the Black Sea.

M. L. KARP: Influence of intrachromosomal and interchromosomal relations upon results of inbreeding and crossing.

E. N. MAKUSHINA: A new species of wheat, *Triticum armeniacum* (Jacq.) sp.n.

K. V. and L. V. ARNOLDI: Some relict elements and the coleopteran fauna of the Middle Donetz region.

A. A. WOIWKIEWITSCH: The question whether or not the structure and form variation of plumage following thyroidectomy may be regarded an index to masculinization.

L. W. POLEZAJEW: (1) Explantation experiments of extremity rudiments. (2) Induction factors of the early stages of extremity formation in Amphibia.

Tokyo

Imperial Academy (Proc., 15, No. 4, 101-109, April 1939).

MATSUBURO FUJIWARA: A problem of diophantine approximations in the old Japanese mathematics.

JURO HORIUTI and TAKAO KWAN: Mechanism of the contact hydrogenation of carbonyl groups in the presence of metallic catalysts.

Appointments Vacant

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

HEAD OF THE DEPARTMENT OF ENGINEERING AND BUILDING in the County Technical College, Guildford—The Principal (June 17).

LECTURER IN MATHEMATICS in the County Mining and Technical School, Nuneaton—The Principal (June 17).

LECTURER IN MECHANICAL ENGINEERING in the Swindon Technical College—The Director of Education, Civic Offices, Swindon (June 21).

LECTURER IN MATHEMATICS in the University of Durham (Durham Division)—The Secretary, Durham Colleges' Office, 38 North Bailey, Durham (June 23).

HEAD OF THE DEPARTMENT OF PHARMACY AND BIOLOGY in the Central Technical College, Birmingham—The Principal (June 24).

LECTURER IN MECHANICAL ENGINEERING in the Cape Technical College, Capetown—Messrs. J. A. Swing and Co., Ltd., Oldwell Street, London, E.C.1 (June 24).

LECTURER IN METALLURGY AND CHEMISTRY and **LECTURER IN MECHANICAL AND STRUCTURAL ENGINEERING** in the Constanine Technical College—The Director of Education, Education Offices, Middlesbrough (June 25).

LECTURER IN MECHANICAL ENGINEERING in the Borough Polytechnic, Borough Road, London, S.E.1—The Principal (June 26).

LECTURER IN PRODUCTION ENGINEERING in the County Technical College, Wednesbury—The Director of Education, County Education Office, Stafford (June 26).

LECTURER IN PHYSICS in the Derby Technical College—The Clerk to the Governors (June 28).

TEACHER OF ENGINEERING SUBJECTS in the Doncaster Technical College—The Secretary, Education Offices, Doncaster (June 28).

LECTURER IN CHARGE OF THE DEPARTMENT OF GEOGRAPHY in the University of Durham (Durham Division)—The Secretary, Durham Colleges' Office, 38 North Bailey, Durham (June 29).

HEAD OF THE ENGINEERING PRODUCTION DEPARTMENT of the Northampton Polytechnic, St. John Street, London, E.C.1—The Principal (June 30).

ORGANISING TUTOR IN THE SOCIAL SCIENCES in University College, Hull—The Registrar (June 30).

RESEARCH ASSISTANT IN ANIMAL NUTRITION (grade III) in the Hannah Dairy Research Institute, Kirkcubbin, Ayr—The Director (July 1).

DEMONSTRATOR IN CHEMISTRY in Guy's Hospital Medical School, London, S.E.1—Prof. C. S. Gibson (July 8).

PROFESSOR OF VETERINARY PATHOLOGY AND DIRECTOR OF THE RESEARCH INSTITUTE IN ANIMAL PATHOLOGY in the Royal Veterinary College, Great College Street, London, N.W.1—The Bursar (July 10).

PROFESSOR OF METALLURGY in the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, W.C.1 (January 31).

PROFESSOR OF FORESTRY in the University of Oxford—The Registrar, University Registry, Oxford.

ASSISTANT IN GEOLOGY in the University of Aberdeen—The Secretary.

A MICROSCOPIST, A PHOTOGRAPHER AND AN ASSISTANT TO DIRECTOR OF RESEARCH to the Printing and Allied Trades Research Association—The Director of Research, 10 Robin Hood Court, London, E.C.4.

Population Problems in Relation to Refugees

WHETHER as indicated by the support accorded to the work of the Society for the Protection of Science and Learning, or by the care taken of individual refugees in particular universities, and the efforts made to find opportunities for men of learning to continue their teaching and investigations, the universities of Great Britain have nobly accepted their responsibilities and shouldered burdens which have often involved individuals in real sacrifice. By the universities at least this practical task of caring for refugee men of science and learning has been recognized as an inseparable part of the task of preserving for mankind its full privileges of freedom of thought and investigation. Nevertheless, Sir John Hope Simpson can conclude in his study of the refugee problem* that Great Britain's record in the admission of refugees is not distinguished when compared with that of France, Czechoslovakia or the United States of America.

Even in academic circles, however, the problem has rarely been considered on wider grounds than those of humanitarianism and the defence of freedom of thought and learning. For this reason alone the admirable dispassionate survey of the refugee problem as a whole which has been conducted under the auspices of the Royal Institute of International Affairs is welcome. This carefully prepared and lengthy report gives an exhaustive study of the origins and course of refugee movements as well as a record of the methods adopted internationally, and by individual Governments, and of the immense efforts made by the great philanthropic organizations.

The scope of the survey is restricted to post-War movements which originated in European countries; in the Ottoman Empire and in the Russian Empire; and refugee movements arising from natural causes such as earthquake or flood are also excluded. For all these limitations, the survey gives us the essential background for assessing the significance of the refugee problem and the many factors which are involved in it, as well as the various solutions proposed and the obstacles to such solutions and to the movement or absorption of refugees.

One of the great merits of this survey is the way in which the problem is presented in its true perspective. Indeed it might be true to say that the absence of a sense of perspective has been one of the main factors in creating the refugee problem. The American quota system, the British immigration laws and the virtual closing to immigration of the British Dominions have been the chief factors which issued in the refugee problem. Sir John Simpson makes it abundantly plain how the stopping of these safety valves has led to population pressures which have profoundly influenced the course of post-War history. Markets have ceased to expand; and labour in the more privileged countries is anxious to defend its standards of living against cheap immigrant competition. The spread of State control over every aspect of life in itself tends to render nationalism more readily inflamed.

The refugee problem accordingly cannot be detached from population and migration questions generally. However strongly we may reprobate the immediate political causes of a particular refugee movement, or however justly the conduct or policy of a particular ruler or nation is to be

* The Refugee Problem: Report of a Survey. By Sir John Hope Simpson. (Issued under the auspices of the Royal Institute of International Affairs.) Pp. xv+687. (London, New York and Toronto: Oxford University Press, 1939.) 25s. net.

condemned, such causes rarely stand entirely alone. The disappearance of the right of asylum and of *laissez faire* liberalism from the policy of Great Britain even ten years before the Great War are contributory factors which should make us defer hasty judgment.

There are, moreover, various points upon which further *ad hoc* scientific inquiry is desirable. Information as to the economic effect of refugee immigration is not entirely adequate. Inquiries in Holland and Belgium suggest that in these countries the advent of refugees has resulted in the employment of nationals in numbers greater than the refugee influx. In Great Britain the fur trade appears to have gained by the transfer of Jewish business from Leipzig to London, and it has been stated by the Home Secretary in the House of Commons that as a result of the settlement of eleven thousand refugees in Great Britain, employment has been given to about fifteen thousand British workers who would not otherwise have been employed. Sir John Hope Simpson says that the number of British workers employed as a result of German immigration is at least twice the number of refugees themselves.

Numerous cases are known in which new manufacturing businesses have been initiated by immigrants, but there are many other influences at work and the contributions made by refugee scholars and men of science are difficult to assess. The question would justify a full investigation. Already there is evidence to show that the presumption that the admission of immigrants is likely as a rule to increase unemployment is by no means so well-founded as may at first sight appear. The element of consumption has to be taken into account. It is indeed impossible to determine whether the admission of immigrants is more likely in general to increase or to diminish unemployment. The answer depends partly upon the particular industrial aptitude of the immigrants and partly on the economic circumstances prevailing at the time in the country they enter.

The question has accordingly to be considered, not on hard and fast rules, but in relation to the general employment and population trends in the country admitting the refugees. When reasonably active conditions of trade prevail, unemployment may be reduced by a freer admission of immigrants if these are likely to be suitable for the occupations where the supply of labour is relatively scarce. Such a principle must, however, be applied in a generous and not in a narrow-minded spirit.

Fairly considerable unemployment figures in a particular occupation can easily co-exist with a genuine shortage of labour, partly because of the small margin of workers of low industrial aptitude always to be found, partly because distinct types of work are often included under the same occupational designation, partly because of regional differences or seasonal and other temporary fluctuations. In many countries, even during the recent recession of trade, shortage of labour in certain industries connected with the production of armaments has persisted. A readier admission of immigrants who would have met the needs of these industries even during this period might have been economically advantageous, apart from its beneficial effect on defence preparations.

From this point of view, decisions taken under the influence of an unsatisfactory state of trade may accordingly prove premature and unwise, apart from all humanitarian considerations. Population questions generally, however, make long-range views and policies even more important. The admission of refugees to Great Britain or any other country cannot be wisely considered without regard to the imminence of declining population and its economic results, the consequences of which would appear to be almost completely ignored by the public and the Government alike. The problems of a declining population, with the consequent difficulties of economic adjustment, are in urgent need of scientific investigation and treatment. Industry, for example, has largely ignored the warnings about the effect of a lower birth-rate on the number of those leaving school and on industrial recruitment, and has scarcely begun to formulate plans to meet a shortage of juvenile labour which has been foretold for more than a decade. A scientific investigation of such problems and of the contribution which immigration policy might offer in minimizing some of the difficulties might well lead to a policy towards the admission of refugees both more generous and humane and more economic and scientific.

Sir John Simpson's report leaves no room for doubt as to the need for further impartial investigation of the questions which are linked up with the refugee problem. It may well make some professional associations uncomfortably aware of their own neglect or selfishness, or both. There is no single or simple solution save that of time, and the report should prevent premature or unsound conclusions being drawn from the solution of the problem of the Greek and Bulgarian refugees, for

example. Colonization on a large scale appears to be impracticable, but the problem would be reduced if more active steps were taken to train refugees in countries of temporary refuge, instead of maintaining them in idleness, and to pass them on to countries of permanent settlement as opportunity arises.

If, however, there are directions in which further investigation might yield invaluable results, the immediate problem, Sir John Simpeon insists, is action. The machinery for Government action was created at Evian in July 1938, and the steps that are most urgently required are no longer those which can be taken by private organizations. The purposeful training of intending immigrants under good conditions which maintain their health and morale; the provision of capital for opening up areas not yet developed and for the necessary institutions of civilization are steps which can only be taken by Governments. Sir John believes that if Great Britain and France and some other European countries such as Norway, Sweden, Denmark, Belgium, Holland and Finland, were to agree to take a quarter of the potential refugees from Germany at once, and accommodate them if necessary in camps until they could be dispersed to countries of ultimate settlement, a substantial step would have been taken towards solution of the problem.

This considered judgment of the report that much more than private charity is essential does not, of course, imply that there are no longer directions in which such assistance should not continue to be given. Apart from their share in the work of the universities in the relief of refugee scholars, scientific workers have particular responsibilities in some of the fields of inquiry indicated above. They must be responsible for the conduct of some of the investigations, and pressure from them might well assist to stimulate the initiation of such investigations. Moreover, the report itself might well stir them to re-examine the narrow view of the problem which has characterized some of their professional associations.

Beyond this, scientific workers have the common interest of all citizens in the policy of their Government in this matter. The post-War immigration policy of Great Britain has been exceedingly cautious. It is at least open to argument that a more generous policy might prove in the long run to be wise and sound from the economic point of view, in that it might offer a contribution to the solution of the very serious problems with which we are confronted in the immediate future through our declining population; while there can be no question that the calls of humanity require us to do all within our power to alleviate the distress inevitably associated with the refugee problem.

Haldane as Strategist, Educationist and Philosopher

Haldane, 1915-1938

The Life of Viscount Haldane of Cloan, K.T., O.M. By Major-General Sir Frederick Maurice. Pp. xv+290+8 plates. (London: Faber and Faber, Ltd., 1939.) 18s. net.

HALDANE'S epitaph describes him, proudly but not unjustly, as "A great servant of State who devoted his life to the advancement and application of knowledge. Through his work in fashioning her army he rendered invaluable aid to his country in her time of direst need". The word "fashioning" is peculiar but possibly appropriate. Controversy turns on the use of the Army "fashioned" by Haldane. In 1905, when Haldane first took office, as Secretary for War, there was lack of co-operation between the navy and army on strategical questions. In January 1906, the question of co-operation with the French Army was raised, and Huguet brought back from the

French War Office two proposals for the British Army: (1) *être liée à celle de l'armée française*, and (2) *se faire sentir dès le début des hostilités*. Colonel Lawrence, the uncrowned King of Arabia, says of the French that the only way to deal with them is to say "hoots" to them. Sir Henry Wilson, who became Haldane's principal adviser on strategical questions, was a francophile, more disposed to say this word to the politicians than to the French. Sir Edward Grey, on January 15, 1906, in a letter to Sir F. Bertie, British Ambassador in Paris, had said the word in diplomatic language—our military contribution "won't save France unless she can save herself". Haldane gave unflinching support to Wilson's strategy, notwithstanding strong opposition from Fisher and the 'blue water' school and from Lord Roberts and the conscriptionists. "Pussy", to give Haldane his nickname, turned tiger on occasion. Lord Riddell states in his diary that Mr. McKenna,

First Lord of the Admiralty, declined to provide transport for the 150,000, which Haldane proposed to land on the Continent, and records McKenna as saying: "Haldane put me out, but the scheme was a mad one and I did what was right. We had nothing to gain by making France the strongest power in Europe". To-day, as the author admits, "many people are of the opinion that it would be a fatal mistake for us to use our little Regular Army again to extend the line of a Continental ally at the outset of a War"; but refrains from expressing his own opinion on the question.

Was Haldane's strategy justified in the War of 1914-18? "It is then certain," the author writes with the support of a map, "that if our Expeditionary Force had not been ready for action by at latest the sixteenth day of mobilization (August 20) the left of the French line of battle would have been completely enveloped, and the German plan for the defeat of the French Armies by the fortieth day of mobilization successful, with the inevitable concomitant that the Germans would have been in possession of the Channel ports". Surely this is strategical science-à-la-Bowe! Our "contemptible little army" was in position as arranged, "aligned" on the left of the French Army. A fateful decision! Haldane himself may have had misgiving. Lord Beaverbrook in "Politicians and the War" asserts that Haldane was not in favour of the dispatch of the Expeditionary Force to France; but evidence to the contrary is produced in the earlier volume of this biography.

After the War, Haldane was impressed by the need for co-operation between navy, army and air force and worked in this cause, especially during his second period of office as Lord Chancellor. Ramsay MacDonald's first offer (December 23, 1923) was the Education Office. In accepting the Lord Chancellors'hip, Haldane insisted on relinquishing part of the legal work in order to become chairman of the Committee of Imperial Defence. In a note written in 1925 he states: "I was convinced, and am convinced that the military advice given me was right and that our military problem in 1914 was to send the largest possible expeditionary force to support the French in the shortest possible time. For that I prepared". In a biography written by a distinguished soldier, we should have expected a full, expert, impartial examination of this question.

So much for Haldane as a strategist. Of his later educational work, some information is given. Haldane became president of Birkbeck College and of the Institute of Adult Education. In 1919, he reopened with the Minister of Education (Mr. Fisher) the question of the Bloomsbury site

for the University of London. The offer of the site by the Government was an inept bungle. Haldane's road to the Valhalla of educationists was paved with good intentions, especially in relation to the University of London. He survived to see the site secured for the University by other men and methods. A quotation is given from Haldane's address on November 9, 1920, to the 'Old Students' Association of the Royal College of Science: "From this it will be seen", the author comments, "that he conceived of the University [of London] as constituting a union of colleges and of its future as depending in the main on the development of those colleges". This may be true of 1920; but was not the conception of the University for which Haldane pleaded eloquently in supporting the Bill of 1898 re-constituting the University as a 'teaching' university. "Professor Huxley was a distinguished advocate of the Bill", Haldane said in the House of Commons, "and gave evidence before the Royal Commission in which he laid down a scheme for a university which is now practically embodied in this Bill". 'Unify without fettering' was Huxley's slogan to define the relations of the University to its affiliated colleges. Supplementing the work of the colleges, he wished to see appropriate appliances for study and research, supplying London "with the analogue of the *École des hautes Études* and the *Collège de France* and the laboratories with the *Professor Extraordinarius* and *Privat Doctores* of the German Universities".

The author reveals that Haldane was "the prime mover in the institution of the University Grants Committee which now distributes more than £2,000,000 annually to the Universities of Great Britain". This committee, appointed by *stat* of the Chancellor of the Exchequer, is a constitutional anomaly, for the Board of Education under the Act of 1899 is "charged with the superintendence of matters relating to education in England and Wales". In his book "Politics from Inside", Sir Austen Chamberlain records that Haldane in 1912 talked to him about the administration of the university grants. "He is trying to get them put under the Board of Education which he says has now been reorganised and has an admirable University branch through which he says they would obtain much larger grants". Chamberlain strongly opposed this suggestion. "I have always feared that the Board of Education would seek to impose their views on what ought to be taught upon the Universities and would stereotype the University courses: whereas the Treasury not being in this matter a department of specialists, was content merely to ascertain that the work carried on was of a University standard and that certain other necessary financial conditions were

observed". If, as we are assured, "every university in the Kingdom should remember him gratefully as the prime mover in the institution of the University Grants Committee", we may also be assured that every university will be grateful that his earlier suggestion of 1912 was not adopted.

Further, "every research student [should remember Haldane gratefully] as the instigator of the system of grants now distributed annually by the Department of Scientific and Industrial Research". This Department, established in 1915 as a War measure, should have been established before the War and Haldane was in a good position to put forward the suggestion. If Haldane was concerned with its establishment, the news is not surprising and redounds to his credit.

A few words may be added on Haldane as philosopher. Chapter v entitled "The Age of Relativity" is devoted largely to this subject. Haldane's first philosophical work was entitled "The Pathway to Reality". In May 1921, his "Reign of Relativity" was published, three editions being required in ten weeks, apart from translations into German, French and Russian. This book went far beyond the physical theory of relativity. The third book of the trilogy, "The Philosophy of Humanism", was based on his Donaldson Lectures at Trinity College, Dublin.

His wide-flung search for reality brought him back to his own mind. "The real . . . is akin in its nature to our own minds, and it is not terrifying". In Emily Brontë's words:

O God within my breast
Almighty ever present Deity!

In triumph or tribulation, Haldane was comforted by his sense of divine immanence.

This book does not solve the enigma of Haldane. Must it be that the pathway to reality will never be trodden by an Englishman? Dr. McNair Wilson, a Scot, in his book "Doctor's Progress" makes some illuminating comments. He says of Haldane: "What interested me most however was the strong Scottish flavour of his mind. He was a Scot with all the weakness as well as all the strength of his people. Vain as only Scotsmen are vain; humble as only Scotsmen are humble. Proud and touchy, too, as only Scotsmen are proud and touchy". Possibly, he adds, men of his race never understand the English. "I am sure that the English never really understand the Scotch". One thing the Englishman will claim—the *wish* to understand a great man who "devoted his life to the advancement and application of knowledge" and "rendered invaluable aid to his country in her time of direst need". T. L. H.

Malayan Medicine

A Dictionary of Malayan Medicine

By John D. Gimlette. Edited and completed by H. W. Thomson. Pp. xvi + 260. (London, New York and Toronto: Oxford University Press, 1939.) 7s. 6d. net.

THIS dictionary has been prepared by one of the very few officers of the Malayan medical service who has regarded the study of native medicine as anything but time wasted on effete superstitions. Nor, in fact, are the modern hospitals of the western States of Malaya a proper environment for such studies, workers in them being insulated from the native atmosphere and fully employed in the study of modern medicine and surgery.

John Gimlette had the fortune to follow his profession in the medieval atmosphere of a delightful State remote until lately from high-roads and railways. To enjoy life in such surroundings, to keep the mind alert and to win the confidence of patients assured of the efficacy of time-honoured herbal remedies and by religion opposed to surgery, a medical man must have qualities of sympathy

and understanding and be interested and intelligent enough to adapt to modern ends means on the surface unpromising. John Gimlette was such a man, and if Kelantan was fortunate to get such a doctor, he too was fortunate to discover his life's work in such congenial surroundings. Kelantan inspired his "Malay Poisons and Charm Cures", which has run into three editions, and now this "Dictionary", which has been the labour and solace of his last years, when he was crippled as a consequence of the practice of his profession. He died before it was completed, and the book was finished and seen through the press by Mr. H. W. Thomson, formerly of the Malayan Civil Service. Anyone who has ever written a dictionary will appreciate the labour and care Mr. Thomson has given to his task.

The dictionary will be invaluable as a work of reference for practitioners in Malay districts. For beginners, indeed, it is too elaborate and they will scarcely find the wood for the trees. They will, for example, have to know that before every plant name the Malay prefixes the word *pokok* "plant" or *dahan* "leaf" and that *farum*, for example, without

the word *pokot* means 'a needle' and nothing else. The dictionary includes not only the names of herbs, but also the names of parts of the body, of diseases, of magical and other medicinal treatments. A classified index has been provided by Mr. Thomson as some guide to those who may feel the need of an English-Malay dictionary.

The information under many of the headings like *kemenyan*, 'benzoin'; *ma'ajun*, 'electuary'; *jintan*, 'cumin' is encyclopædic; and the lexicographer gives some comparative data from Arabian and Indian medicine, but this line of inquiry especially in the field of Indian remedies could be much further extended. Oddly enough, Dr. Gimlette seems never to have read or heard of a translation by a Kelantan Malay of a medical treatise very popular with Indian Sunnis, the "*Mujarrabat-i Dirbi*", but as with his usual modesty he admits he had "only a practical and

general knowledge of the Malay language", it is amazing that with that limitation he has produced two works of outstanding merit and permanent value. That such a work could be achieved by one who did not profess to be an expert linguist should be an inspiration to others, and one may hope to see some medical officer ready now to take up the study of the many manuscript and lithographed works that exist on Malay medicine.

No more appropriate subject could be found for a thesis or book by one of the Malays who have graduated from the Medical College, Singapore. There are numerous works on Indian medicine to hand for comparative purposes. More and more, research is discovering the debt that Malaysian culture owed to India both in the Hindu and Islamic periods, but of its debt in the field of medicine, which must have been very great, no study has yet been made. R. O. WINSTEDT.

Physical Science of Glass

The Properties of Glass

By George W. Morey. (American Chemical Society Monograph Series, No. 77.) Pp. 572. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1938.) 62s. 6d. net.

THE glass industry both in England and in the United States is to-day going ahead fast, a pleasing state of affairs which is believed to be due largely to the awakened realization that the soundest foundation for a strong industry is the understanding of its fundamental scientific principles.

The monograph under notice was commenced so far back as 1924 and began with two series of researches to provide necessary information for it, which was then lacking. It has thus been fourteen years in preparation. The literature quoted contains 781 references, of which 399, constituting more than half the total, refer to papers published since 1924; a statement which affords proof that the subject as it is to-day, treated with the aid of physical chemistry and based on physical properties as functions of composition, is largely new.

The result of all this work is an eminently scholarly and exhaustive monograph which is bound to be of immense value to the wide circle who have to do in some way or other with glass. The author's expert knowledge has enabled him to sort the wheat from the chaff in regard to the reliability of much of the information in the literature.

After some introductory sections, in which the history, definition and composition of glass are

dealt with, the succeeding chapters, numbering sixteen in all, deal in turn with the various physical properties. Each is a veritable mine of information relating composition to a particular property. The chapters contain numerous tables, phase diagrams and a certain amount of mathematics with, of course, references to the original papers, which are conveniently arranged for quick reference in the old-fashioned way. There is a comprehensive index at the foot of each page.

The author early gives a definition of glass which is worth citing as showing the attitude of science towards it: "A glass is an inorganic substance in a condition which is continuous with, and analogous to, the liquid state of that substance, but which, as the result of having been cooled from a fused condition, has attained so high a degree of viscosity as to be for all practical purposes rigid."

The relation between composition and temperature with reference to the melting and crystallizing process in mixtures containing several components is nowadays compactly expressed by means of phase equilibrium diagrams which, to the competent, give a great deal of information. The word 'competent' is very necessary, for some of the diagrams are of extraordinary complexity; we commend particularly to the attention of followers of the phase rule since the early days of Willard Gibbs and van't Hoff, who used it to work out the formation of the Stassfurt salt deposits, the sketch of the solid model of the ternary system: Na_2SiO_3 — $\text{CaO} \cdot \text{SiO}_2$ — SiO_2 . This chapter,

entitled "Devitrification", affords an illustration of the progress which is being made in solving these abstruse problems with the aid of the phase rule; similar problems which concern the mixture of silicates present in igneous rocks are being studied in like manner and with remarkable success at the Geophysical Laboratory in Washington.

To many, the chapter on optical properties will be found of special interest; optical glass has been recognized as one of the key materials of civilization and an essential munition. Lens designers, who demand varying relations between refractive index and dispersion, have caused a wide search for suitable glass compositions, which has in turn led to the production of highly specialized glasses—

for example, those which are transparent to X-rays and ultra-violet light, or conversely which are opaque to these wave-lengths: both are now articles of commerce. There can also be obtained coloured glasses which are opaque to all but a narrow spectral range. It is most convenient to have the data in regard to the action of glass on light collected in one chapter, and the extent of the information may be judged from the fact that no fewer than thirty-six optical glasses manufactured by Chance Brothers are listed with their optical properties and approximate composition.

The examples selected indicate the remarkable thoroughness of the book, which is well worth even the high price charged for it.

Experimental Psychology

Experimental Psychology

By Robert S. Woodworth. Pp. xi + 889. (London: Methuen and Co., Ltd., 1938.) 18s. net.

TWENTY years ago it was still possible to get the main results of the application of experiment to the problems of psychology within a reasonably small volume, and several excellent text-books were produced for that time. The rapid increase in the amount of published experimental work has made all such books out of date, and the teacher of experimental psychology has been forced to use seriously incomplete text-books and to supplement them in his teaching by his own knowledge of the technical journals. The task of making a single volume representative of the present position of experimental psychology seemed too laborious for accomplishment. This, however, has now been done by Prof. R. S. Woodworth, and his book will be welcomed by all students of the subject.

Prof. Woodworth has good qualifications for this task. It is particularly fortunate that he is free from a common tendency amongst psychologists to work under the banner of some particular school and to evaluate all work from the point of view of that school. The author's freedom from such fads enables him to deal fairly with experimental investigations of many different types and to recognize valuable work whether it is done by behaviourists or by *Gestalt* psychologists. At the same time, this catholicity of choice does not involve an absence of critical judgment. Few things can be duller than psychological volumes which are mere records of published researches, good, bad and indifferent. Prof. Woodworth seems to have used as his criterion for the inclusion of any piece of experimental work the fact that it

makes a genuine contribution to the understanding of some psychological problem, and the general correctness of his judgment on this matter makes his book both useful and interesting.

If we treat the book as a survey of the present position of experimental psychology, we can find in it causes for satisfaction and a good many for dissatisfaction. This book should be a complete answer to those who complain that in the years since experimental psychology developed, nothing has been found out in psychological laboratories. There is, nevertheless, still much conflict about simple matters of fact, which is a result of the inconclusiveness of many published researches. Many experiments are carried out on too few subjects and with insufficient regard for the necessities of experimental design and of the statistical treatment of results. Very commonly the raw data from which the experimenter draws his conclusions are not published, so that no one else can ever determine how well justified his conclusions are. It is, for example, surprising to find in this book how many of the results of quantitative experiments are given as percentages without any indication of the actual numbers from which they have been derived. The methods of design and report of many experiments seem indeed to have been devised for the purpose of making it certain that no intelligible conclusion shall ever be drawn from them.

This, however, is a matter that is improving and it is to be hoped that severer standards in devising experiments and reporting their results will much lighten the task of a psychologist who, ten years hence, may try to make a new survey of the complete field of experimental achievement in psychology.

R. H. THOMLESS.

A Text-Book of Inorganic Chemistry

Edited by Dr. J. Newton Friend. Vol. 6, Part 4: Arsenic. By Reece H. Vallance. Pp. xxxi+351. (London: Charles Griffin and Co., Ltd., 1938.) 25s. net.

THIS volume of a well-known text-book deals fully with the inorganic chemistry of arsenic. A special feature is the detailed description of the industrial preparation and uses of the various arsenic compounds. In most cases, sufficient detail is given of the experimental methods to make it possible to repeat them in the laboratory, a notable case being the preparation of arsenic hydride. The information is critically presented and is up to date. Very full references to the literature are given, and very few, if any, important papers can have been missed. The physico-chemical aspect is well represented, as, for example, in the very clear account of the rather difficult subject of the forms of arsenious oxide. The section on analysis is brief but full of useful information.

The volume shares with its companions the valuable feature of being equally suitable for reading by advanced students and as a work of reference. It speaks highly for the skill of the author that he has achieved this result, and the volume is one which should be in every chemical library. The editor announces in the preface that the original scheme of the whole work is now complete and that a new edition is in preparation in which, where the amount of new work justifies it, a separate book will be devoted to each element.

Electron and Nuclear Physics

By Prof. J. Barton Hoag. Second edition of "Electron Physics". Pp. x+502. (London: Chapman and Hall, Ltd., 1938.) 20s. net.

THIS is the second edition of the well-known "Electron Physics", which appeared in 1929. It is a remarkably up-to-date summary of the experimental aspects of atomic physics, with a bare minimum of the essential theory. Descriptions are given of nearly forty experiments which are suggested as suitable laboratory exercises; perhaps the most ambitious of these is an experiment on the disintegration of lithium by 50-70 kilovolt protons. It is obviously not the author's intention that any one student should work through the whole of the experiments, but there are very few students who could not learn a great deal by merely reading the detailed instructions and working out some of the numerical problems in this book. The text abounds in valuable practical hints, and in addition there are four special chapters on laboratory techniques (including high-vacuum, small-current, counter and high-voltage practice).

The text suffers frequently in elegance, and occasionally in clarity, from the concentration of so much matter into so small a bulk. This is, however, a most valuable book for the young physicist, and the reader is left with the impression that the physics students of the University of Chicago are singularly fortunate in the enthusiasm of their teachers and the equipment of their laboratories.

H. R. R.

The Statesman's Year-Book

Statistical and Historical Annual of the States of the World for the Year 1939. Edited by Dr. M. Epstein. Seventy-sixth annual Publication: Revised after Official Returns. Pp. xxxviii+1508. (London: Macmillan and Co., Ltd., 1939.) 20s. net.

THIS indispensable statistical survey of the world follows its customary arrangement and once again in some fifteen hundred pages records an amazing array of facts. The British Empire and the United States fill the first two parts of the book, while the remainder—about one half in actual pages—is occupied by other States arranged in alphabetical order. As a rule the book is revised to March in the year of publication and so two European States appear as independent which have since lost that status. The careful revision of statistics from official sources gives this volume an authoritative standing which should make it invaluable in these days when world affairs are much in discussion and factual information is most desirable. Lists of official and unofficial books dealing with each State are a most useful aspect of the volume. There are coloured maps of Central Europe and of the country traversed by the remarkable Burma-China road between Lashio and Chung-king.

Concise School Physics

Electricity and Magnetism. By R. G. Shackel. Pp. viii+467-661. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1938.) 2s. 9d.

THIS is the third and final part of "A Concise School Physics", which is also available in a single volume. It carries the story well up to matriculation stage and contains 144 pages of copiously illustrated descriptive matter, about 34 pages of questions and answers, and four of mathematical tables. The general treatment follows good conventional practice and the writing is very condensed, so that the book reads like copious notes of excellent lectures supported by adequate laboratory work. The author, avoiding educational fads, has obviously striven to make his difficult story as straightforward as possible for beginners. The book is amazingly cheap at the price and it should prove very useful in class work which is being directed by a capable teacher.

Introduction to Physiological Chemistry

By Dr. Meyer Bodansky. Fourth edition. Pp. ix+686. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 20s. net.

Laboratory Manual of Physiological Chemistry

By Prof. Meyer Bodansky and Prof. Marion Fay. Fourth edition. Pp. vii+295. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 10s. net.

PROF. BODANSKY undoubtedly has a flair for writing students' text-books. These two volumes form a pair—theory and practical—suitable for senior medical students or for those taking degree courses in biochemistry or physiology. Both works are now in their fourth edition and are exceptionally good.

J. C. D.

Aeroplane Controls*

By Prof. G. T. R. Hill, University College, London

MAN imposes his will on a machine by the use of a control. We are all familiar in a general way with the kind of control by which many of the machines which transport us from place to place are guided; the most recently arrived means of transport, the aeroplane, has controls which are much more complicated in their effects than we find with earth-bound transportation. The vastly greater possibilities of movement possessed by the aeroplane can be stated with greater precision if we consider the number of degrees of freedom it possesses, and then compare it with trains, cars or ships.

A train or tram running on a straight length of line has but one degree of freedom; it can only move along the line and it needs only a single control—that of speed. It is true that this speed control is usually shared between two controls, one of which is responsible for increase of speed and the other for decrease; but, as on a tram, these may be combined in one handle and are essentially one control. A car has three degrees of freedom, if we consider it when travelling in a wide smooth desert; it can move forwards, under certain conditions it may be skidded sideways, and it can be steered so that it turns about a vertical axis. The same limitations apply to a ship, if we think of a calm sea. In these two cases we find that two separate types of control are required—the speed control, which may be sub-divided as before, and the steering for controlling the direction about the vertical axis.

Coming now to the aeroplane, we find no less than six degrees of freedom. The aeroplane can move forwards, sideways and upwards, and rotate about three axes at right-angles to each other, that is to say, it can pitch, roll, and yaw.

We do not provide direct controls for each of these degrees of freedom any more than we do on a car or ship. The skidding or sideways motion of a car is controlled by special combinations of two controls, the steering and the speed. On an aeroplane four controls of the motion are provided; we control the three rotations and, in addition, the power of the engine by means of the throttle. This last control alters the thrust of the propeller, and on all modern types of aeroplane an air brake is provided which gives negative thrust, so that throttle and airbrake are essentially one control, similar in nature to the speed control on the tram.

Unfortunately, the three rotations are not usually each controlled by a simple movement of one control. Pitching by the use of the elevator is nearly independent of the other motions, but a turn is much more complicated, as it requires a proper combination of rolling and yawing and, on a steep turn, of pitching as well; not only this, but also the motion of pure rolling requires the application of both ailerons and rudder in due proportion, and so does the motion of pure yawing.

Coming now to the indirect control of vertical and lateral motion, we find that a pitching rotation changes the lift on the aeroplane and thus a rise or fall is obtained, though this is of course necessarily accompanied by the pitching rotation; in other words, it is not a simple motion in a given direction. Lateral motion, or sideslip, is produced by a special combination of aileron and rudder control, and with big sideslip the elevator control comes in as well.

The control of an aeroplane thus differs from that of a car or ship primarily in the fact that a much greater variety of motions is possible, and, further, to produce many of the simple motions a certain combination of various controls is needed.

We come now to a discussion of the relation between the movements of the pilot's hands and feet and the resulting motion of the aeroplane. There are three simple kinds of control which may be used; we may have a control of position, or a control of velocity, or a control of acceleration. To give everyday examples, the act of lifting a glass from the table to the lips is a direct control by the hand of the position of the glass; the rotation of the steering wheel of a car is a control of the rate at which the car turns, that is, of its angular velocity, and the pressure on the brake pedal is a control of its acceleration, in the negative sense. Each of these types of control is a reasonable one, though simple experiments performed with beams of light moved successively by the three types of control indicate that the position control is the easiest to manage and the acceleration the least easy.

However, it seems probable that real difficulty arises when a control changes its type with time. Take, for example, the aeroplane elevator control; if the stick is pulled back a little and held there, the first thing that happens is that the aeroplane has imposed upon it an angular acceleration in pitch; this falls away very rapidly, and leaves the aeroplane with a certain angular velocity, and

* From a Friday evening discourse delivered at the Royal Institution on February 17.

ultimately this dies away and the position of the stick controls the attitude and forward speed of the aeroplane.

These considerations lead us directly to a discussion of what qualities in a control are responsible for its being described as *pleasant*. I hold that we should go to great lengths to give pilots the easiest and most pleasant controls that we possibly can, so that by relieving their minds and bodies from all avoidable strain, they may be able to concentrate more fully and effectively on their other duties. A pilot coming to fly an aeroplane which is good on the controls will learn to fly it in the shortest possible time, undoubtedly a matter of tremendous importance in these days; when he knows it well he will love to fly it and will feel at one with his machine, and surely he and his mount will be a more effective combination for either peace or war than the pilot with poor controls, disgruntled, tired and at odds with his craft.

If we are agreed that it is worth while devoting time to a study of the characteristics of a pleasant control, we must admit straight away that while a test pilot, for example, has a very clear idea when he flies a new aeroplane as to whether the control is pleasant or not, he is in great difficulty in defining the quality he observes. While the pilot may describe the control as light, firm, crisp or free from lag, the designer always wants to know *how* light, *how* firm, and so on; in other words, he wants a definite answer in figures, and for all practical purposes so far he has been unable to get any figures which he can interpret usefully.

We are now entering upon dangerous ground, for in addition to studying the characteristics of the aeroplane we have to link up with those sensations that pilots like and dislike; the ancients thousands of years ago were well aware of the perils of attempting to argue about personal taste, but my view is that it is the greatest possible mistake to let this frighten us off the field, and aeronautical research should grapple boldly with these problems, even though they have been aptly described as being "not quite aerodynamics".

Experimental work is now in progress in Great Britain from which it is hoped that a foundation will emerge on which the designer may build up the control qualities of his new design with much greater precision and confidence than is possible to-day. An attempt will be made to codify a pilot's likes and dislikes, not only in general terms but also on a quantitative basis.

The ultimate object of the use of the controls of the aeroplane is to produce the flight path which the pilot desires, and in any quantitative study it is no good measuring the forces and couples which the controls apply without a knowledge of what has to be overcome by those forces and couples.

The functions of the controls may be regarded as four-fold, namely: (i) maintaining balance, or trim, in steady straight or curved flight; (ii) overcoming inertia when starting and ending a manoeuvre; (iii) overcoming air damping, which usually resists motion, but in some important cases assists it in an undesirable way; (iv) overriding the natural stability or instability of the aeroplane.

The first function is well understood, because it is relatively simple to analyse steady flight conditions, and it is fairly easy to make measurements; both on models and also in flight, where there is plenty of time available for taking readings.

The second function of the controls concerns the relation of their power to the inertia of the aeroplane, and the effect of inertia depends of course on the rate at which manoeuvres are carried out, and on absolute size, or size relative to the pilot, whose size is constant. These effects are familiar if we think for a moment of ships of different sizes and study their manoeuvres. Small yachts turn quicker than large ones, and yachts turn about as quickly as aeroplanes of the same size, though of course the forward speeds of the aeroplanes are something like thirty or forty times as great.

It is not, however, in the steady rates of turn, but in the entering and checking of the turn that inertia shows its effect, and although large craft turn slower, inertia effects are greater than on small craft. On a liner, for example, it may take nearly half a minute to check the swing by reversing the helm on a steady turn, and it is this great time lag in the control which makes the operation of bringing a large liner alongside a quay under its own power a very tricky operation. A lag of even as little as a tenth of a second can be noticed in an aeroplane control, and bearing in mind that most aeroplanes have to be brought into relatively gentle contact with the ground at the end of each flight at speeds of the order of sixty miles an hour, lags of much more than a tenth of a second are quite unacceptable to the aeroplane pilot.

The third function of the controls, the overcoming of the damping of the fixed surfaces of wing, tail, etc., provides the general guide to the power required from the control organs; thus the movable elevator, which causes pitching, may be about half the size of the fixed tailplane, which resists or damps pitching motion. Proportions such as this have been reached as the result of long experience, but the harmonizing of the three controls, elevator, ailerons and rudder, still gives rise to a great deal of experiment of the hit-and-miss variety on new types, before they can be regarded as satisfactory.

Then finally, there is the relation of the natural or inherent stability, or instability, of the aeroplane to the power of the controls. I propose to illustrate this point by a homely example. In the case of a cyclist riding at a good speed, so long as his craft is endowed with good stability by virtue of its speed, the control movements of his handlebars are very small, but as the speed falls, so he has to work harder and harder in moving his handlebars more and more violently from side to side, until at last his fullest powers of control are inadequate and he crashes. Now this has a close parallel in the air, where stability deteriorates as the speed falls, just as on the bicycle, and it is always for the slow end of the speed range of the aeroplane that it is difficult to provide adequate control surfaces, particularly when it is borne in mind that these surfaces must also be capable of operation at the high-speed end of the speed range.

It is not possible to discuss questions of stability here in detail, but the intimate connexion which must always exist between stability and control can never, in my opinion, be too strongly emphasized.

This brings my discussion of the general considerations surrounding control problems to a close, and I would now like to refer to the results of some new experimental work and their bearing upon particular difficulties which have arisen from the great increase in performance of aeroplanes in recent years.

The trim and stability of a glider, or of an aeroplane gliding with its engine shut off, present no great difficulties to the experienced designer. When the aeroplane is flying under power, the slip-stream from the propeller passes first over the wing and later over the tail-plane, changing the air forces on any surface with which it comes into contact. Experiments with models show that the slip-stream from each propeller, by the time it has reached the tail-plane of a representative modern type of twin-engined aeroplane, has a nearly flat under-surface. This provides an explanation of why two different types of aeroplane, which may look very similar, behave quite differently in flight. In one case it may be that the tail-plane is below the bottom of the slip-stream, and thus experiences only the air pressures arising from the normal speed of the aeroplane through the air; in the other case, with the tail-plane just in the slip-stream, the air forces may be more than twice as great and the upsetting effect of this on fore and aft balance, or trim, is obvious.

The sizes and speeds of aeroplanes are rapidly increasing as the years go on, and the reason that the aeroplane pilot has not yet found salvation in a power-assisted, or servo, control is to be found in the danger involved if there is lag in the

mechanism. The very minute degree of lag which is tolerable has already been referred to, and by a continuous exploitation of the possibility of aerodynamic balancing of the control surfaces, it has, up till now, been possible on even the biggest types to avoid the need for a servo-mechanism at all. But yet closer aerodynamic balancing will be needed in the future, and a new system has recently been invented by several people in different countries almost simultaneously.

The control flap has its hinge situated well behind the leading edge in the familiar way, but that part of the surface in front of the hinge is entirely shrouded by curtains formed by extensions of the top and bottom surfaces of the main wing, extending back almost to the hinge, with a small gap or vent at top and bottom between their extremities and the moving control surface. The front part of this surface thus works in a kind of box, and the pressure on top of it is controlled by the air pressure existing outside the wing at the position of the top vent, and similarly for the under side; the essential point is that the box is divided into two parts, sealed from each other by

Fig. 1.

the nose of the control surface, which touches at all points in its travel the curved back of the main wing (Fig. 1). The absence of any air flow through the gap which usually exists between control surface and wing is found to avoid the undesirable pressure changes which usually arise on the nose of the control surface as it moves, thus spoiling the balancing over anything but a small angular range. Irving, of the National Physical Laboratory, has been one of the co-inventors, and the results of his first experiments are most promising.

Another development which, like the tricycle undercarriage, is a revival of an old idea and goes back, to my knowledge, to 1904, when it was embodied by the Wrights in one of their patents, is what is known as the *two-control system*. The standard system of to-day, with the three controls, elevator, aileron and rudder, is universal in all countries; at various times attempts have been made to abolish either the ailerons or the rudders. It seems, however, impossible in the light of modern knowledge to design an aeroplane which can carry out perfect turns at all speeds with either a rudder only or ailerons only, and an interesting new arrangement is being tried by a well-known American aeronautical engineer, Weick, of the Engineering and Research Corporation, of

Washington, D.C. Weick connects up both the ailerons and the rudder to a single control wheel, the rotation of which operates them both in a pre-arranged proportion. By this means it is possible to make nearly perfect turns at one speed and very satisfactory turns at all speeds. Encouraging results have attended the early trial flights, in which an experienced test pilot observed that he got smoother riding in bumpy weather with the two-control system than with the standard three controls. If the early promise of this experiment

Fig. 2.

is fulfilled, a real advance in simplification of control will have been made, and with the increasing complication of everything connected with the aeroplane, a fundamental step in the opposite direction, such as that proposed by Weick, will be most refreshing to the hard-pressed pilot.

In order to minimize the very real danger of the first test flights on large new types, there is a procedure which has been adopted, notably by

one firm in Great Britain, Messrs. Short Brothers, which consists of building a *flying model* of the large aeroplane. This flying model may be something like half the size of the projected type, and its weight would then be only one-eighth; the control forces are in that case reduced to one sixteenth, and the pilot thus has no difficulty in managing his model. It is of course far quicker and cheaper to modify the model to correct any faults in trim and stability, and it is possible to ensure that the control forces on the full-size aeroplane are within the capacity of the pilot's strength. Then minor modifications should suffice to harmonize the controls and achieve the high standard which we know is possible of attainment.

The large types built by Shorts, just referred to, are the "Empire Boats" and their Service counterparts the "Singapore", and the flying model was known as the "Sealion Senior". Although this latter type was fitted with floats, nevertheless the wings and tail, including all control surfaces, were used as the basis for the design of its larger counterpart; the flying model must take its fair share of credit for the remarkable ease of handling in the air which is characteristic of these fine boats.

The thought may perhaps arise that I am exaggerating the importance of the role taken by stability, and particularly by control, in the advance of the science and art of flight. I have prepared a diagram (Fig. 2) showing the rise in speed, the common criterion for judging progress, and also in wing loading, showing what has been accomplished in the last thirty-five years. It will be seen how speed and wing loading have risen together in such a way that it is impossible to dissociate one from the other, and I hold that it is only through improvement in stability and control that we can now attain the speeds we do by flying safely with wing loadings twenty and thirty times as great as those of the most famous aeroplane of all time—that in which the Wrights made their first flights in 1903.

The Ordnance Geological Survey: Its First Memoir, 1839

By Dr. F. J. North, National Museum of Wales, Cardiff

IN the spring of 1839, R. A. C. Godwin-Austen commenced a letter to H. T. de la Beche with the following words: "I am not much in the habit of buttering my friends, but in the present instance you must not complain at being compelled to pay for a shillings-worth of that commodity". (A shilling was the postage charge for a letter from Newton Abbot to Swansea.) The writer then described his efforts to secure a copy of de la

Beche's "Report", and continued, "I read it before dinner and after: I dipped in it with my tea, and went on devouring it until the 'dead hour'. I was at it again this morning. . . ."

The reference was to the "Report on the Geology of Cornwall, Devon, and West Somerset"—the first volume to be published on behalf of the newly founded Ordnance Geological Survey. It was de la Beche's own idea to supplement the

maps by descriptive memoirs, and Colonel Colby (superintendent of the Trigonometrical Survey) had stipulated that "Mr. de la Beche shall undertake and at his own cost and risk, to publish all these . . . Geological Sections, Memoirs and other matters which may be necessary to illustrate the use of the map, where geologically coloured", but, as shown in a previous note¹, de la Beche had his own way of dealing with the authorities, and the report was eventually published "By order of the Lords Commissioners of Her Majesty's Treasury".

The present note relates to a controversy that arose while the report was being prepared, and by reason of which the work of the Ordnance Geological Survey nearly came to an untimely end.

When de la Beche was surveying in Cornwall, he received a letter which greatly disturbed him. "I am sorry," wrote Colby, "to have to tell you that extremely unpleasant reports of the inaccuracy of your Geological Survey are in circulation, and have got into quarters where the want of geological information renders it difficult to rebut them. . . . Who is the author of these reports I cannot ascertain, but they can only be effectively met by bringing the work forward and shewing its utility. . . . The Government feel that they have paid for a portion of work, which is not before the public, and when the work is impugned they dread their responsibility."

De la Beche lost no time in replying, and his letter contained these paragraphs: "The reports in question arose out of a paper by Messrs. Sedgwick and Murchison, read before the British Association held at Bristol, in which they differed from a copy of the Ordnance Geological Map of North Devon, with which Gardner inadvertently furnished one of these gentlemen, such map being unpublished at the time. . . . The indecent attack . . . the cause of all the present reports, was therefore made without giving me any notice of the subject, and while the Geological Map of N. Devon and the Report were still unpublished. . . . By your kind letter, my dear sir, it is but too clear that I have personal enemies, and unfortunately it is equally clear that they are actively employed against me. While I toil day after day without rest, endeavouring to do my duty to the public, and to return zeal and the best use I can make of my abilities for the confidence reposed in me, they can, and as it appears do, buzz their accusations about, not neglecting the quarters where they conceive they can do me the most mischief, so that do what I will I have no chance."

From Colby's letter and de la Beche's reply it might appear that Sedgwick and Murchison were the instigators of an attack on de la Beche and

that the campaign had been carried out of the geological debating room, where it really belonged, to official circles, where it was calculated to jeopardize the continuation of the Survey. Actually, however, the matter provides an excellent illustration of how misunderstandings arise, and how serious they may become if one of the protagonists is inclined to interpret honest criticism as a personal attack.

As an example of the news that de la Beche was getting, we may take this letter (from a person whose writing I have not yet identified): "I heard from various quarters some time ago that they were persecuting you, and suspected that Lyell and Murchison were at the bottom of it. I went to Greenough to ask him. He told me you were safe, but that Spring Rice [that is, the Chancellor of the Exchequer] had been informed of the truth, and that you would be well looked after. . . ."

George Bellas Greenough, who was president of the Geological Society in 1834 when the first geological maps of Devonshire were published, seems to have done all in his power to smooth away the difficulties, and persuaded de la Beche not, as he was at first inclined, to resign his appointment, pointing out that Colby's letter had very likely "made us more apprehensive of mischief than there is any occasion for".

The bone of contention was that de la Beche had regarded the Culm deposits of Devon—rocks which contain layers of anthracite-like coal, and fossil plants like those of the coal measures—as a member of the 'Greywacke' series, which in other areas was known to underlie, and, therefore, to be much older than the Carboniferous strata.

Finding that the Culm beds seemed to pass downwards without interruption into the undoubtedly older rocks beneath, de la Beche argued that the presence, in the Culm, of plants like those in the coal measures, did not mean that the rocks were contemporaneous with the coal measures, but that the coal-measure plants came into existence much earlier than some geologists supposed, and when he stated as much in his "Geological Manual", published in 1832, Murchison contested the view, and offered to help him to re-write the relevant chapter. He knew, therefore, that Murchison, at least, did not agree with him.

Two years later, de la Beche re-affirmed his views in a communication to the Geological Society, when he was again criticized by Murchison. "You will have heard from Greenough," wrote Edward Turner, the secretary, "how your discovery of coal and its fossils in the greywacke was last Wednesday turned topsy turvy without scruple. . . . Murchison, in fact, said that he had never seen the country, but would nevertheless take upon himself to affirm, so identical were

the fossils with those of the ordinary coal fossils, that your coal also belonged to the Carboniferous beds. . . . Murchison clearly thinks it impossible for the fossils of the carboniferous coal field to occur below his Dudley (that is, Silurian) beds".

Sedgwick, at this period, agreed with de la Beche, and wrote that he had always supposed the Devon anthracite to be in the Greywacke, and was not surprised to learn that the plants were identical with coal-measure fossils. He concluded by saying: "The fossillogists are going Mad. The foundation of our Conclusions . . . must ever rest on the evidence of superposition, given by actual sections. Our friend Murchison has examined an astonishingly fine series of upper fossiliferous greywacke, and finding no coal plants in it, resolved in his own mind that the said plants should not be found in it anywhere else."

The note read at the meeting of the British Association was followed up by a paper read before the Geological Society in 1837, and in the meantime the matter had given rise to much discussion. Lyell, who had succeeded Greenough as president of the Society, had written to de la Beche, asking him to re-consider his position. Among other things he said: "In any district of much disturbed strata the admission of such an anomaly as the identity of the vegetation of two very remote eras on any grounds which were stated seems to me unphilosophical. . . . If you are prepared to say you have changed your mind, pray give me the opportunity of saying it on your authority in my speech."

All this shows that neither Murchison nor Lyell wished to take an unfair advantage of de la Beche; it simply means that they thought he had made a

mistake, and said so in the proper place for such views to be expressed.

Unfortunately, de la Beche was working so far away from London that he had few opportunities for meeting kindred spirits, and he was often, as his letter to Colby suggests, physically tired. Moreover, as the owner of plantations in Jamaica, he had suffered as a result of propaganda connected with the slave trade, which, in the words of Caroline Fox, had given him a "low view of mankind". In the circumstances, it is not surprising that he should have imagined the worst when he received Colby's letter, and learnt that he was being criticized in geological circles.

Although in a half-hearted way de la Beche eventually adopted the identification of the Culm proposed by Sedgwick and Murchison, there are passages in the report which indicate that he was not really convinced that the evidence of fossils could be regarded as determinative, when the field evidence appeared to point to some other conclusion—all of which goes to show the danger of dogmatism when scientific principles are under discussion.

In the controversy to which this note relates, we find doubt being cast upon a principle that Robert Hooke had conceived towards the end of the seventeenth century, that William Smith had enunciated towards the end of the eighteenth, and that is now recognized as the foundation of modern geology: namely, that the assemblage of fossils in a given series of strata is peculiar to rocks of that age, so that strata can be identified by the fossils which they contain.

¹ NATURE, 143, 254-5 (1939). The present note, also, is based upon manuscripts deposited in the National Museum of Wales by the late Colonel J. L. D. Nicholl of Merthyr Mawr.

The Study of Animal Behaviour

THE study of animal behaviour has a long and arduous history. It cannot, however, be claimed that either the scope of the subject, or its methods, have been clearly defined. In interest it ranges from the ecological facts of the interaction of animals and their environments, through the details of life-history and their physiological analysis, on to questions of perception, motivation, learning and adaptive behaviour. Its methods embrace those of the field-worker, those of the physiologist, and those of the psychologist. Its philosophy, again, is in some quarters undefined, in others aggressively, even if vaguely, teleological and organismic, and elsewhere frankly empiricist. With all this diversity, those outside the subject can scarcely regard it as more than a concatenation

of discrete interests and different methods. For the same reason, those within it can scarcely be blamed if their activities cover but a very narrow part of the whole subject. Nevertheless, ever since the turn of the century attempts have been made, in societies and journals abroad, to integrate what is, after all, a distinct, even though very wide, field of scientific exploration.

Great Britain has not been to the fore in this work. Indeed it was only three years ago that a society relating to the subject was founded here for the first time. This society, the Institute for the Study of Animal Behaviour, has as its aims "to promote the study of animal behaviour, to encourage the undertaking of research and the publication of the

results of research in this field", and to carry on any further activities which it may from time to time regard as furthering these objects. It publishes a *Bulletin* which is devoted to reviews of recent advances in the study of animal behaviour, and it also provides research grants to investigators. Occasionally, too, it holds meetings, and it was at one of these meetings, held on June 13 in conjunction with the Zoological Society of London, that Dr. Julian Huxley briefly outlined the aims of the Institute, of which he is president, in the opening remarks to a symposium which dealt with modes of analysis of animal behaviour.

The topics considered in this symposium were perception, motivation, instinct, learning and memory, and in some measure at least the discussion thus emphasized the main compartments of animal psychology. Perception is of primary importance at every level of behaviour. It is the starting point of the responses which animals are constantly making to changes in their immediate surroundings. The methods by which it needs to be analysed are as varied as the forms which it can take. Vision, for example, has to be studied in terms of brightness—discrimination and form and colour perception; and apart from the mere statement of the kind of vision possessed by any given animal, the problem has to be explored from the point of view of the anatomical and physiological mechanisms which subserve these functions—mechanisms which are by no means necessarily the same in different species. Auditory acuity, tactile and thermal sensitivity, to mention just a few other perceptual modalities, each requires its own comprehensive mode of analysis. The particular perceptual problem dealt with at the symposium—insect communication—showed clearly how complicated a process of analysis can be, and how much the perceptual world of one animal may differ from another.

Some insects, as Dr. A. F. Rawdon-Smith pointed out, can discriminate between sounds which differ by a factor other than intensity. Quite clearly they discriminate the quality of a given sound by a process altogether different from human frequency discrimination. For example, a virgin female cricket will react to a telephone that is transmitting the chirruping of a male even when the sound is so distorted as to be unrecognizable to the human ear. Since no insect possesses a cochlea which could subserve harmonic analysis, the only possible basis of discrimination is that different sound qualities produce afferent impulses of different temporal pattern in the auditory nerves. But here, as Dr. Rawdon-Smith explained, a major difficulty is encountered. Owing to the refractory period of the nerve fibres, it is to be expected that they would discriminate only low

frequencies, whereas in fact study of the passage of impulses shows that the auditory receptors of insects are incapable of responding to such frequencies and react only to frequencies of much higher magnitude. The solution to this problem was obtained by means of a carefully designed physiological experiment carried out by Dr. R. J. Pumphrey and Dr. Rawdon-Smith. It was found that the high frequencies given out by stridulating insects are carriers for a low-frequency modulation. High-frequencies themselves have no 'meaning' to insects. Their function is to carry the low-frequency modulation, and it is the latter which characterizes sound to the animal. The mechanism of auditory perception in insects is thus much less akin to that in man than it is to wireless telephony.

Dr. Rawdon-Smith's exposition was an eloquent demonstration of the possibilities of analysis of perception, and of the immense field that awaits exploration. No animal's perceptual world can be regarded *a priori* as being the same as another's. Things which are significant in one world may not be perceived in another, and each perceptual world presents its own problems of organization. The latter have been closely studied, particularly by *Gestalt* psychologists and philosophers, but while the primary issues have at times been obscured by generalities, the actual facts regarding different perceptual worlds in the animal kingdom have always remained the central problem of students working in this field of animal behaviour.

This has not always been the case with animal motivation, for here general issues have frequently obscured definite problems. The study of animal motivation is concerned with the central and peripheral nervous organization which makes response possible, and with the working of this nervous apparatus; with the analysis of other influences, for example hormonal factors, which affect behaviour; and with the definition and measurement of the various 'drives' for the fulfilment of which animals strive. The latter has been a fruitful field of experimental psychological exploration. The investigation of the part played by hormones has also yielded facts of great interest, even though the actual manner in which hormones affect behaviour has not been elucidated as yet. On the other hand, the neurological aspect of the problem has been left mainly in the hands of anatomists and physiologists, in spite of the fact that the fundamental issues of nervous physiology must form the primary facts of a study of behaviour. That they do has, of course, been generally admitted by students of behaviour, but in so far as they have not been immediately concerned in this field of study, animal psychologists have been content to base general theories of behaviour on concepts derived, for example, from the field of

reflex physiology. The rigid 'behaviourism' of Watson was one such general theory. While it did much to organize knowledge of behaviour and to attract attention to the subject, it was far too static in its formulation to survive in the face of a growing volume of facts. Its history, too, exposes the danger of a general theory being so formulated that it does not take into account the possible changing nature of the ideas on which it is based.

This issue was vigorously dealt with by Mr. J. Z. Young, who compared the incorrect conception of a reflex system as something which operates whenever its afferent side is stimulated, with a reflex system in which an afferent impulse becomes effective only when the motor neurons of the system are in a particular state of excitability due to impulses reaching them from other neurons with which they are in synaptic connexion. He went on to consider the importance of the fact that the higher nervous centres are in constant activity. For example, in cephalopods the anatomical arrangements are such that certain combinations of afferent stimuli can set in action self-re-exciting chains of neurons, the continued activity of which facilitates certain pathways. His suggestion is that the setting-up of such activities may constitute the change which takes place in a nervous system during the process of learning. Mr. Young's paper made it perfectly clear that the old analogy of the nervous system as a static telephone exchange which passes on messages to the relevant motor neurons must give way to a conception of an exchange always in active change itself.

Although general theories of behaviour that are based upon neurological concepts may even yet be inadequate, they are much more valuable to animal psychology than discussions as to the reality of concepts such as instinct. Dr. J. A. Loesser's contribution to the symposium, which was substantially the same as an article of his published in *NATURE* of May 27, p. 880, was concerned with this question, and unfortunately his attempt to banish the concept in favour of even less tangible concepts of behaviour cannot be regarded as a successful one. Dr. Loesser's main point is that every organic action represents merely the satisfaction of an impulse, and that in so far as no response of an animal can have any conscious or unconscious relation to self- or race-preservation, it cannot be an instinctive action; therefore there is no such thing as instinct. A hen, for example, does not sit on eggs because she wishes to hatch the next generation of hens, but because sitting on cool curved objects soothes irritating surfaces of her body. This may all be very true, but the fact remains, as Dr. Loesser admits, that whatever the basis of so-called instinctive behaviour, subjective

aims and objective purposes often appear to coincide. The argument is purely one of definition. Instinct is widely defined as that faculty, other than a rational process, which makes inborn animal behaviour seem purposive. As Prof. Lashley effectively argues in a recent article, "the anti-instinct movement was aimed primarily as the postulation of imaginary forces as explanations of behaviour". It scarcely helps the subject to dismiss the presumed hereditary basis of instinct, and to continue talking, as Dr. Loesser does, about the "psyche and consciousness", or the "genuine risk and genuine reflection" of behaviour.

Fortunately, the learning processes and adaptive behaviour of animals lend themselves to a more satisfactory type of generalization than the unlearned reactions which usually go by the name of instinct. The literature on this question is extensive, and the experimental work which is being carried out is as a rule sufficiently well designed to allow of the constant re-testing of the general theories of learning which have been derived from previous studies. An excellent example was given by Mr. G. C. Drew in his contribution to the symposium. One of the well-known theories of learning is the Law of Effect, which states that reactions which are rewarded tend to be stamped in, while those which are punished tend to be eliminated. This hypothesis has been thoroughly substantiated so far as rewards are concerned, whereas recent work has thrown considerable doubt on the part which punishment is supposed to play in the process of learning. Indeed, work by Drew and others has shown that where an electric shock is the punishment in experiments on rats, a mild shock has an equally facilitative effect on the speed of learning whether it be given for the wrong response or for the correct response, whether it be associated with both types of response, or whether it be associated with the reward.

Experiments of this kind are still not as numerous as they might be, nor as consistent with each other as is to be desired, but they are representative of an approach in the analysis of behaviour which is truly fruitful. So, too, were the experimental studies on delayed reaction and memory reviewed by Dr. S. Zuckerman. These concerned the ability of animals to make a discrimination between an incorrect and a correct stimulus when their responses are separated from their perception of the problem by intervals of varying length. Other experiments which were described dealt with the observation that chimpanzees can be taught to regard disks of various sizes and colours as symbols for specific foods. The fact that the animals will work for these disks, fight or beg for them, and hoard them, even if it

be only for a day, until they have the opportunity of exchanging them for the foods they represent, raises a considerable question from the point of view of the genesis of abstract and symbolic behaviour.

If it succeeded in nothing else, the symposium undoubtedly did indicate to those who were present the vast field of interest which can be defined under the term 'animal behaviour'. It is clearly impossible for any one science to deal with all aspects of this subject. This very fact is

one of the best arguments for the existence of an organization, such as the Institute for the Study of Animal Behaviour, prepared to undertake the task of integrating the numerous studies, carried out in different departments of science, which are related under the heading 'animal behaviour'. The task that lies before the Institute is, however, far more than just the reviewing of separate advances in the subject, for this activity cannot but lead to the more responsible one of indicating the lines along which research needs to be directed.

Obituary Notices

Dr. Jan Koliha

THE National Museum of the Kingdom of Bohemia, at Prague, has suffered an irreparable loss in the untimely death of Dr. Jan Koliha, head of the Palaeontological Department of the museum since 1931.

Dr. Koliha was born on May 3, 1890, at Police nad Metuji in Eastern Bohemia, where his father was a teacher. He had already begun collecting natural history specimens in his teens, and when he proceeded to the Charles University of Prague, in about 1900, he studied natural science and obtained the degree of Ph.D. for a dissertation on "The Atrémata of the Krušná Hora Beds" (published in *Palaeontographica Bohemica*).

Koliha next became assistant in geology and mineralogy to Prof. Cyril Purkyně at the Technical University, and also at the National Museum under Prof. Perner. The latter advised him to abandon his studies of the Bohemian Cretaceous and devote himself to the Palaeozoic strata of his country, which are well represented to the south and south-west of Prague.

While still a student Koliha had made the acquaintance of the great zoologist and palaeontologist Prof. Antonín Friš, who died in 1913. Friš lived to see the collections of the National Museum removed to the fine buildings at the top of Wenceslas Square (1892). Here Dr. Koliha, together with the late Dr. J. S. Procházka, acted as assistant to Prof. Kafka. On the death of the latter (1929), Dr. Procházka became the head of the Palaeontological Department until his death in 1931, when Koliha succeeded him. From this year the galleries containing Barrande's collections were called the Barrandeum, and Koliha was given the title 'Custodian of the Barrandeum'. He likewise became responsible for all the palaeontological collections, with the exception of fossil plants, which were under the care of Dr. Němejc.

Dr. Koliha was the chief authority on the Lower Palaeozoic fossils of Bohemia. He is especially to be remembered for his research on the Tremadocian of Eastern Bohemia (1925). Drs. Kodym and Matějka of the State Geological Survey had found black clay shale near Český Brod (East Bohemia) in a locality hitherto supposed to be Cretaceous. Dr. Koliha

examined some of the material and on the basis of the contained fossils proved it to be of Lower Ordovician age. Later he succeeded in correlating it with the Tremadoc Shales. An account of this discovery is given in the *Journal of the State Geological Institute of U.S.R.*, vol. 2, pp. 305 ff. The importance of this discovery was shown by the fact that it placed the Ordovician fauna of Eastern Bohemia in quite another sea to that which existed in the Barrandian basin at the same time. The Tremadocian of East Bohemia belongs to the Baltic-Scandinavian facies.

Dr. Koliha was well known and honoured not only in his own country, but also in Great Britain, Germany, Sweden, and the United States. As a specialist in the older Palaeozoic he was unrivalled, and material from all over the world came to him for determination. He was likewise a good zoologist. He possessed a surprising knowledge of English literature. He was also acquainted with Swedish and Welsh, and spoke excellent French.

Dr. Koliha was a kind friend and a good colleague. He was for many years a member of the Geographical Society of Prague, of the Geological and Mineralogical Society of Czechoslovakia and also of the National Museum Society, to the meetings of which he contributed many inspiring lectures and other communications on palaeontological matters. He died on April 7, after long suffering. His place at the Museum has been taken by his colleague Dr. Němejc.

I am indebted to Prof. Perner of the Charles University and to Dr. F. Prantl, of the National Museum, for some of the details of Dr. Koliha's work and career.

T. OAKES HIRST.

We regret to announce the following deaths:

Dr. E. T. S. Appleyard, research assistant in physics in the University of Bristol, on June 15, aged thirty-five years.

Prof. A. E. Kennelly, emeritus professor of electrical engineering in Harvard University and the Massachusetts Institute of Technology, on June 18, aged seventy-seven years.

Dr. E. Kidson, O.B.E., director of meteorological services in New Zealand since 1927, aged fifty-seven years.

News and Views

Prof. Walther Nernst, For.Mem.R.S.

ON June 25, Walther Nernst, well known as a physical chemist, will celebrate his seventy-fifth birthday. Nernst was born at Briese, West Prussia, and studied at the Universities of Zurich, Berlin, Graz and Würzburg. He worked under F. Kohlrausch at Würzburg, where he took his degree. His thesis connected his name for all time with the thermomagnetic effects he had discovered. Eventually, he became professor of physical chemistry in the University of Göttingen and principal of the laboratory that he had just equipped for this branch of study. Numerous papers dealing with a diversity of problems were published as the result of work in the new laboratory, among them such subjects as the ionic theory of solutions, electrocapillary phenomena, residual current, polarization capacity, over-voltage, the lead accumulator and the theory of nerve stimulation which explains the painlessness of the application of high-frequency electric currents, known as diathermy. The invention of the Nernst electric lamp made the name of the young physicist well known all over the world. In 1924, Nernst became president of the Reichsanstalt. His "Textbook of Theoretical Chemistry", the fifteenth edition of which has recently appeared in Germany, is well known all over the world and has been translated into several languages. During the Great War he spent some time at the front and was decorated with the Iron Cross of the first and second class. In 1920, he was awarded the Nobel Prize for chemistry. Prof. F. Krüger has written an appreciatory article in the May issue of *Research and Progress* (Berlin, N.W.7, Unter den Linden 8) on Nernst's life and work, filled, he says, with most intensive labour but richly rewarded in respect of research and teaching.

NERNST's work covers many fields of theory and investigation. His theory of galvanic cells, published in 1889, in which he applied the new theory of ions to the explanation of the development of electromotive force and introduced the idea of an electrolytic solution pressure, still forms the basis of the theory of the cell. Equally important was his study of the theory of the diffusion of electrolytes and the development of the formula for the liquid contact potential (1888-89). The application of the quantum theory to physical chemistry interested him greatly, and his experimental investigations of the specific heats of solids at low temperatures laid a sound basis for one aspect of this theory. Among other important results was the fact that the specific heat of diamond becomes vanishingly small at low temperatures. This result was a consequence of Nernst's so-called Heat Theorem, or the Third Law of Thermodynamics, which he put forward in 1908. This has the most fundamental importance in chemical thermodynamics and gave a new impetus to

theoretical and experimental studies in this field, in which a large number of workers in all parts of the world took part. Another example of Nernst's insight into fundamental problems was his enunciation of the so-called chain mechanism of photochemical reactions, published in 1918. There is scarcely a branch of modern physical chemistry which has not been enriched by some important contribution from Nernst, and his influence on the development of the science has been most fruitful. His insistence on the equal importance of thermodynamics and the atomic theory at a time when the latter was beginning to fall into discredit in some quarters is a tribute to his sound judgment. As an investigator and as a teacher he stands out as one of the great leaders in science.

Plaque in Memory of Edward Clodd

THOSE who knew Edward Clodd personally and the multitude who were instructed by his numerous books and articles will welcome the placing of a plaque on June 15 on Strafford House, his Aldeburgh home during 1889-1930. It was here that he kept his library, where he spent all his spare time, and to which he retired. Strafford House recalls many pleasant and stimulating occasions to those who were privileged to be Clodd's guests. Throughout a long period Clodd invited mixed gatherings of men of very varied interests—literary men who had made their mark in different ways; leading men in other departments of learning, law, history, economics, and politics; administrators of Protectorates, Colonies, and the like; men who had come to the front rank in chemistry and physics, biology, anthropology, and archaeology. Any particular gathering contained representatives of some of these intellectual activities, each of whom blossomed out under the hospitality of the genial host, whose far-reaching interests embraced most aspects of the humanities and sciences. Not only were the talks and discussions memorable, but also the walks and especially trips in the little yacht the *Lotus*, where Clodd busied himself with sailing and in ministering personally to the material needs of his guests. Strafford House thus became a pleasant meeting place for men and women of varied pursuits and was a transient intellectual centre that had a definite social value for some forty years.

Museums and Schools

AN exhibition designed to demonstrate some of the opportunities for co-operation in function between museums and schools in the work of education opened in the Department of Archaeology and Egyptology of University College, University of London, Gower Street, London, W.C.1, on June 20 and will remain open daily until July 15. The material exhibited

- has been contributed, mainly from their publications, by the museums of London and of the United States of America. It serves to bring out with considerable clarity the very different approach by the museums of the two countries to the problem of education. In London, largely owing to the manner in which the great national collections originated, and the way in which they have been built up, emphasis is laid on the function of the museum as a store-house
- of research and advanced critical appreciation, as well as, of course, as a place of exhibition of such
- part of the national wealth as is embodied in objects of artistic or historical interest and value concentrated in London. In the United States, on the other hand, the museums rely almost entirely upon funds from unofficial sources, whether from endowment or in the form of current income. In consequence, the latter have consistently stressed their educational function, directing it, naturally, in the first instance to the satisfaction of the interests or needs of their more immediate clientele.

This difference is to be noted in the character of the posters advertising the national collections of Great Britain exhibited by the London Transport Board, and those shown here by the United States Museums, which consist of carefully devised and prepared propaganda material. The same difference is to be noted in the character of the two sets of publications. Whereas the English museums have prepared series of postcards and guides which offer a wealth of material bearing upon nearly every aspect of art, science and history, from which teachers are left to select for themselves, in the United States the museums, undertaking the direct educational function, circulate among the schools illustrative material selected by their own education departments, but rely mainly on the organized work and lectures of their own educational staffs, for which special accommodation is provided in the museum building.

Human Problems of Management

In an address at the Commencement Exercises, Massachusetts Institute of Technology, on June 6, Sir Harold Hartley pointed out that, apart from new inventions and discoveries, the great changes in industry in this century have been largely in the direction of transforming traditional methods depending on the personal skill of the operator to scientifically controlled processes in which measurement has largely taken the place of craftsmanship. A new standard of certainty based on scientific measurement has invaded every branch of industry and engineering. The human problems of management, however, are equally important and are much more difficult than the selection and working of inanimate material. Success or failure may depend on the wise choice of men, in which there is no figure of merit as guide. There are also the wider human problems of industry and the collective life of the factory; the emotional response of the individual, the human understanding of the supervisor may influence efficiency and output as much as scientific planning. These human problems

of management, Sir Harold said, become increasingly important with the size of the concern, and the rapid growth of the great corporations constitutes a new factor in our social organization, so that any danger of their inability to utilize human effort to the best advantage is an urgent problem. When an organization becomes too large for personal leadership, it is in danger of losing its character and vitality, of becoming mechanical, with all the loss of efficiency implied thereby in a human agency.

ORGANIZATION, however, implies not only order in the distribution and co-ordination of the functions of the separate parts, but freedom for the individuals within their sphere of action. The remedy for the dangers of specialists through their ignorance outside their limited sphere of knowledge is a synthesis, which is the object of a large industrial undertaking in securing the co-operation of a team of specialists. Its smooth running depends on the ability of each of its component groups to engage intelligently in its particular task in proper co-ordination with the rest. Sir Harold Hartley does not believe that individual initiative disappears with increasing size. Without initiative there cannot be the steady flow of ideas, not merely outwards from the centre but inwards from each section, which is essential for success. The key problem is that of supplying adequate motive power in place of the self-interest motive, which must largely disappear. Accordingly, he stressed the importance of the study of incentives based on personal satisfaction, the development of the team spirit, and of the value of recognition in sweeping away negative inhibitions which hinder the possibility of achievement. It is the business of a leader to find the opportunities for success and to see that everyone is made to feel his part in them and to know that his part is recognized.

Pre-Roman Archaeology in Shropshire

IN view of recent developments in the study of British archaeology and prehistory in the period preceding the Roman invasion, considerable interest is attached to the announcement that the earth-works which crown the slopes of the Wrekin in Shropshire are to be excavated by the Society of Antiquaries of London in co-operation with the Shropshire Archaeological Society. It is thought probable that the Wrekin was the headquarters of the tribe of the Cornovii before they were removed by the Romans to the riverside site of Viroconium or Uriconium, the modern Wroxeter, some time about A.D. 80-70, much as the tribesmen were removed from Maiden Castle to Dorchester in the same period. Uriconium itself, the Roman site, has recently been excavated by Miss Kathleen Kenyon, and it is now the opinion of archaeologists that the time has come to investigate the earlier site. It will be a matter of interest to see whether the suggestion thrown out by Dr. R. E. Mortimer Wheeler of an indication in his recent excavations in southern Brittany pointing in the direction of Shropshire is in any way borne out by the results of the investigation now contemplated.

Permission for the work has been given by Lord Bernard, the owner, and the work will be under the direction of Miss Kenyon. Excavation will begin in the current year, and it is hoped will be completed in 1940. A committee has been appointed for the purpose of raising funds to meet the cost of excavation, of which Mr. A. W. Clapham, president of the Society of Antiquaries, is chairman, with Sir Charles Marston and Sir Frederic Kenyon as vice-chairmen, while among the members of the committee are Lord Harlech, Lord Powis, Lord Baldwin, Sir Charles Peers, Dr. R. E. Mortimer Wheeler and Mr. J. P. Bushe-Fox. Contributions to the excavation fund may be sent to the Assistant Secretary, Society of Antiquaries, Burlington House, Piccadilly, London, W.1.

Imperial Studies in Chinese Archaeology

Owing to the preoccupation of Chinese antiquarians with literary rather than material evidence, an exceptional interest attaches to an imperial scroll now on exhibition in London, which was painted in A.D. 1729 by command of the Emperor Yung Chen. The scroll is of paper, measuring 49 feet long by 24½ inches wide, and forms an illustrated record in colour of some of the personal possessions of the Emperor, including objects in bronze, jade, ivory, pottery and porcelain. More than two hundred objects are represented. To the student of Chinese archaeology and the development of Chinese art, the interest of this early catalogue lies in the fact that the objects range in date from the early Chou dynasty, about the close of the second millennium B.C., down to porcelains of the early eighteenth century of our era. It is, in fact, a contemporary manuscript catalogue, illustrated by hand, of a remarkable collection of antiquities, which are shown as a continuous band of colour plates. At the time the scroll was painted, the Emperor, who died in 1735, was engaged in preparing the plans for his tomb; and it was from this tomb that the scroll was obtained by a British officer at the time of the Boxer Rebellion. It is now on view at the galleries of Messrs. Spink and Son, 5-7 King Street, St. James's, in aid of the Maternity Ward of the Royal Northern Hospital, London. As no scroll of this type has previously been exhibited in Europe, it has been displayed at full length on the walls of the exhibition hall and is accompanied by a key, in which the various objects have been drawn in outline with notes by experts on their type and ceremonial use. In view of the wide range in character and date of the objects depicted, the value of the scroll thus elucidated for archaeological and æsthetic studies is obviously considerable.

The History of Cement

THE summer meeting of the Newcomen Society was held in Suffolk on June 7-10 with Ipswich as the headquarters. The itinerary included visits to the bell cage at East Bergholt, weaving factories at Sudbury and Hadleigh, the post mill at Saxsted, the tide mill and steelyard at Woodbridge and the

works of Ransome's, Sims and Jefferies, Ltd. After the annual dinner on June 8 three papers were read, one of them being by Dr. A. P. Thurston on "Parker's 'Roman' Cement". In 1796, James Parker, of whom little is known, took out a patent for "Cement or Terras to be used in Aquatic and other Buildings and Stucco Work". This cement was made by burning in kilns the hard stone-like concretions called septaria, found around the coasts of Essex and Kent wherever the London clay bordered the shore and formed low cliffs. Previously this material had been used for building, but when the making of Parker's cement began there was a great demand for it, and the practice grew up of dredging it from the bottom of the sea off Walton-on-Naze and elsewhere. In 1857 there were between three and four hundred smacks engaged in this dredging. The principal factories for cement manufacture were at Harwich, and at one of these 'Roman' cement was made until 1890. Joseph Aspdin's patent for 'Portland' cement was taken out in 1824, but it was the improvements effected in its manufacture by I. O. Johnson at Swanscombe which led to 'Portland' cement superseding 'Roman' cement. Dr. Thurston's paper was accompanied by a bibliography of the subject.

New B.B.C. Stations

ON June 14, the revised West Regional Scheme of the British Broadcasting Corporation was brought into operation by the opening of the new transmitting stations at Start Point and Clevedon. These stations now radiate simultaneously the West Regional programme on wave-lengths of 285.7 and 203.5 metres respectively. The Start Point station is situated near the most southerly point of Devon, and is intended to serve the whole of the south coast from Cornwall to Hampshire or Sussex; while Clevedon on the North Somerset coast will serve the areas around Bristol, and the northerly parts of Somerset and Devon which cannot be covered satisfactorily from Start Point. Both stations have been so located as to take advantage of transmission largely over a sea path, and thus avoid the heavy attenuation of signal strength encountered in wave propagation over the poorly conducting terrain of Dartmoor.

SOME technical details of the Start Point station were given in the *Wireless World* of June 15, from which it is learned that the new station is at present using a power of 100 kw., which will ultimately be raised to 150 kw. In order to give the greatest service along the south coast, the aerial system has been designed to give its maximum radiation in the east and west direction, with a minimum, but by no means negligible, radiation in a southerly direction over the English Channel. This directional radiation has been secured by the use of two steel mast-radiators, 450 ft. high, spaced about three eighths of a wave-length apart. Both mast aërials are connected to the transmitter, one directly and the other through a suitable phase-shifting network. This network has been carefully adjusted during the initial test-period to give the desired distribution of signal radiation.

- The carrier-wave frequency is controlled to an accuracy of better than one part in a million by a high-precision quartz crystal, and the modulation arrangements of the transmitter have been designed to give a very high programme quality.

Infestation of Grain by Insects

- A SURVEY of the conditions of infestation in the grain trade in Great Britain was initiated about a year ago (NATURE, June 4, 1938, p. 1004), as a result of which it appeared that research into control and remedial measures against pest infestation of all stored produce was desirable. At the request of a Standing Conference representing the industrial interests co-operating in the work, the Department of Scientific and Industrial Research has agreed to undertake this research and an advisory service for industry. The work will be carried out with the technical and financial co-operation of industry, by the Imperial College of Science and Technology at the Biological Field Station of the College, at Slough, under the direction of Prof. J. W. Munro, professor of zoology and applied entomology at the College, to whom inquiries relating to this new service should be sent. Industrial organizations interested in the work should communicate with W. McAuley Gracie, chairman of the Standing Conference on Pest Infestation, Department of Scientific and Industrial Research, 16 Old Queen Street, London, S.W.1.

National Parks

THE winter number of the *Tree Lover* (3, No. 26, De la More Press, 2a Cork Street, London, W.1) includes an article on the case for national parks, which deals with the report of the Standing Committee on National Parks. In discussing this important question, many fall into the mistake of comparing Great Britain with Canada, the United States and other countries of the New and Old World of much larger size and with extensive tracts of wild, undeveloped countryside where great national parks or game reserves have been formed. These enthusiasts are apt to forget that Great Britain is, compared with such countries, a very small and densely populated island. This being said, the case for such national parks as are, or may be, feasible is a very strong one. As pointed out in the article in question, such a movement "falls in most signally with the aims of the Health Campaign on which the Government is at present engaged. If abundance of Playing Fields is essential for this, still more essential is the provision, or preservation, of national 'walking grounds', and regions where young and old alike can find refreshment and inspiration in the enjoyment of unspoilt Nature". The proposals of the Standing Committee on National Parks are well known. The chief question in connexion with these proposals is where the money is to come from. The suggestion is the Treasury. There is also a considerable body of influential opinion which considers that this question is one for the general public. That in fact if the public really want the national parks a fund should be opened to provide the money for their formation

and upkeep; that the British public will attach a greater value to, and have a greater interest in, the maintenance of national parks provided by their own endeavour than if they are more or less controlled by the Government and therefore nobody's child.

Meteorology for Airmen in India

A PAMPHLET of the India Meteorological Department, having the title "Meteorological Organisation for Airmen", brings up to date the information required by airmen in India who wish to take advantage of available information about actual and expected weather on the various aviation routes in that country. There are several classes of meteorological station in the organization that is concerned with meeting the demands of aviation, of which the most important are the forecasting centres where synoptic weather charts are prepared twice a day, namely, for civil aviation (Karachi, Calcutta and Poona), and for military aviation (Karachi and Peshawar). The India Meteorological Department is responsible for the aviation weather service on the trans-India route from the Gulf of Oman to Akyab, as well as along other internal air routes in India. The positions of the four types of meteorological station more directly concerned with the supply of information—the civil and military forecasting centres, the pilot balloon stations where the winds aloft are measured, and the aeronautical wireless stations—are clearly shown on a folding map. The codes for transmitting information about the weather have become more numerous in the course of years, in proportion as the information required has become more detailed and precise, and practically the whole of this pamphlet is taken up with them. Attention is directed in a foreword to a change instituted on July 1, 1937, which resulted from the establishment of an independent meteorological service in Burma. From that date the Calcutta Meteorological Office ceased to issue weather reports and forecasts for air routes in Burma and the 'general inference' for the Rangoon-Bangkok section, these being taken over by the Meteorological Office at Rangoon, but it has continued to issue reports and forecasts for the Calcutta-Akyab route.

"Earning whilst Learning" in American Universities

THE economic depression in the United States compelled university administrators and students to devise fresh plans for enabling poor undergraduates to pay their way. The Federal Government decided to help, not with scholarship grants but by financing work projects through the National Youth Administration. So new ways were discovered for using student labour and some proved so beneficial to all concerned that they became permanent. A summary of the more important is given in *Bulletin* No. 9 of the Office of Education (Supt. of Documents, Washington, D.C. 10 cents). This gives particulars of factories, printing-presses and other money-earning projects, of co-operative housing and other schemes for reducing students' living costs, and of the 'self-help' colleges which aim at making education as

nearly as possible self-supporting. These are described as strongly Christian in intent and influence, proclaiming the dignity of labour and the fundamental importance of training in heart and hand as well as head. Yale's bursary employment scheme, providing employment for more than four hundred of the residents in its new undergraduate hostels, is described in some detail. It is so popular that well-to-do students have applied for bursary work without stipend, because of the opportunities it offers for personal development. Harvard also has lately introduced an employment scheme in connexion with its new dormitories. The report emphasises the increasing recognition of the value of money-earning labour as a part of education, especially its contribution to character-building, and the advantages of co-operative living arrangements.

The Temporary Ley

THE Welsh Plant Breeding Station, Aberystwyth, has just issued a bulletin entitled "The Temporary Ley", price 7s. 6d. It is divided into four sections. The first compares the results obtained with station-bred and commercial grasses when used in simple mixtures. Although in the first year the commercial seeds gave the best yields, distinct advantages were shown by the station-bred varieties in the third year. Relative aggressiveness of the different species in a mixture is also an important point; timothy, for example, failing to become established when sown in conjunction with cocksfoot or perennial rye grass. Section 2 deals with the yield and persistency of different strains of grass and clover. Mixtures containing indigenous species gave both higher yields and better response to phosphatic manuring than those in which such species were in the minority or lacking. Pasture management and its effect on the sward is the subject of the third section. Swards differing widely in botanical composition were subjected to various systems of management, and it was found that the importance of a species is determined by the individual reaction of the plant to the type of management, as well as its ability to withstand competition from other components of the sward under those conditions. The final section consists of an article by Sir R. George Stapledon, director of the Station, on the establishment and maintenance of temporary leys. This will perhaps be of particular value to the agriculturist as it deals largely with the practical aspect of the question. Final emphasis is laid on the fact that success depends on the combination of a well thought-out seeds mixture with good management.

A Pioneer Garden Journalist

A SHORT chapter of garden history in the early eighteenth century is unfolded by Mr. W. Roberts, in a paper on Richard Bradley, F.R.S. (*J. Roy. Hort. Soc.*, 64, Pt. 4; April 1939). Bradley was the first professor of botany at Cambridge, and though he does not appear to have conferred much sound teaching upon his students, nor given academic dignity to the University, he was responsible for a series of

volumes which exerted considerable influence upon horticulture at that period. "A General Treatise of Husbandry and Gardening" was one of his greatest contributions, and forms the main subject of Mr. Roberts's paper. The text introduces "Such Observations and Experiments as are New and Useful for the Improvement of Land", and, indeed, Bradley's experiments represented his major contribution to horticulture, at a period when it was the fashion only to copy and quote. He states that his expenses in the study of the nature of plants and soils cost him upwards of £2,000, and he also travelled widely. Though his undertaking to establish a Botanical Garden at Cambridge did not flourish greatly, he distributed much garden knowledge of an exact order.

Earthing with Driven Copper Electrodes

A HUNDRED years ago, when electricity was usually generated by the use of frictional or Wimshurst machines and detected by gold leaf electroscopes, it was well known that an electric charge on a conducting surface could be dissipated by connecting the charged surface to earth. It is now found that owing to the increasing electric power behind modern networks, in order to get safe operation special attention has to be paid to the conductor connecting charged metallic objects to earth. Copper electrodes of small diameter cannot be driven with a sledge-hammer unless the ground be soft, as the rod will bend or the top will be deformed. The Copper Development Association of Thames House, Milbank, London, S.W.1, has published a booklet entitled "Copper for Earthing" which gives several useful hints on this problem. The most satisfactory method of driving copper electrodes into the earth is by means of an electric hammer which delivers a large number of light blows. The usual procedure is to choose the wettest or the most low-lying spot in the neighbourhood and drive a copper rod of small diameter into the earth to a depth of about eight feet. The earth resistance is then measured; if too high, several more rods can be driven in and connected in parallel. This is necessary for earthing mains where a possible fault current may be very large. The booklet points out that, even now, earth connexions are sometimes made by a few feet of conduit buried outside the house or under the floor in contact with a small iron plate or with the hot-water piping system. Sometimes even a large electric machine is earthed by binding the wire round a loose rock lying on the ground. In one case the earthing wire was found to terminate in a bottle of water!

London's Water in 1937

THE results of the chemical and bacteriological examination of the London waters for the twelve months ended December 31, 1937, are contained in the thirty-second annual report of the Metropolitan Water Board, recently issued (P. S. King and Son, Ltd., 14 Great Smith Street, Westminster. 10s. 6d.). Much of the report was drafted by the late director, Col. Marold, before his death last July, and the task

of completing it has fallen upon the deputy director, Mr. Denison Byles. The total average output from the works for the year was 310.79 million gallons per day. Of 22,000 routine samples examined bacteriologically, about 98 per cent were of first-class purity (absence of *Bact. coli* in 100 c.c.). Details are given of several researches carried out in the laboratories. In the Bacteriological Section, various methods for the isolation and identification of *Bact. coli* have been tested and compared. In the Biological Section, investigations into the algal flora of raw and stored waters have been continued. In the Chemical Section, a further account is given of the use of a new photo-electric turbidimeter. The chief analytical results for each month in the year of the several sources of supply are given in a series of tables.

The Brotherton Collection

THE third annual report of the Brotherton Collection Committee, University of Leeds, states that a beginning has been made in the work of valuing the Collection, case by case, and of cataloguing the uncatalogued books (University of Leeds: The Brotherton Collection. Pp. 4. Leeds: The University, 1938). A scheme has been drawn up for the purchase of new books, which would be confined to certain authors and subjects wherein the Collection is already strong, so that relative completeness could be obtained. The very extensive collection of pamphlets on Sheffield has been re-arranged. Mr. J. A. Symington, first keeper of the Brotherton Collection, relinquished that office on July 31, 1938, and on the recommendation of the Brotherton Collection Committee, the Council of the University of Leeds appointed Dr. Richard Offor, the University Librarian, to be Keeper of the Collection from August 1.

The Earthquake of May 10, 1939

FROM instrumental reports from Fordham, Georgetown, St. Louis, Victoria, Honolulu, Manila, Pasadena, Philadelphia, Chicago and Burlington, the U.S. Coast and Geodetic Survey has determined the epicentre of the earthquake of May 10 at 7h. 44^m. G.C.T. to be provisionally lat. 51° N., long. 179° W. This is to the south of the Andreanof Islands, which form part of the Aleutian Islands, and is on the circum-pacific ring of instability somewhat to the west of the epicentre of the great earthquake of November 10, 1938.

Conference on Photography

THE Manchester and District Branch of the Institute of Physics has arranged a Conference on Photography, to be held in the Physics Department, University of Manchester, on July 3 and 4, under the chairmanship of Dr. F. C. Toy. Among those taking part are Prof. N. F. Mott, Dr. J. C. M. Brantano, Dr. W. F. Berg, Dr. D. A. Spencer, Dr. S. O. Rawling, E. R. Davies, C. W. Bradley, Dr. J. G. Wilson, Dr. C. A. Adams and Dr. H. A. Bruck. The subjects to be discussed include the atomic physics of photography, colour photography, theories of developers, and

applications of photography in research. Further particulars can be obtained from Dr. W. H. Taylor, Physics Department, College of Technology, Manchester, 1.

Marine Biological Association

At the annual general meeting of the Marine Biological Association of the United Kingdom, Dr. George Parker Bidder was elected president of the Association in succession to Lord Moyné, who had held office for the past nine years. Lord Moyné, Lord Mildmay of Flete, and Sir Reginald Dorman-Smith were added to the list of vice-presidents. Mr. H. C. Maurice, Lord Rothschild, Mr. J. R. Norman and Mr. Morley Neale were elected new members of council.

Announcements

LIEUT.-COLONEL J. H. M. GREENLY has agreed to continue as president of the Institute of Fuel for a further year, and will deliver his second presidential address on October 19. The Council of the Institute has awarded the Melchett Medal for 1939 to H. A. Humphrey, late consulting engineer to Imperial Chemical Industries, Ltd., for the outstanding work he has done in the development of fuel and appliances in connexion therewith.

MARCO TIFFENEAU, professor of pharmacology and materia medica in the Faculty of Medicine, University of Paris, has been elected a member of the Section of Chemistry of the Paris Academy of Sciences, in succession to the late Prof. G. Urbain.

THE German Chancellor has awarded the Goethe Medal for Arts and Science to Prof. Ernst Rudin, professor of psychiatry in the University of Munich, for his work on German racial hygiene.

THE annual meeting of subscribers and friends of the Rothamsted Experimental Station, Harpenden, will be held on June 28, when the principal speaker will be Sir E. Kaye Le Fleming, chairman of council of the British Medical Association.

FOLLOWING the nineteenth annual general meeting of the British Non-Ferrous Metals Research Association on June 29, the Association's new laboratories in Euston Street, London, N.W.1, will be formally opened by the Right Hon. Oliver Stanley, president of the Board of Trade, and a memorial to Thomas Bolton will be unveiled.

THE *Internationale Zeitschrift für Psychoanalyse und Imago*, which was temporarily suspended, resumed publication in March 1939. The present address is 96 Gloucester Place, W.1, and the price 34 shillings.

ACCORDING to the figures issued by the Metropolitan Life Insurance Company, the average duration of life for men in the United States in 1936 was 60.81 years, or 1 year and 3 months longer than in 1930.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 1071.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Multiple Activities of Anhydro-oxy-progesterone

THE introduction of anhydro-oxy-progesterone (pregneninolone, ethinyl-testosterone) by Inhoffen and Hohlweg¹ and Ruzicka, Hofmann and Meldahl², and the demonstration by the former authors of its high progesterone-like activity when given by mouth, opens up the possibility of an important advance in endocrine therapy (see, for example, Zondek and Rozin³); but its multiple biological properties also make the substance of considerable theoretical interest.

In our experience, anhydro-oxy-progesterone, tested as described by McPhail⁴, is equally active by mouth and by injection in producing progestational proliferation in rabbits. A total of 5 mgm. in propylene glycol produced the same average response, when given by either route, equal to that given by about 0.5 mgm. of progesterone injected in oil solution. In addition to this strictly progesterone-like activity, the compound, unlike progesterone, will cause growth of the uterus of the immature or ovariectomized rat or mouse without previous treatment with oestrone, that is, it shows metrotrophic activity similar to that of oestrone or testosterone. Thus, injection to the spayed rat causes a mixed oestrone-like and progesterone-like effect. The capacity to produce an increase in uterine weight is about the same whether the substance is given orally or by injection, but there is evidence that oral administration results in progestational proliferation of the endometrium less complicated by oestrous changes than does injection.

In addition to the rather generalized gynaecogenic property of causing growth of the uterus of the immature or ovariectomized animal, anhydro-oxy-progesterone also seems to be oestrogenic in the strict sense that it will cause cornification of the vaginal epithelium of the ovariectomized rat or mouse. Fully cornified vaginal smears were produced by the injection of 2-4 mgm. to spayed rats, and 0.8 mgm. to spayed mice. When the substance is given orally, however, its activity on the vagina is lower, since 4 mgm. produced only a little cornification in the presence of leucocytes in some rats, while 1.6 mgm. did not cornify the vagina of the mouse. Vaginal opening in the rat was also less frequent in animals receiving oral doses than in those receiving equal amounts by injection.

In the capon comb-growth test, anhydro-oxy-progesterone shows weak androgenic activity. Tested on groups of five Brown Leghorn capons, 30 mgm. by mouth produced an average increase in length plus height of 3.5 mm.; 30 mgm. by injection produced an increase of 4.6 mm., equal to that produced by about 0.5 mgm. (5 I.U.) of androsterone. By injection on to the comb, 0.15 mgm. produced an average increase of 2.2 mm.

Of the activities of anhydro-oxy-progesterone investigated, therefore, only its effects on the rodent vagina appear to be less when the substance is given orally than when it is given by injection. In addition to this remarkable activity by mouth, anhydro-oxy-progesterone seems to be the only compound so far described which possesses progesterone-like, metrotrophic, androgenic and oestrogenic properties.

Nicotinic Acid Requirements of Insects: a Biological Test for Nicotinic Acid

THE importance of vitamin B for the growth and development of insects has been stressed by several investigators. But very little is known of the ingredients of the vitamin B complex which are actually required by the insects.

We have found that the moth *Galleria mellonella* can be cultivated on a medium containing one part of yeast and two parts of wax. It was noted that purification of the wax and autoclaving of the yeast in a strongly alkaline solution at 130° during a lapse of time which is sufficient to destroy both the vitamins B₁ and B₂ (riboflavin) does not impair the normal development of the insect. However, its development is stopped if the autoclaved yeast is thoroughly washed with water and alcohol. Upon addition of the aqueous or alcohol yeast extract the development is resumed.

It follows from our experiments that nicotinic acid exerts the same favourable effect as the yeast extract. Nicotinic acid can thus be identified with the vitamin B-component which is indispensable for the development of *Galleria*. This does not certainly imply that vitamins B₁ and B₂ have no influence whatever¹. Since our experiments were not carried out in sterile conditions, the possibility remains open as to the production of these vitamins by some micro-organisms. Anyway, as a matter of fact, no development did take place in the absence of nicotinic acid.

Further experiments have shown that as small a dose as 5-10 γ nicotinic acid per 100 gm. of the medium lacking vitamin was sufficient to produce the above effect. After 8-10 days there were no living larvae left in the medium lacking nicotinic acid, whereas big, well-developed larvae were creeping about

- in the medium with the above-mentioned dose of nicotinic acid. Smaller doses (1 γ) proved insufficient and gave inconstant results.

Thus the development of the newly hatched *Galleria* larvae can serve as a most sensitive biological test for detecting minute quantities of nicotinic acid.

Radiations from Radiomanganese

- THE radiations from radiomanganese, ⁵⁴Mn, have been investigated by various experimenters and, as a result, it has been concluded that a γ -ray of energy 1.7 Mev. is present, together with a complex spectrum of negative electrons. This spectrum has been analysed into partial spectra with maximum energies 1.2 and 2.9 Mev. respectively.

I have made, recently, single counter absorption measurements¹ of the β -particles from this body and coincidence experiments utilizing β - γ ¹ and γ - γ ² coincidences in turn. The β -absorption measurements confirm the upper energy limit deduced by previous authors, and are consistent with a β -particle spectrum composed of the above two partial spectra in the ratio of 0.40 : 0.60.

The β - γ coincidence experiments show a correlation of all β -particles with γ -rays. In Fig. 1 are plotted, logarithmically, the β - γ coincidence rate per quantum detected by the γ -counter (curve a), and the β -absorption curve (b). The curves are closely parallel beyond an absorption thickness of 240 mgm. per sq. cm., and the former has been scaled so as to be superimposed on the latter in this region. The coincidence rates are explicable in terms of a γ -ray of 600 kev. ($\pm$ 50 kev.) following the β -particles in the harder partial spectrum and a γ -ray of 2.5 Mev. following those of the softer spectrum. These coincidence experiments yield, directly, an upper limit of 1.1 Mev. for the softer β -partial spectrum.

The γ - γ coincidence experiments, on the other hand, demonstrate the successive emission of two γ -rays by some of the excited ⁵⁴Mn nuclei. The γ - γ coincidence rate obtained can be explained quantitatively by the assumption that the softer

Fig. 1.

Fig. 2.

LEVEL SCHEME FOR DISINTEGRATION OF RADIOMANGANESE

Figures in brackets represent intensity of radiations per disintegration

β -particle spectrum is associated with two γ -rays of energy 1.7 Mev. and 600 kev., emitted in cascade, this assignment of energies being chosen, in preference to any other pair giving the same γ - γ coincidence rate, since the efficiency of detection of a 1.7 Mev. γ -ray together with that for a 600 kev. ray is equivalent to that for a γ -ray of 2.5 Mev.¹, and the β - γ -coincidence rate is thereby uniquely explained.

The level scheme shown in Fig. 2 is therefore obtained. It predicts a γ -ray of energy 600 kev. of 2.5 times the intensity of the harder γ -ray. The presence of this γ -ray (of 600 kev.) has been confirmed by Ward (of this Laboratory) using a pressure ionization chamber. At the same time, it has been shown that there is no appreciable intensity of the γ -ray transition shown dotted in Fig. 2.

Apparent Existence of a Very Penetrating Radiation from Radium and (Radium + Beryllium)

A few years ago, one of us¹ observed a very penetrating radiation emitted by a strong source of radium, having an absorption coefficient in lead of about $\mu = 0.03$ cm.⁻¹. We have recently reinvestigated this phenomenon, as there were grounds for supposing that the radiation might consist of mesotrons. The arguments in favour of this view may be summarized as follows:

Mesotrons may be formed, according to Heitler², in processes such as:

$$h\nu + {}^1_1\text{H} \rightleftharpoons M_+ + {}^1_0n,$$

$$h\nu + {}^1_0n \rightleftharpoons M_- + {}^1_1\text{H},$$

provided that $h\nu$ is greater than 10^8 ev. It is now known that energies greater than 10^8 ev. are liberated during the 'fission' of heavy nuclei. The absorption coefficient of mesotrons in lead is $\mu = 0.03$ cm.⁻¹, which is similar to that of the unknown radiation referred to above.

Further, Joliot and Kowarski³ found some very energetic tracks in a Wilson cloud chamber from silver bombarded with neutrons, while more recently Mouzon, Park and Richard⁴ have reported a few straight β -ray tracks in a cloud chamber ($H = 1,500$ gauss) from uranium bombarded with neutrons.

These facts, taken together, suggested that the observed penetrating radiation from radium might consist of mesotrons emitted occasionally during the breakdown of radium atoms under neutron bombardment⁵.

To test this hypothesis, measurements were made on the radiation from a source of 900 milligrams of (radium + beryllium), by means of a Geiger-Müller counter, made of brass 1 mm. thick, having a diameter of 5 cm. and length of 15 cm., filled with air at a pressure of 7 cm. mercury. Source and counter were each surrounded on all sides by 30 cm. of lead, and space of 50 cm. left between them for insertion of absorbing screens.

A large count, about 250 impulses per minute above the background, was obtained with the 900 mgm. (radium + beryllium). When the latter source was replaced by a 600 millicurie (radon + beryllium) source (having almost the same neutron output), the same large effect was still obtained, showing clearly that the phenomenon was independent of the presence of radium atoms.

A small count was, of course, to be expected from the neutrons from the sources, but not one of this order of magnitude.

The Geiger-Müller counter was then replaced by an air ionization chamber of the same dimensions, connected to a linear amplifier, but no particles were detected having an ionization greater than about one sixth of a polonium α -particle, namely, approximately 20,000 ions.

Absorption measurements in lead gave a coefficient $\mu = 0.03 \text{ cm.}^{-1}$, in agreement with the earlier findings. This value is the same, however, as that found by Goldstein and Rogozinski⁶ for the absorption of neutrons in lead. We therefore decided to eliminate drastically all possibility of neutrons reaching the counter by putting the source, with its lead protection, inside the 'water room' surrounding the cyclotron in the Collège de France. The water tanks are 1 m. wide and 4 m. high, and the ceiling is also covered with 50 cm. of water. Under these conditions, a count of 15 impulses per minute per curie above the background was obtained, which was surprisingly large in view of the small solid angle subtended by the counter. By emptying progressively the water tank between source and counter, the counting rate steadily increased. The maximum rate was calculated to correspond to about 1 impulse per 500 neutrons reaching the counter. Finally, the tank was refilled, and the lead protection of the counter covered with a layer of boric acid 1 cm. thick to absorb slow neutrons. When all neutrons were thus prevented from reaching the counter and its lead screens, the count from 1 curie of (radon + beryllium) diminished practically to zero.

The supposed penetrating radiation from radium and (radium + beryllium) was therefore due entirely to gamma-rays excited by neutrons in the lead protection round the counter, in the brass wall of the counter, and in the air inside it.

Grateful acknowledgments are made to the Union Minière du Haut Katanga for the loan of (radium + beryllium) sources, to the Britannia Lead Company, Ltd., for the loan of eight tons of lead ingots,

to Imperial Chemical Industries, Ltd., for the loan of two tons of lead shot, to the authorities of the Radium Institute for the use of an underground room, and to the Middlesex Hospital and the Radium Institute for (radon + beryllium) sources.

Forbidden Transitions in Nitrogen

It has been possible to observe the forbidden transition $^3D \rightarrow ^4S$ in atomic nitrogen by a method similar to the one which led to an unusually large relative intensity of the green auroral line¹. The essential part of the method is the weakness of the discharge which generates the afterglow.

The first such observations on the high-pressure nitrogen afterglow led to the remarkable enhancement of the $^3P \rightarrow ^4S$ line at $\lambda 3466.4$. When the experiments were repeated, using panchromatic plates, the weaker nebular line at approximately 5200 Å. appeared. No exact wave-length measurements have been made; but approximate measurements indicate clearly that the new line in the green is the expected nebular line². The afterglow in which this line appeared was produced in a small quartz bulb of about 150 c.c. capacity and the pressure was about 30 mm.

A number of experiments during the past year indicate that high pressures and small volumes are favourable for the production of forbidden transitions. The absence of first-positive bands, especially those which are expected on the basis of collisions between metastable atoms and molecules of nitrogen³, is surprising and may mean that either the number of metastable entities is extremely small or that collisions of the second kind between metastable entities are highly improbable.

Further experiments are in progress in order to clarify these points.

Distribution of Fluorescence Excitation of Bivalent Europium in Calcium Fluoride and of Bivalent Samarium in Calcium Sulphate

In an earlier communication¹, it was mentioned that prolonged treatment of rare earth preparations with short-wave ultra-violet radiations produces an effect similar to that obtained with radium rays.

The accompanying reproductions show the effect very distinctly. In all cases the same preparation of calcium sulphate with 10^{-6} samarium was used. The photographs were taken on material sensitized in each case for the required range. A shows the untreated preparation reflecting the light of the mercury vapour lamp. B and C were taken after the preparation was treated for 30 hours with light of the wave-length 240 m μ . The bands then were excited by illuminating with filtered ultra-violet. In C at the left of the band which extends from 689 m μ to 734 m μ also the band at 630 m μ can again be recognized as in B.

The mercury lines marked are those at 405, 436, 546, 577 m μ .

Similarity of the X-Ray Patterns of Tanned and Mechanically Deformed Collagen Fibres

THE X-ray pattern of the collagen of animal skin has been shown^{1,2} to undergo a characteristic alteration on combination of the collagen with various tanning agents. As seen in patterns produced by the ordinary technique (a mass of fibres of random orientation; unfiltered copper radiation; specimen to film distance of from two to five centimetres), this alteration consists of a remarkable diffusion of the originally sharp 'inner' ring (the side-chain spacing of 10-12 Å.). The resultant diffuse halo extends clear into the central spot, and the periphery of the ring loses its original sharpness. In addition to this, the 'outer' ring (the unit backbone spacing of 2.9 Å.) becomes greatly diminished in intensity, and in extreme cases disappears completely. The extent of these changes depends upon the proportion of the tanning agent combined with the collagen, the effect being more pronounced with higher tannin fixations.

It has been suggested^{3,4} that they are due to a distortion of the protein grid, caused by the penetration into the grid of the large molecules or molecular complexes of the tanning agent. In agreement with this hypothesis, it is found that the greatest effect on the pattern is produced by those materials which are of relatively large molecular size and complexity, such as the natural vegetable tannins and the basic chromium salts, while substances of a simpler nature and presumably smaller molecular size produce little or no effect. Formaldehyde and certain synthetic tannins are in the latter group. An exception to this rule is apparently found in quinone, which produces

an effect very similar to that of the larger tannin molecules. This may possibly be explained by a polymerization of the quinone in the alkaline solutions necessary for tannage with this substance.

We have now found that collagen which has been subjected to treatments calculated to produce mechanical deformation of the fibrils shows an X-ray pattern practically indistinguishable from that described above for tanned collagen. In carrying out these experiments, the mass of collagen fibres is first compressed into a coherent disk in a hydraulic press. This is the method we ordinarily use in preparing samples of powdered fibrous collagen for X-ray photography, and such treatment does not change the pattern in any perceptible way. Several such disks are then passed, under great pressure, between the rollers of a machine designed for rolling metal wires. The flattened disks are again reduced to the powdered state by passing through the Wiley mill, and from this powder a disk of the same weight and thickness as the original is formed in the hydraulic press. The pattern obtained from this disk, when compared on the same film with the pattern from one of the original unrolled disks, shows all the changes the characteristic features of which have been noted above. The intensity of the effect increases with additional rollings. We have also found that the same effect can be obtained merely by prolonged grinding of the collagen in the Wiley mill, where the material is subjected repeatedly to the shearing action of the knives.

These experiments have been carried out with purified collagen prepared from ox skin, and also with the tendon Achilles of the ox. Further details will be published elsewhere.

Magnetism and Polymerization

THE graphs below refer to results we have obtained for the magnetic susceptibility of dimethylbutadiene at the commencement of polymerization. Fig. 1 is for the mass susceptibilities of samples of dimethylbutadiene distilled and sealed in nitrogen, and polymerized in the dark by heat at a temperature of 140° C. Fig. 2 is for a similar treatment of

Fig. 1.

—□— Dimethylbutadiene sealed in nitrogen.
—△— " + 1% benzoyl peroxide.
—○— " + 2% benzoyl peroxide.

Fig. 2.

- Dimethylbutadiene sealed in *vacuo*.
 —Δ— " + 0.5% benzoyl peroxide.
 —▽— " + 1.0% benzoyl peroxide.

dimethylbutadiene distilled and sealed in *vacuo*. It will be noticed that in the absence of catalyst there is a fall in diamagnetism over the first three hours and that thereafter there is a progressive rise in diamagnetism as is to be expected¹.

We consider that measurements of this type will throw light on the nature of the induction period in polymerisation reactions. Induction periods have been identified with the time of formation of polymerisation nuclei; thereafter the polymerisation proceeds as a chain reaction². It is probable that the polymerisation nuclei are activated molecules, and the simplest assumption to make is that they are free radicals. This would explain our magnetic result, as such free radicals would necessarily be paramagnetic, and their formation in the dimethylbutadiene would result in a fall in diamagnetism.

If the first series of results be examined further, it will be noticed that the initial fall in diamagnetism is in the neighbourhood of 13.6 per cent. It is possible to calculate the concentration of free radicals which would give this lowering if the assumption be made that the free radicals are of the type of dimethylbutadiene with one free electron. The mass susceptibility of dimethylbutadiene by this series of measurements is approximately -0.75×10^{-6} . In a paramagnetic molecule with one free electron³, the paramagnetic contribution to the molecular susceptibility is theoretically 1270×10^{-6} . The diamagnetic contribution in this case is -61.5×10^{-6} . The mass susceptibility of such a molecule will thus be 0.133×10^{-6} . The concentration of free radicals of this type necessary to lower the mass susceptibility of dimethylbutadiene by 13.6 per cent can now be calculated to be 0.10 mols per cent.

If the concentration of catalyst necessary to give a smooth curve be now considered, it is evident that this must be less than 1.0 per cent by weight, or, if the results for the material sealed in *vacuo* be considered, it lies somewhere between 0.5 and 1.0 per cent by weight, for there still seems to be a lowering of diamagnetic susceptibility with 0.5 per cent catalyst in *vacuo*. It is thus necessary to have a concentration of catalyst somewhere between 0.17 and 0.34 mols per cent to give a smooth curve. If we consider that all the molecules of accelerator are active in promoting the polymerisation, it is a significant fact that the concentration of active centres calculated from the magnetic result should lie so near the concentration of the catalyst.

'Acidity' of Quartz

WHEN quartz powder, obtained by finely grinding pure Brazilian pebble, is put into neutral water the pH is rapidly lowered to about 6.4. This acidity has been attributed to silicic acid, but such an explanation seems unlikely for the following reasons.

Pure quartz has an extremely low solubility in water free from carbon dioxide, namely, only a few parts per million at room temperature, and the rate of solution would not be great enough to cause the acidity produced. Further, the dissociation constant of silicic acid¹ is very small (about 10^{-10}) and there is doubt whether the behaviour of silicic acid can be represented in terms of dissociation constants². Silica sol prepared under conditions where adsorption of hydrogen ions is impossible is quite neutral³. Hence the acidity rapidly imparted to water by quartz dust is probably not due to silicic acid, and it is suggested that carbon dioxide adsorbed on the quartz is responsible for the effect.

Samples of the quartz dust were heated to about 300° C. in *vacuo* until the evolution of gas ceased. After cooling in *vacuo*, these samples were quite without effect on the pH of neutral water. An approximate computation showed that the quantity of gas evolved (all of which may not have been carbon dioxide) was ample to account for the observed acidity. The addition of pure sodium chloride (itself quite neutral in water) increased the acidity of the quartz dust-water system. This is also consistent with the view that the acidity is due to carbon dioxide, for the presence of sodium ions lowers the bicarbonate ion concentration, thus increasing the fraction of the dissolved carbon dioxide that is present as carbonic acid, with a consequent increase in the hydrogen ion concentration.

Chelate Structure of *o,o'*-Dioxyazobenzene in Solution

THE idea that the *o*-oxyazo compounds have the chelate structure is now quite convincing. It is supported by much chemical and physical evidence, such as the slight acidity, anomalous chemical reactivities referred to phenolic hydroxyl, small association factor, slight solubility in polar solvents, molecular refraction data, absorption spectra, etc. The strongest support for the chelate structure was found by Hendricks and others¹ in the study of infra-red absorption spectra in carbon tetrachloride solution. On similar grounds they concluded from the absence of the absorption band at $c. 1.4\mu$ corresponding to the first overtone of hydroxyl vibration that *o,o'*-dioxyazobenzene has the doubly chelated *trans-trans* configuration as (1). From the chelation of both the hydroxyl groups in (1), it may be expected that the *o,o'*-dioxyazobenzene, like the *o*-mono-oxyazo compounds, is very slightly acidic. But the former is actually found to be very easily soluble in weak alkali. It may therefore be supposed that the chelate structure of the *o,o'*-dioxyazobenzene is

somewhat different in character from that of the *o*-mono-oxyazo compounds.

Comparison of the absorption spectra of *o,o'*-dioxazobenzene and the mono-methyl ether of its homologue has now shown, as seen in the accompanying graph, that both substances in alcohol give almost the same absorption curve in the whole measured range of the visible and ultra-violet, whereas in carbon tetrachloride they show quite a notable difference. It has been observed² that the absorption spectra of substances having the inner molecular chelate ring structure such as *o*-oxyazobenzene, *o*-oxybenzaldehyde, etc., are generally affected only very slightly by polar solvents, which is now also confirmed with the *o'*-methoxybenzeneazo-*p*-cresol. The exceptional behaviour of the *o,o'*-dioxazobenzene cannot therefore be explained otherwise than as follows: In alcoholic solution the *o,o'*-dioxazobenzene, being stabilized through solvation by the polar solvent molecule, has the structure (II),

similar to that of the mono-methyl derivative (III), with one non-chelate phenolic hydroxyl group, which satisfactorily explains the enhanced acidity or the solubility in weak alkali. The marked displacement observed in carbon tetrachloride, especially of the first absorption band at longer wave-length ($\lambda_{\max}$ at about 400 $m\mu$), is due to the change of the structure, namely, the chelation of the second hydroxyl group in this solvent, in agreement with the conclusion of Hendricks and others³. On the other hand, the *o'*-methoxybenzeneazo-*p*-cresol cannot undergo such a change, so that its spectral behaviour remains normal.

In accordance with this result, the *o,o'*-dioxazobenzene does not combine with dry ammonia in a non-polar solvent such as benzene, carbon tetrachloride, etc., which is in fact the characteristic property of the *o*-oxyazo compounds⁴, whereas in a polar solvent such as alcohol, salt formation occurs very easily.

From the above spectroscopical evidence, it is concluded that the chelate structure of the *o,o'*-dioxazobenzene is rather mobile in comparison with that of the *o*-mono-oxyazo compounds, and that it undergoes with relatively small activation energy the reversible change (I) $\rightleftharpoons$ (II), which is the cause of its enhanced acidity and its marked tendency to the formation of metallic lakes.

A detailed discussion on the structure of the *o,o'*-dioxazo compounds and their alkali salts will be published elsewhere.

The So-called 'Colonial Nervous System' in Bryozoa

It was already shown by Darwin¹ that vibracula of all the members of a Bryozoan colony are capable of synchronous movement. This and similar phenomena regarded by Müller (1860) and Hinck (1880²) as being due to the action of the "colonial nervous system" are now usually ascribed to a reaction of each member of the colony to a stimulus transmitted through a non-nervous route.

It was shown, however, by Gerwerhagen (1913³) that in *Cristatella* the colonial wall is provided with a nerve plexus which is connected with nerves of tentacle sheaths of individual polypides. Gerwerhagen regarded this plexus as a motor one. Marcus (1926⁴) considers this plexus as being both motor and sensory. Moreover, he has demonstrated experimentally the transfer of stimuli from one polypide to another both in *Cristatella* and *Fredericella*.

So far, the nerve connexions and transmissions of stimuli from one member of the colony to another have been demonstrated only for the representatives

of Phylactolemmata. In Gymnolemmata, on the other hand, such nerve connexions have not yet been detected, and Marcus as well as other workers considers these organisms as being also devoid of nervous stimuli transmissions between the individual members of the colony.

While studying the nervous system in *Membranipora crustulenta* and *M. pilosa*, I found in the cystid wall of each zoecium of these Bryozoa a nervous plexus composed of small nerve cells and long fibres. In *M. pilosa* this plexus forms a single thread winding along the internal wall of the zoecium. This plexus sends nerve fibrils which penetrate through the pores of the anterior and posterior walls and the pores in the communication plates of the side walls into the neighbouring zoecia, where they are connected with analogous plexuses (see accompanying drawing of zoecium of *M. pilosa*; r.p.n., c.p.n.). These plexuses are connected with the nerve fibres of the tentacles which run along

their basal surface (*t.s.n.*). Thus, each plexus is connected with the central nerve ganglion (*g*) of its own polypide as well as with similar plexuses of the polypides of neighbouring zoecia. In *M. crustulenta* the plexus forms a nerve-net in the basal wall of the cystid.

I have also found that the polypides frequently react in groups to the stimulation of the frontal cystid wall, especially in the region of the operculum.

COLONIAL NERVE PLEXUS (= SMOOTH LINE) AND A PORTION OF THE INDIVIDUAL NERVOUS SYSTEM (= DOTTED LINE) IN *Membranipora pilosa*, AS SEEN FROM THE BASAL SURFACE.

g, ganglion; *c*, connexions of the nerves of the tentacle-sheath with the circular colonial nerve plexus; *t.s.n.*, basal nerve of the tentacle-sheath; *lc.pl.*, side trunk of the colonial nerve plexus; *lc.pl'*, a similar trunk belonging to neighbouring individual; *r.pl.n.*, nerve fibre penetrating through communication plate; *c.p.n.*, fibres penetrating through pores; *p.m.n.*, nerve of the parietal muscles; *v.n.*, visceral nerves.

I think therefore that the nerve plexus described above is responsible for the transmission of stimuli from one zoecium to another.

The occurrence of such a system not only in Coelenterata (Parker, 1920¹) but also in more highly differentiated animals such as Bryozoa is a fact of general biological interest.

Distribution of *Rathkea*

THE genus *Rathkea*, one of the Anthomedusae, is represented on the Atlantic coast of North America by three species: (1) the widely distributed *blumenbachii*, (2) the northern *octopunctata*, and (3) the southern *elegans*. The species *octopunctata* is widely distributed in the North Atlantic¹, being found off the coasts of Norway, Barents Sea, Heligoland, the British Isles and New England. Fewkes² noted the presence of *octopunctata* in Narragansett Bay and stated that it is common off the New England coast in March. A well-marked variety of *octopunctata*, namely, *grata*, A. Agassiz, is confined to the Atlantic coast of North America, where, according to Mayer³, it is common north of New Jersey.

On December 16, 1938, a dozen specimens of *Rathkea octopunctata*, var. *grata*, were found in the mouth of the Patuxent River at Solomons Island, Maryland. The number increased greatly during the week following until by December 22 more than a thousand individuals were collected in a fifteen-minute plankton tow. This surface tow was taken with a No. 6 net twelve inches in diameter, and covered a linear distance of about seven hundred feet in water less than ten feet in depth. After nine days, December 25, the number of *Rathkea* began to decrease, and by December 29 only occasional specimens were observed.

An examination of the specimens of *Rathkea* collected on December 22, 24 and 29 shows several points of interest as regards certain taxonomic characters. The endoderm of the tentacle bulbs and the manubrium varied from a deep brilliant orange to a bright red in colour. The bell was more nearly dome-shaped than pyriform in many individuals. The bell measurements ranged from 1.4 mm. to 4.0 mm. in height and from 0.8 mm. to 3.7 mm. in width. The number of tentacles present in the four radial clusters varied from three to five each, while the number in the interradial clusters varied from one to three each. The marginal tentacles were from one and a half times to twice as long as the height of the bell, and were carried out and upward in swimming.

More than three fourths of the total number of medusae examined bore medusa buds on the interradial of the manubrium. About one half of the specimens had two or three medusa buds and thirty individuals had four, one in each interradius. The medusa buds were as large as, or larger than, the manubrium of the parent medusa, and all had at least one tentacle in each of the radii. A few were noticed that possessed two tentacles in the radii.

The conditions under which this form occurred should be noted. The salinity during the latter half of December varied from 13.30 per mille to 15.45 per mille. Corresponding values for the previous month were above normal, ranging from 17.02 per mille to 17.64 per mille. Dissolved oxygen values during the period in question ranged from 7.32 to 8.27 c.c. per litre in contrast to values of 5.40 to 7.40 during November. Temperatures during the December period were characteristically low, ranging from 2.5° to 5.9° C., and represent a contrast to the high values (7.20°–14.6° C.) prevailing between November 17 and December 16. Two factors, the high salinity of November and the low temperature of December, may be of importance in explaining the presence of *Rathkea* in waters south of its normal range.

A possible explanation for the sudden decrease in numbers of *Rathkea* may be found in observations made on *Cyanea* which were collected on December 30. Analysis of the stomach contents of these specimens disclosed the presence of *R. octopunctata* var. *grata* in abundance. As high a number as eighty-four were found in one *Cyanea*, which measured 8.3 centimetres in diameter. Further stomach analysis of each of the *Cyanea* revealed the presence of numerous fragments of *Rathkea*, including medusa buds, marginal tentacles, manubria and pieces of the bell.

Sound Absorption of Snow

I HAVE only just seen the letter of Messrs. Kaye and Evans on "Sound Absorption of Snow" in *NATURE* of January 14, p. 80.

During my expedition to the Jungfrauoch last summer, we had interesting evidence of the absorptive capacity of snow in a shaft which we dug in the firn. By the time this had reached a depth of about 35 ft., it was impossible for those at the top to hear the words of the men working below, even if raised in a shout, and it became necessary to signal, even at this small depth, by means of a bell.

Points from Foregoing Letters

THE biological activity of anhydro-oxy-progesterone when given by mouth has been further tested by C. W. Emmens and A. S. Parkes, who find that it has metrotrophic, androgenic and oestrogenic properties. It causes cornification of the vaginal epithelium of the ovariectomized rat or mouse and progestational proliferation of the endometrium, to a somewhat less extent than when given by injection, but is equally effective in producing an increase in the weight of the uterus.

It is stated by D. Rubinstein and L. Shekun that nicotinic acid is indispensable for the development of the moth *Galleria melonella*. As a very small dose of nicotinic acid, that is, 5-10 γ per 100 gm. of the deavitaminated medium is required, the development of the newly hatched *Galleria* larvae can serve as a most sensitive biological test for detecting minute quantities of nicotinic acid.

The radiations from radiomanganese, ⁵⁴Mn, have been investigated by J. V. Dunworth using the coincidence method. β - γ and γ - γ coincidence measurements together with single counter β -absorption measurements enable a consistent level scheme to be suggested. An additional γ -ray of 600 kev. of high intensity was predicted and its presence in the ⁵⁴Mn spectrum has been confirmed by A. G. Ward using a pressure ionization chamber.

In following up earlier work suggesting the emission of mesotrons from (radium + beryllium), M. E. Nahmias, F. L. Hopwood, T. E. Banks, W. H. Ramm and L. G. Grimmett find that the observed effects were due to gamma-rays excited by neutrons in the lead protection of the Geiger-Müller counter.

The nebular line at 3486.4 Å. in atomic nitrogen has been observed by J. Kaplan in a high-pressure afterglow in nitrogen. The unusually high relative intensity of the forbidden lines appears to be characteristic of afterglows which are generated by weak discharges. The weaker nebular line at 5200 Å. appeared on panchromatic plates.

H. P. Eckstein has shown that by irradiation of rare earths with short-wave ultra-violet a result can be obtained which is comparable to the effect of radium treatment. The trivalent samarium originally

present shows after irradiation the characteristic bands of divalent samarium produced by radium treatment.

J. H. Highberger and H. J. Kersten find that collagen fibres (prepared from the skin or the tendon Achilles of the ox), after they have been subjected to strong mechanical deformation by rolling or prolonged grinding in the Wiley mill, show an X-ray pattern practically indistinguishable from that obtained with tanned collagen fibres.

J. Farquharson and Miss P. Ady find from measurements of the magnetic susceptibility of dimethylbutadiene, as it polymerizes, that in the complete absence of accelerator there is an induction period during which there is a fall in diamagnetism, probably due to the formation of paramagnetic centres in the dimethylbutadiene. On calculating the concentration of such centres, it is found to be the same as the concentration of catalyst necessary to give a smooth curve.

G. Van Praagh finds that quartz dust which has been heated to 300° C. *in vacuo* does not affect the pH of neutral water, and suggests that the acidity usually observed is due to adsorbed carbon dioxide.

From observations on the absorption spectra in alcohol and in chloroform, Haruo Shingu concludes that the chelate structure of *o,o'*-dioxynobenzene is rather mobile in comparison with that of the *o*-monooxyazo compounds. It undergoes readily a reversible change which gives it an enhanced acidity and a marked tendency to the formation of metallic lakes.

S. Hiller has demonstrated in *Gymnolemmata* the existence of nerve connexions and transmissions of stimuli from one member of a colony to another. This shows a more general occurrence of such a system in Bryozoa.

The presence of the northern variety of *Anthomedusa Rathkea octopunctata* as far south as the mouth of the Patuxent River, Maryland, is ascribed by R. A. Littleford to the unusual low temperature, and to the high salinity in the previous month. The medusae decreased in number due to the predatory activities of *Cyanea*.

Research Items

Dental Caries in the Punjab, Northern India

A RECENT diet and health survey of the Kangra District, Punjab, Northern India, carried out by the Public Health Department and Dr. D. Curjel Wilson, has shown a high incidence of rickets and osteomalacia, and definite vitamin D, calcium, and phosphorus deficiencies in the diet of the population. Fifty children with rickets were examined clinically and dentally by G. F. Taylor and C. D. Marshall Day (*Brit. Med. J.*, May 6, 1939). A radiological examination of ten subjects showed that four had no caries, and in the remaining six, fourteen cavities only were found—an average of 1.4 cavities per head. In 96 temporary and 135 permanent teeth, two cavities were in the temporary, and twelve in the permanent teeth. The children came from a hill district and live in primitive conditions, the diet consisting mainly of carbohydrates, with relatively small proportions of protein and fats. Meat and fruit are almost entirely absent; and very small quantities of milk and vegetables are consumed. Sugar is rarely eaten. Two meals a day only are taken, of rice and chapattis made from home-ground flour. Rickets and osteomalacia are common. It is concluded that vitamin D deficiency alone does not cause either dental caries or hypoplasia of the teeth. The low incidence of dental caries and the excellent teeth and jaw formation are characteristic of the peasant of the Punjab, and have not been seen equalled by the authors in either Great Britain or America. An investigation of the teeth of 800 school children of the middle class in Lahore, having a diet more in keeping with European standards, including soft carbohydrates and sugar, showed an average of 6 cavities per head. The evidence appears to lend support to the 'detergent' theory of Sir Wallace, which postulates that the physical nature and cleansing action of the diet is more important than other factors in the promotion of dental caries.

Parthenogenesis in Vertebrates

A RECENT issue of the valuable series of monographs "Actualités Scientifiques et Industrielles", No. 651 (Hermann et Cie., Paris) falls into the group dealing with "Biologie et Reproduction" and has been written by the editor of the group, Jean Rostand. Parthenogenesis in invertebrate animals is well known and a usual method of multiplication in not a few species; but it is less often recognized that natural parthenogenesis of a limited kind occurs among fishes and batrachians, is in varying degrees a regular occurrence in the unfertilized ova of birds, and has long been known in mammals, both in ovarian and free ova. The phenomenon is generally confined to a rudimentary segmentation, limited in extent and, as in birds, proceeding more slowly than the segmentation which follows fertilization, although conforming with it in its general lines. The discovery of natural parthenogenesis led to the development of artificial parthenogenesis and this, particularly amongst batrachians, has led to a long series of experiments in which a wide variety of physical and chemical activators has been studied. The 62 pages of "La Parthénogénèse des Vertébrés" give a succinct account of present knowledge of both natural and

artificial parthenogenesis, and point to gaps which future investigation might profitably endeavour to close. For example, no success has attended attempts to prolong the natural parthenogenesis which is normal in ova of domestic fowls, nor has anything been done here to test artificial activators. Amongst reptiles no positive evidences have yet been discovered of parthenogenesis, natural or artificial.

Cactus-feeding Moths of the Family Phycitidae

A SMALL Argentine moth (*Cactoblastis cactorum*) of the above family has largely saved a great area in Australia from being converted into desert owing to the spread of prickly pear. Plants of this kind are common over the United States, Mexico and South America, where they are kept more or less under control by various insects and by competition with other plants. Nearly half a century ago a few prickly pear plants were introduced into Australia from North America and were intended solely for gardeners. The continent had no indigenous cacti and these few examples proved to be the progenitors of millions which ran wild. The invasion is now a matter of common knowledge, and by 1925 more than sixty million acres in Queensland were rendered useless by prickly pear. After almost every possible method of control had been considered or exploited, salvation came in the form of the inconspicuous small moth *Cactoblastis*, the larval activities of which eventually reduced the prickly pear to a state of real control, and fifteen million acres are now available for settlement and cultivation which had previously become completely useless. Various Lepidoptera have larvae which feed upon cacti, and many of them belong to the family Phycitidae. These have recently been classified by Carl Heinrich, senior entomologist of the U.S. Bureau of Entomology and Plant Quarantine (*Proc. Nat. Mus.*, 86, 331-413; 1939). This information is now available for Australian and other entomologists. So far as is known, it is only the species *C. cactorum* that is really effective as a controlling agent under Australian conditions. The other species caused but little effect on the plant, mainly, perhaps, because their larvae feed scattered in an individual fashion, whereas those of *C. cactorum* feed in companies and may amount to many thousands on a single plant. Altogether there are no fewer than eighteen genera, including nearly fifty species of Phycitidae, the larvae of which are known to feed on prickly pear.

Fungal Rotting of Sequoia Timber

THE Californian redwood tree, *Sequoia gigantea*, does not appear to be a common host for parasitic organisms, but J. A. Macdonald has recently described a fungus which has rotted the wood of young trees growing in Scotland (*Ann. App. Biol.*, 24, No. 1, 83-86, Feb. 1939). Cultural and microscopical characters show that the species concerned is *Coniophora puteana*. Several species of *Coniophora* have been described as secondary parasites; but it seems clear in the present investigation that the organism is acting as a primary pathogen. The fungus can attack blocks of healthy *Sequoia* wood, and can also infect lime, maple, horse-chestnut, hornbeam, alder, oak, elm, beech, willow and birch.

Properties of Virus

Hideo Moriyama and Shunkichi Ohashi have recently published a review of their own and other modern researches upon the physico-chemical nature of viruses (*J. Shanghai Sci. Inst.*, Sect. 4, 4, 63, Feb. 1939). They describe a general method for the isolation of virus protein, and show that the activities of ultra-microscopic organisms are inseparable from such material. With regard to virus production in the host, it is stated that "viruses can be considered as a coagulant of protoplasm-proteid, in which some chemical change is produced by the physico-chemical influence of the virus". The problem is complicated by the fact that other minute particles of protein are known, which have no virus activity, and the paper under review considers the minute physical and chemical differences between these two similar states of protein. Immunity to virus attack is considered, and also the fascinating problems as to how viruses arise, and whether they can have separate multiplication away from living host cells. Animal viruses provide almost all the data, though plant viruses are occasionally mentioned to demonstrate similarity to their related zoological parasites. A plea is also made for a new subject of 'virology', and, indeed, the paper forms an excellent summary for teaching purposes.

Virulence of Bacteriophage

MANY different kinds of virus which attack animals and plants show considerable range of virulence. It would be reasonable to suppose that the same character would be observed for bacteriophage, a virus disease of bacteria, and there have been several investigations of this problem. Hideo Moriyama and Shunkichi Ohashi (*J. Shanghai Sci. Inst.*, Sect. 4, 4, 51-51, January 1939) have recently worked with a phage of *Bacillus coli*, and they find no confirmation of the statements made by earlier workers that the size of a phage plaque upon an agar plate culture of the bacteria is inversely proportional to the size of the phage particle producing it. The size of plaque is considered to be governed solely by the velocity of multiplication of the phage. Thus strains of phage which produce large plaques are more virulent than those which can only make small ones under similar conditions. The differing virulence of various strains tends to be perpetuated in subsequent culture. Lowering of virulence can, however, be induced by incubating phage with bacteria in media containing neither calcium nor magnesium salts, or in media containing citrate or oxalate radicals, and this induced change appears to be of a permanent nature.

Changes in Level of Land

The relative vertical movement of land and sea is generally so slow a process that its detection by measurement rather than by inference is difficult. There is a considerable amount of evidence of such changes on the coasts of Europe in recent geological times. The only method, however, of detecting movement in progress is to keep a careful record of sea-level by one or more autographic and continuously acting tide gauges. H. L. P. Jolly has discussed this problem in a paper on "Supposed Land Subsidence in the South of England" (*Geographical J.*, May 1939). The Ordnance Survey tide gauges erected at Dunbar in 1913, Newlyn in 1915, and

Felixstowe in 1917 provide some data. Precautions are taken to rule out any purely local subsidence or a settling of the structure carrying the gauge. The Dunbar record shows no aggregate change of mean sea-level over twenty-three years, but those at Newlyn and Felixstowe show a rise of sea-level during twenty-five and twelve years respectively. The Felixstowe record was interrupted in 1929. Mr. Jolly discusses at length the nature and value of the evidence, and notes that a gauge was established last year at King's Lynn and that another is projected on a site in the north of Scotland. The question of relative vertical movement between one part of the land surface and another will be settled when it becomes possible to carry out a new geodetic levelling of Great Britain. Comparisons between the first levelling in 1840-60 and the second in 1912-21 are vitiated by inaccuracies in the older works.

The International Temperature Scale

THE International Conference in 1927 defined the International Temperature Scale so as to conform as closely as possible with the thermodynamic scale according to measurements then available, and regarded it as capable of improvement as more accurate ones were obtained. Since that time, more accurate methods of measurement have been devised and Dr. H. T. Wensel, of the U.S. Bureau of Standards, has examined the results and has made suggestions for securing greater accuracy in the definition (*J. Res. Bur. Stand.*, April). Below 660° C. the scale was defined by the standard resistance thermometer, from 660° C. to 1,063° C. (the gold point) by the standard thermocouple and then up to about 5,000° C. by the Wien radiation formula. Dr. Wensel suggests that 630.5° C., the freezing point of antimony, should be substituted for 660° C., and that the Planck formula $I = c_1/\lambda^5 (\exp(c_2/\lambda T) - 1)$ should be substituted for the Wien above 1,063° C. He considers that the most accurate values of the constants are $c_1 = 3.732 \times 10^{-4}$, $c_2 = 1.436$, $\lambda_m T = 2,892 \times 10^{-4}$ and σ of Stefan's expression for the total radiation $= 5.70 \times 10^{-4}$, all in c.g.s. units. More accurate values of a number of auxiliary constants than were available in 1927 are also given.

Parabolic Orbit of a Comet by a Graphical Method

T. CROSS has developed a method of finding how a preliminary orbit of a comet can be determined graphically to an accuracy of about 1' (*J. Brit. Astro. Assoc.*, 49, 6; April 1939). The method is similar to that described by G. F. Chambers in "A Handbook of Descriptive and Practical Astronomy", but contains numerous simplifications. It has also certain features in common with M. Davidson's method by means of a model in which three dimensional measurements are possible (see *Mon. Not. Roy. Astro. Soc.*, 90, 5; March 1930). Cross has taken Finster's Comet as an illustration, and has obtained an orbit very close to that which was computed for an interval of 10 days. It is necessary to use a fairly large scale to be certain of four-figure accuracy. Of course parallax and light-time corrections are superfluous in the method, and those who are skilful as draughtsmen will find it possible to obtain a preliminary orbit, assuming parabolic motion, without a great mathematical equipment. The method is not suitable for finding the orbit of a minor planet.

Composition and Temperature of the Upper Atmosphere

ON May 4, in the lecture theatre of the Royal Institution in London, a joint discussion on the upper atmosphere was held by the Chemical Society, the Physical Society, and the Royal Meteorological Society. Instead of attempting to cover the whole subject, it was thought advisable to confine the discussion to topics in which the sciences represented by these societies were equally interested: chemical composition, density, and temperature. The electrical state of the upper atmosphere, the study of which is exclusively the domain of the physicist, was for example touched upon only in so far as it has a bearing on the subjects mentioned. Six speakers had been invited briefly to introduce various aspects, and after their contributions a general discussion was opened. Time permitted only a statement of experimental results; their theoretical explanation would probably be an appropriate subject for another meeting.

Prof. F. A. Paneth (Durham) reviewed recent attempts towards the direct chemical investigation of the stratosphere. This research was undertaken in order to decide to what extent the air of the stratosphere can be considered as being at rest; if it be fairly undisturbed by convective currents, then we should expect to find in the stratosphere the percentage of the lighter gases increased at the expense of the heavier ones. Two gases have been used for this comparison: the 'light' gas helium and the 'heavy' gas oxygen. (In the case of helium a special survey had first to be carried out to prove that on the surface of the earth its abundance shows no variations.) The results of the two dozen or so analyses so far made in England, Russia, Germany and the United States indicate that the helium and oxygen content is constant throughout the troposphere, and in the stratosphere up to about 20 km.; but that above this height the amount of helium is greater; and of oxygen smaller, by a few per cent. Even above 20 km. there is, however, no regular increase of this change in composition with height. The obvious conclusion is that in these layers diffusive separation of lighter and heavier gases makes itself felt, but that the atmosphere is still far from being undisturbed by turbulence.

It was mentioned that the three gases which are present in the troposphere in varying concentration, namely water vapour, radon, and ozone, lend themselves also to direct chemical investigation, and that attempts at their measurement in air samples from higher strata are in progress.

The following speaker, Prof. S. Chapman (London), pointed out that the chemical evidence obtained indicated that the conditions at heights somewhat above 20 km. seem specially to favour diffusion, because of the exceptional stability of the air at those levels. This is apparently due to an upward increase of temperature for some distance above 20 km.—a subject more fully dealt with by later speakers. It seems, however, unlikely that this diffusion process has free play at greater heights, because in this case the lightest gases, hydrogen and helium, would there entirely predominate over nitrogen and oxygen, in contradiction to the spectroscopic findings with which Prof. Chapman dealt in the main part of his address. The spectrum of the

auroral light is due almost, if not entirely, to oxygen and nitrogen, and shows no trace of hydrogen or helium.

Besides revealing that the atmosphere throughout its whole content is principally a nitrogen-oxygen mixture, spectroscopic evidence has given information about the state in which these two gases are to be found. The emission spectra of the aurora and of the night-sky show bands due to molecular nitrogen; in the strongly excited auroral emission, light comes from ionized as well as neutral nitrogen molecules. Neither of the two emission spectra shows bands of molecular oxygen, but in both of them lines due to atomic oxygen are prominent. This dissociation is probably almost complete above 100 km.; lower down, molecular and atomic oxygen coexist, and also their combined form ozone. Nitrogen is more easily ionized than dissociated by sunlight; the regular presence of ions in the upper atmosphere is indicated by radio evidence. The ions present are probably molecular nitrogen N_2^+ and atomic oxygen, O^+ ; negative oxygen ions O^- are also likely to be formed, by attachment of electrons to neutral oxygen atoms.

The vertical distribution of ozone was discussed in more detail by Dr. G. M. B. Dobson (Oxford). It can be found either by sending up an instrument in a balloon and measuring the amount of ozone above the instrument at any height, or by making observations from the ground. The latter method can give the information wanted if the changes in the absorption of zenith light by ozone are watched while the sun is rising or setting; from the curves thus obtained the vertical distribution of ozone can be calculated in a somewhat complicated way. It is all the more gratifying that the results agree very well with measurements made by the balloon method. Over Europe the concentration of ozone increases steadily from the ground, reaches its maximum between 20 km. and 25 km., and decreases rapidly at greater heights. The details of the distribution seem to depend on the geographical position and on meteorological conditions; it is not yet clear whether over America the rate of increase of ozone is the same.

The other three speakers dealt with the closely interrelated problems of the density and temperature of the upper atmosphere.

Dr. F. J. W. Whipple (Kew) first reviewed the results obtained by direct temperature and density measurements by means of free balloons, which in general have not gone above 25 km. although a few have reached, or slightly surpassed, 30 km. (The frequently quoted record of an attained height of 35 km. is probably untrustworthy, due to instrumental failure.) The lowest temperature ever recorded in the upper atmosphere was 182° K. at a height of 16 km. above Batavia. Such low temperatures are only found by ascents in the tropics; European ascents show in nearly every case temperatures in the stratosphere between 220° and 280° K.; in no case has any indication been found of any considerable departure from the uniformity which characterizes the stratosphere. In the lower atmosphere the density is greater in winter than in summer, but in the upper atmosphere this relation is reversed, the transition taking place at a height of 8 km.

In the second part of his address, Dr. Whipple discussed the use of air-waves for sounding the upper atmosphere. The fact that there are zones of abnormal audibility outside the 'zones of silence' suggests that the sound waves can travel through the air at a considerable height and then be deflected back to ground. The usual explanation given is that the uniform temperature of the stratosphere extends to some limiting height and that above that height temperature increases uniformly. The result of calculations of this kind is that the height of the trajectory of an air-wave is generally a little above 40 km. Sometimes, when the time of passage is exceptionally long, the computed height is considerably greater, 60 km. or more, but in such cases the results are more open to doubt. The velocities found for the waves correspond with temperatures averaging about 280° K. at 40 km., 310° K. at 45 km., and 335° K. at 50 km.

The first proof, however, that the temperature of the stratosphere beyond heights which can be reached by sounding balloons is not constant but increases considerably, was not provided by sound observations but inferred from the heights of appearance and disappearance of meteors. Prof. F. A. Lindemann (Oxford) explained this evidence, which was found by him and Dr. Dobson as early as 1922. The meteor phenomena can only be accounted for by the assumption that the density of air at heights around 100 km. is about a thousand times as great as the hypothesis of a constant temperature from the bottom of the stratosphere upwards would lead us to expect, and so the conclusion is reached that the temperature below the 100 km. level must be considerably higher; the scarcity of meteors disappearing at heights of about 55 km. was the first indication of a rapid rise of temperature in this region. Not only the sound phenomena discussed by Dr. Whipple, but also recent optical observations by F. Link on the variation of the zenithal brightness of the sky during the twilight hours are in excellent agreement with the meteor evidence.

Dr. E. V. Appleton (London) gave an account of the structure of the higher atmosphere as elucidated by the radio-physicists. In the radio exploration of the ionosphere two quantities are measured, namely, the height of reflection and the coefficient of reflection. Both quantities yield information of interest.

From the measurement of the heights of reflection on different frequencies, the electronic structure of the various layers can be deduced, from which it is possible to estimate the values of the 'scale height' H at the appropriate levels. A thick layer is produced by the absorption of solar radiation if the atmospheric density varies slowly with height (large H) and vice versa. There is evidently some factor operative which brings about an increase of H between 100 km. and 300 km., for at the level of the E Layer (100 km.) the scale height is found to be 11.0–11.5 km., whereas at the level of the F Layer (300 km.) the scale height is 40–50 km. An increase of scale height can only be the result of an increased temperature or of the presence of a light atmospheric constituent such as helium. The former is considered by Dr. Appleton to be the more likely; the calculated temperatures are 385° K. for the E Layer and about 1400° K. for the F Layer. Measurements of the reflection coefficient of radio wave yield approximate values of the air density at the level of reflection. These indicate molecular densities of 10^{12} and 10^{10} at the levels of Layers E and F respectively.

From the evidence from sound described by Dr. Whipple, it seems necessary to assume temperatures of more than 330° K. at 50–60 km. height. Since radio observations indicate a temperature rising from a lower degree than that at about 90 km., there should be a temperature fall between 60 km. and 90 km. Recent radio experiments seem to show directly that at a height of 75 km. there is a temperature of only 200° K. The technique applied in the study of this region (the use of wireless waves of about 18 km. length) was only touched upon by Dr. Appleton, but described in greater detail by Mr. J. A. Ratcliffe (Cambridge) in the course of the general discussion which followed the introductory addresses.

Another important contribution to the general discussion was made by Dr. D. F. Martyn from Australia. He communicated the results of 19 months' continuous observations of the maximum ionization densities of the F_2 region, carried out at half-hourly intervals in two stations in Australia, which seem to prove a connexion between this ionization and the meteorological conditions at the ground. This relationship can, in Dr. Martyn's opinion, scarcely be explained by changes in the temperature of the upper atmosphere. The most likely explanation appears to be that there exist large-scale movements of air in the high atmosphere in parallel with the main air mass movements at low levels—that, for example, a large influx of tropical air at low levels is accompanied by an influx of air of special characteristics (probably high humidity and/or low ozone content) at the very high levels up to 250 km.

For those attending the meeting, it must have been satisfactory to learn that the items of information obtained by such widely different methods about the conditions in the upper atmosphere can be put together into a consistent picture. There are still many gaps to fill, due not only to the scarcity of the material yet collected but also to the obvious limitations of the methods; while the sampling and direct measuring is confined to the heights which sounding balloons can attain, the optical, acoustical and electrical methods can only reveal the chemical and physical state of certain heights in which peculiar phenomena occur. It is, on the other hand, very gratifying to see that where overlapping occurs, the results obtained by entirely independent methods corroborate each other or, at least, are not contradictory. One can, therefore, attempt to summarize the main points of our present-day knowledge of the composition, temperature and density of the upper atmosphere, as reflected in this discussion.

The atmospheric gases (with the exception of water vapour, ozone and radon) are present in constant proportion up to the height of approximately 20 km. Between 20 km. and 30 km. the helium content increases, the oxygen content decreases by a few per cent, but there is no indication that this separation process of light and heavy gases becomes more marked with height: the total atmosphere is essentially a nitrogen-oxygen mixture. Under the influence of sunlight these two gases are ionized, and oxygen dissociated, so that the higher atmosphere consists mainly of nitrogen molecules and oxygen atoms, while lower down there is also molecular oxygen and ozone. Ozone has its highest concentration per volume at about 25 km.

The temperature decreases fairly regularly from the ground level upwards, assumes (in the latitude of

Great Britain) at 10–11 km. height a value of about 220°K . which remains constant to at least 30 km. From a few kilometres below 40 km. upwards, the temperature increases until it reaches at 50–60 km. more than 330°K ., whereupon it falls again, to a lower level than that of the stratosphere; the minimum, of about 200°K ., is reached between 70 km. and 90 km. From here onwards the temperature rises again; at 100 km. it is about 380°K ., at

300 km. it is in the neighbourhood of 1400°K ., and may increase still further with height.

Thanks to the rise in temperature from 40 km., and again from about 90 km. onwards, the density of the atmosphere is much greater above these heights than would be caused by gravity distribution if the temperature of the stratosphere remained constant. At 100 km. it is of the order of 10^{12} molecules/c.c., at 300 km. it is still 10^{10} molecules/c.c. F. A. PANTH.

Institution of Gas Engineers

THE seventy-sixth annual general meeting of the Institution of Gas Engineers, held in London during June 6–9, was noteworthy as the centenary of the death of William Murdoch, the versatile Scot, who is acclaimed as the father of the British gas industry. Mr. Robert Robertson, engineer and manager of the Bristol Gas Co., presided.

In a symposium on the present and future prospects of the town's gas industry, eleven Dominion and Overseas engineers, describing the conditions in their own countries, revealed that the idea of distilling coal for lighting gas arose in several places, but it was recognized that no one deserves more credit than Murdoch for establishing the practicability of coal gas manufacture.

These contributions showed that in every country the rise of newer industries such as those of oil and electrical supply has exerted an influence on the use of gas in certain directions, accentuated by the greater efficiency of appliances. Nevertheless, the merits of a clean gaseous fuel has sufficed not merely to maintain but also to increase the consumption of gas even in those countries where all coal must be imported while hydro-electric power is abundant. The president of the Swiss Gas Association, for example, says that in spite of the great financial efforts of the electrical industry, the Swiss housewife appreciates the value of the gas flame with its instantaneous heat, its great power and quality of being visibly regulated within wide limits.

In Norway the need for coke has a dominating influence, and the gas industry can supply only 8 per cent of the country's needs. Large losses, apparently, have been incurred there by too optimistic investments of public funds in hydro-electric works in the erroneous belief that the power so generated might replace gaseous fuel.

The president's address—a review of the development of the gas industry—contained a notable announcement of a new departure in its policy of organized research. In this, the industry has been a pioneer, for thirty years ago—long before the days of research associations—the Institution began the practice of supporting co-operative research. During this time it has furthered a programme of research done at the University of Leeds, and the president's address referred to nearly fifty reports issued from this source. In the meantime, many gas undertakings, contractors and associations concerned with by-products have produced an increasing volume of experimental work. It is estimated that about a quarter of a million pounds in the aggregate is spent annually in development work. Nevertheless, such is the state of flux in the utilization of fuel that a widening of the organization of research is projected.

Until recently, investigation could be confined to established practice of making and using gas, but to-day the industry is seeking to widen the range of coals suitable for gas making and to convert these into solid, liquid and gaseous fuel in any desired proportion—even to complete gasification by the use of high-pressure technique. It is now proposed to establish a Gas Research Board supported by the subscriptions of gas undertakings and manufacturers of plant and appliances. The first president will be Sir David Milne Watson, and a director of research will be appointed. The Board will be constituted so as to qualify for Government grants if and when this is thought desirable. It is proposed to use the facilities available in existing institutions—at least in the immediate future. The functions of the Board will be: (1) the collection and dissemination of information concerning research of interest to the gas industry, (2) the provision of contact and co-ordination between research workers similarly engaged, (3) the observation and reporting of work in progress and (4) planning and arranging of future work.

Dr. E. F. Armstrong gave a lecture in memory of Murdoch tracing the growth of the gas industry and speculating on its prospects.

Non-technical readers would be interested in a paper by L. W. Andrew and A. Barrow on comfort heating by gas. To-day gas is being increasingly sold on two-part tariffs which encourage the freer use for major heating and raise the question as to the extent to which it can replace solid fuel for continuous heating. The advantages of cleanliness, flexibility and reduction of labour have long been recognized, particularly for intermittent heating. For central heating, solid fuels, especially coke, have appeared to show an unassailable advantage, but coal gas is increasingly entering this field when cleanliness, high rent and automatic control offer sufficient inducement. 'Central heat' is normally conveyed by means of hot water, but 'central' heat can more cheaply and simply be conveyed in a potential form as coal gas, and the problem to-day is to devise means for converting this into effective and acceptable sensible heat.

The paper distinguishes between 'warmth' and 'comfort'. For comfort, it would appear to be desirable to have air at $50\text{--}60^{\circ}\text{F}$. in movement without perceptible draught, supplemented by radiant heat received on the front of the body from an incandescent source. Shorter infra-red rays of length below 3μ capable of penetrating the skin, according to L. Hill, are of particular value. In addition, tradition in Great Britain requires an open fire with the character associated with the open coal fire. The authors believe that these requirements can be met by

combining 'background' heating by flameless appliances with suitable gas fires. For continuous domestic heating they think the radiating gas fire will take a new form, whether in some measure resembling the coal fires of the past—as it may in the near future—or taking a more revolutionary form. In support of this view they exhibited a gas fire of new design such that any ordinary person walking past would take it for a coal fire of conventional type. Instead of the formal geometrical radiants, it exhibited a face of black mass enclosing glowing cavities surmounted by a play of real flames. There must be many to-day

who would find it worth while to pay something extra for the merits of a coal fire without its demerits.

For commercial buildings new designs of overhead radiating panels—both high and low temperature radiators—are now available. In factories, the 'unit heater' which provides a stream of warm air directionally propelled offers many advantages. All these offer considerable advantages over central heating by circulation of hot water, and the paper suggests that great developments may be expected in gas heating.

H. J. HODSMAN.

Structure of Trilobites

By Dr. W. T. Calman, C.B., F.R.S.

THE trilobites are generally recognized as occupying a key position in relation to the phylogeny of arthropods, and until we have some certainty as to their structure and relationships it is not possible to speculate profitably about the mutual affinities of insects, crustaceans and arachnids. In the course of the last sixty years, a great deal of information regarding their appendages has been obtained, for the most part by American paleontologists; but the results of different investigators have not been easy to reconcile and very divergent conclusions have been drawn regarding the systematic position of the group.

Dr. C. D. Walcott, who was the first to obtain definite information about the appendages, worked chiefly on the Ordovician genus *Ceraurus*, which he studied in thin sections. Dr. C. E. Beecher (whose final memoir was completed after his death by his pupil, P. E. Raymond) studied abundant material of *Triarthrus*, from the same epoch, as exposed in surface view by splitting the rock. The results of these two workers seemed to reveal an extraordinary difference of structure in the limbs of the two genera. The legs of *Ceraurus* were provided by Walcott with a pair of corkscrew-shaped gills attached near the base, while those of *Triarthrus*, according to Beecher, were simply biramous, with the outer branch segmented and fringed on one side with flattened filaments. Taking up the subject again towards the end of his life, Walcott maintained that the 'spiral gills' really existed but now allotted only one of them to each limb and provided it with a row of flattened filaments like those described by Beecher in *Triarthrus*. In a review of Walcott's paper¹, I pointed out that the row of filaments, attached to the successive turns of an open helical spiral, would not remain in one plane as they are seen to do in the fossils, unless the spiral were rigid to an improbable degree.

Dr. Leif Sterner, in an important memoir², discusses the whole subject in the light of a re-examination of Walcott's and Beecher's preparations. He has also applied Sollas's method of serial grinding and reconstruction to *Ceraurus*, and has obtained some very interesting and convincing results. In the first place, the fundamental differences which Walcott supposed to exist between the appendages of *Ceraurus* and *Triarthrus* have disappeared. The spiral structures are proved to depend on misinterpretation of the sections. In *Ceraurus*, as in *Triarthrus*, the appendages are simply biramous, with an outer

branch consisting of a segmented stem fringed on one side with a single row of flattened rod-like or filamentous structures which may, or may not, have served as gills. In view of the poor state of preservation of the appendages in *Ceraurus* and the obscurity of the traces that they have left in the rock, it is not surprising that many details of their structure must remain uncertain, but Sterner appears to be justified in claiming that all the trilobites so far studied have appendages built on the same plan. Beyond this, however, his far-reaching deductions can only be treated with much reserve.

Impressed with his discovery in *Ceraurus* (and, very doubtfully, in other genera) of a 'precoxal' segment to which the outer branch of the limb is attached, he designates this outer branch 'pre-epipodite' and deduces from this that the trilobites have no close relationship with the crustacea but are, on the other hand, intimately associated with the eurypterid-arachnid group. To do this, he has to minimize the importance of those characters in which the trilobites diverge from the Arachnida and approach the Crustacea. To anyone with a sense of morphological values, however, the flagelliform pre-oral antennules, the five pairs of biramous gnathopod-bearing head appendages following them, and the furcal filaments (of *Neolenus*) far outweigh the fact that the peduncle of the biramous limbs is unsegmented; as it is, by the way, in not a few Crustacea.

The resemblances between trilobites and primitive arachnids have been often pointed out and are generally admitted; but Sterner does not strengthen his case by taking seriously Schultze's far-fetched comparisons between trilobites and ticks (Ixodidae). To reason from fortuitous and isolated coincidences of structure is to play into the hands of those who are so ready nowadays to proclaim the bankruptcy of morphology and phylogeny. Anyone who is tempted by such slapdash methods may be recommended to consider the numerous and striking resemblances between trilobites and isopod Crustacea, and then to study carefully the evidence for the derivation of the Isopoda from primitive Mysidacea, which have scarcely anything in common with trilobites except that they are arthropods.

University Events

CAMBRIDGE.—Dr. L. E. R. Picken, of Trinity College, has been re-elected to the Balfour studentship, for research on the molecular morphology of living cells.

Grants from the Balfour Fund have been made to the following: D. A. Webb, of Trinity College, £20, for expenses whilst working at the Millport Marine Station; to D. A. Webb, of Trinity College, £40, for expenses whilst working at Prof. Krogh's Laboratory in Copenhagen; Dr. C. H. Waddington, £25, towards the expenses of visiting the Marine Laboratory, Woods Hole; M. G. M. Pryor, of Trinity College, a sum not exceeding £40, for expenses whilst working under Prof. Kühn in Berlin; Dr. V. J. Chapman, £25, towards the cost of an expedition to the West Indies; Dr. R. J. Pumphrey, £20, for expenses whilst doing research at the Plymouth Marine Station.

The Frank Smart studentship in botany will be vacant on October 1. Any graduate of the University is eligible for the studentship provided that not more than eighteen complete terms have elapsed after his first term of residence. Women also are eligible. The successful candidate must devote himself to research in botany under the direction of the Professor of Botany. A student may be appointed for one year or for two years. The value of the studentship is £210 a year. A candidate must send his name, with a statement of the course of research which he proposes to undertake, and such evidence of his qualifications as he thinks fit, to Prof. F. T. Brooks, at the Botany School, on or before September 30.

OXFORD.—At Encaenia on June 21, the following among others received honorary degrees: *D.Sc.*, Sir Edward Mellanby; *D.C.L.*, the Marquess of Lothian, Sir Maurice Gwyer, Admiral Sir Herbert Richmond and the Hon. Vincent Massey.

Dr. Robert Gunther has resigned his appointment as honorary University reader in the history of science at Oxford. He will remain in charge of the Museum of the History of Science. Work on the Oxford dictionaries, hitherto carried out in the lecture room of the old Ashmolean Museum, is being transferred to the new Bodleian extension.

Dr. E. G. T. Liddell, Trinity College, and Mr. D. L. Hammick, Oriol College, have been elected members of the Hebdomadal Council.

Prof. R. S. Troup is resigning the professorship of forestry on July 31, 1940.

E. F. Caidin, Queen's College, has been elected to a junior research fellowship (in chemistry) at Queen's College. Dr. A. H. Cooke, Christ Church, has been elected to a lectureship in physics (the equivalent of a research fellowship) at Christ Church. Miss A. Pellow, St. Hugh's College, has been elected to the Moberly senior scholarship (in engineering).

The following new appointments have been made: E. B. Ford, Wadham College, reader in genetics; C. F. W. R. Gullick, lecturer on economic geography; Dr. R. A. Hull, St. John's College, demonstrator and lecturer in physics; R. N. Chrystal, demonstrator and lecturer in entomology; A. C. Hoyle, Pembroke College, and Dr. N. V. Polunin, Christ Church, demonstrators and lecturers in botany.

SHEFFIELD.—Prof. R. P. Linstead has resigned from the Firth chair of chemistry, on his appointment to the chair of organic chemistry in Harvard University.

Science News a Century Ago

Giraffe Born at Zoological Gardens

ON June 25, 1839, Prof. Richard Owen read to the Zoological Society "Some Notes on the Birth of a Male Giraffe at the Zoological Gardens". The animal was born on June 19. The period of gestation, said Owen, had been, as nearly as possible, ascertained to be fourteen months, eighteen days, or fifteen lunar months. The young animal, when born, was perfectly motionless, and apparently dead, or strangled, its lips and nose being tinged with blood; but after gentle friction had been used for a short time, breathing and motion quickly followed. The mother was in no way depressed or debilitated. The animal came into the world like other ruminants, with the eyes open, but the hoofs were disproportionately large, and very soft and white at their expanded extremities; the skin was marked as distinctly as in the adult; the horns were represented by stiff and long black hairs, and the mane was well developed.

Allan Cunningham (1791-1839)

ALLAN CUNNINGHAM, an eminent botanist and traveller, was born at Wimbledon, Surrey, on July 13, 1791, his father being a gardener. Having become connected with the Gardens at Kew, he became known to Sir Joseph Banks and on September 4, 1814, he was appointed botanical collector in the southern hemisphere for the royal gardens. Sailing from Plymouth in October 1814, he did not return to England until July 1831. In turn he visited Rio de Janeiro, and parts of Brazil, New South Wales, New Holland, Van Dieman's Land, New Zealand and Norfolk Islands. Though after his return home he was in somewhat indifferent health, he was offered the post of colonial botanist in New South Wales, but declined it in favour of his brother Richard, who, however, was killed by natives in April 1835. Cunningham now accepted the office and proceeded to Sydney, but his strength failed him and he died on June 27, 1839, at the age of forty-eight years.

Becquerel's Electrical Experiments

"M. BECQUEREL," said the *Athenaeum* of June 29, 1839, "has read the first part of a memoir before the French Academy of Sciences, containing an account of his new experiments on the electric forces of contact. These led him to conclusions concerning the causes of certain effects which differ from those of Davy, who ascribed them to mere contact. M. Becquerel refers them to friction and hopes to prove it by the following experiments. First, two conducting plates made of platina were adapted to an excellent electroscope; one of them was touched with a very dry piece of chalk, and the other with the finger; on separating the plates, it was found that no electric effect had been produced. Secondly, a layer of calcined lime, highly dried, was spread on a piece of wood, equally dry; upon this was carefully placed, so as not to allow of friction, a plate of copper, fixed to a handle; it was then put in contact with one of the plates of the condenser, while the other was touched with the finger. After repeating this several times, no electric discharge was obtained, but if the copper disc were placed on the lime with friction, the condenser was charged after touching a few times, and the greater the friction the stronger the charge."

Societies and Academies

Paris

Academy of Sciences (C.R., 208, 1445-1540, May 8, 1939).

J. CHAZY: Value at infinity of the solutions of certain differential equations.

C. MAUGUIN and J. LAVAL: Fourier lattice and thermal agitation.

H. COLIN and J. AUGIER: A novel glucide in the Floerke of the genus *Polysiphonia*—the α -D-mannoside of sodium L-glycerate.

G. BERTRAND and L. SILBERSTEIN: Boron content of soil. Although present in most soils, the quantity is so small (10-30 mgm. per kgm. of fine soil), that its estimation is only possible with specially purified reagents.

F. GRANDJEAN: The 'probability' of the existence of organs and of characters.

H. VINCENT: New experimental researches on hepatic 'dysphylaxy' in coli bacillary infection.

G. GIRAUD: A type of problem relative to elliptic equations with two independent variables.

J. DE LAPPARENT and R. HOGART: Leverrierite of the lateritic formations of French East Africa.

M. KRAEMER: Fermat's theorem.

E.-J. GUMBEL: Duration of decline as a measure of independence.

S. CHIRUBINO: Kronecker's index and the algebraic correspondences between curves.

L. BERG: Limiting values of analytical functions of two complex variables in domains possessing an observable bounding surface.

H. GUILLIEMET: Influence of the periodic transversal movement of the leading edge of the wing of an aeroplane on the reaction exerted by the fluid.

R. LINDUO and J. VILLEY: The permanent limiting discharge flow of a current of air around a source.

J. DUFAY and J. GAUZIT: Application of interference to the study of stellar spectra.

J. MARIANI: Geometric interpretation of spin.

G. BIHNE: Integration of M. De Donder's equation.

D. DERVICHIAN and M. JOLY: Transformations of higher order in mono-molecular layers.

L. AGOSTINI: An apparatus for measurement of the specific heats of gases working on very small supplies of gas.

MME. M. MORNAU-HANOT: Transport of electric charges by droplets.

A. MARSAT: Some consequences of the diffusion of light by corpuscles suspended in the atmosphere.

MME. S. VEIL: Liesegang periodicities by attack, in gelatin, of coarse solid suspensions.

A. PORTVIN: Specific character of structures formed in the fractional decomposition of austenites with cooling as a function of the temperature of the isothermal stage.

M. MOUSSEON and R. GRANGER: Some optically active stereoisomeric alicyclic acids, alcohols and aldehydes.

G. DARENS: Action of aqueous solutions of ammonia on halogen derivatives: new method of preparation of aliphatic diamines.

R. VINILLEROSSA: Mechanism of formation of thioacetic dichloride: polymolecular anhydride-chlorides of thioacetic acids.

F. SALMON-LEGAGNEUR: α - α -Diphenylsuccinic acid.

P. FLURY and MME. R. BOISSON: Action of periodic acid on acetone and on diethylacetone.

J. LAVAL: Diffusion of X-rays outside some directions of selective reflection by crystals [possibly due to thermal agitation].

M. BRENETTOFFER: Lower Cenomanian of the fosse coconienne (Hautes-Alpes et Drôme).

H. BERRIER: Magnetic results for 1939 from the coast of French Somaliland.

MME. A. VASSY and E. VASSY: Influence of solar radiation on the mean temperature of the atmospheric ozone.

C. COMBIER: Some new problems raised by the photography of the shadow of the earth.

P. QUINCY: A counter of large ions giving directly the spectrum of mobilities.

J. DEBRACH: Variations of the effective nocturnal radiation, in the course of clear nights.

M. SIMONET and P. DANHEBEAU: Meiosis in two hybrids of *Cistus*, *C.* $\times$ *hybridus* Pourr. and *C.* $\times$ *rodiei* Verg. var. *antipolitensis* Dans.

MME. M.-L. VERRIER: The theory of Exner and the comparative histophysiology of compound eyes.

A. PERRARD: Numeration of the Purkinje cells in the cerebellum of various birds.

E. WOLFF: Action of diethylstilboestrol on the genital organs of the chick embryo. It has a powerful feminizing effect, analogous to that of oestrone.

N. PERAKIS: Magnetochemical analysis of the egg of the urchin (*Echinus melo*).

F. OBATON: Influence of colchicine on the development of *Photobacterium phosphoreum*. It increases the luminosity of cultures, due to acceleration of development.

G. JEANNERET, C. WANGERMER and G. RINGENBACH: Electric charge of the blood and transfusion shock. Post-transfusion shock depends on the sign of the electric charge of the donor's blood.

Amsterdam

Royal Netherlands Academy (Proc., 42, No. 3; 1939).

J. BÖNNIKEN: Steric conditions in the cyclic acetone-acetals of the *ortho*-diphenols.

R. WEITZENBÖCK: Projective invariants of four and five straight lines in the four-dimensional space R_4 .

MISS W. A. LUB: Isotopic constitution of nickel and chromium. The existence of the ^{61}Ni isotope with an abundance of 0.1 per cent is confirmed and that of the ^{54}Cr isotope rendered probable.

P. G. MOLENAAR: A differential invariant of the second order of the binary cubic differential form.

W. BEIJERINCK: Diatoms from the brooks of the province of Drenthe (Holland).
